THE COMMERCIAL PRODUCTS OF INDIA
THE COMMERCIAL PRODUCTS OF INDIA

BEING
AN ABRIDGMENT OF "THE DICTIONARY OF THE ECONOMIC PRODUCTS OF INDIA"

BY
SIR GEORGE WATT
C.I.E., M.B., C.M., LL.D. (ABD. AND GLASG.), F.L.S.
Officier d'Académie, Corresponding Member Royal Horticultural Society of England
Honorary Member of the Pharmaceutical Society of Great Britain
Daniel Hanbury Gold Medallist
Formerly Professor of Botany Calcutta University, Superintendent Indian Museum
(Industrial Section) and Reporter on Economic Products to the Government of India

PUBLISHED UNDER THE AUTHORITY OF HIS MAJESTY'S SECRETARY OF STATE FOR INDIA IN COUNCIL

LONDON
JOHN MURRAY, ALBEMARLE STREET, W.
1908
PREFACE

The history of this Work may be told briefly. The Dictionary of the Economic Products of India, written by me and published 1885–94, having been out of print for some time, it was resolved by the Government of India that a corrected and abridged edition should be brought out. The instructions provided that the work should be limited to a single volume, the arrangement of which should follow that of the Dictionary; that it should be confined to products which are of present or prospective industrial or commercial importance; and that Sir W. T. Thiselton-Dyer, Director of the Royal Botanic Gardens, Kew, be requested to exercise supervision over the compilation of the work. In acceding to this request, Sir William recommended that a definite plan for the work should be settled before commencement by a small committee in communication with the author. This recommendation was adopted by the Right Hon. the Secretary of State for India, the committee appointed being empowered to make recommendations on any other points of detail not sufficiently provided for in the instructions issued by the Government of India. The Committee were as follows:—Sir W. T. Thiselton-Dyer, K.C.M.G., C.I.E., F.R.S., Director of the Royal Botanic Gardens, Kew, Chairman; Mr. J. S. Gamble, C.I.E., F.R.S.; Professor
Wyndham R. Dunstan, F.R.S., LL.D., Director of the Imperial Institute; and Sir Thomas Holderness, K.C.S.I.
Lieut.-Colonel D. Prain, C.I.E., F.R.S., was subsequently appointed a member of the Committee. The writing of
the work was commenced in 1904 and completed in 1907. During its progress the manuscript of many articles was
submitted to scientific experts who were good enough to allow me to consult them. Among these I may
mention the generous help received from the members of the advisory committee, more especially Sir William
Thiselton-Dyer, who, during his long and honourable connection with Kew, had gained a unique knowledge
of the products of India, and was ever ready and willing to assist in forwarding the best interests of the
work. Sir Thomas Holland, K.C.I.E., F.R.S., Director of the Geological Survey of India, kindly perused all
the articles on "Metals and Minerals," and made numerous valuable suggestions. Mr. T. H. Middleton,
M.A., Assistant Secretary, Board of Agriculture, permitted me to consult him regarding "Live Stock." Dr.
Harold H. Mann contributed towards the article on "Tea"; Mr. H. M. Leake, M.A., on "Indigo"; Mr.
C. A. Barber, M.A., on "Pepper." Mr. E. M. Holmes was good enough to read the proofs of certain passages
on drugs; Professor A. H. Church, F.R.S., very readily responded to my inquiries, and Dr. J. A. Voelcker
advised me on doubtful points in agricultural chemistry. Mr. F. W. Thomas, Librarian India Office, rendered
invaluable service regarding the origins of Indian classical and vernacular names. Professor E. Rapson, of
Cambridge, was similarly good enough to help me on several occasions with the Indian classic authors, Dr.
G. A. Grierson, C.I.E., was most liberal in his responses, and Mr. W. Foster was ever ready to supply infor-
mation regarding the Records of the India Office.
I may venture to explain that an effort has been made to render all trade statistics on the standards of English weights and measures, and while giving the rupee values to state now and again the equivalents in pounds sterling (1s. 4d. to the rupee). Unfortunately, by the time the press order had to be given, official returns later than 1905–6 were not as a rule available for all aspects of trade, so that while incidentally quoting such returns as were to hand of a later date, the main contentions of the work turn on the positions attained in 1905–6.

I cannot close these explanatory remarks without stating that the bulk of the work has been written from the material sent to me from India by Mr. I. H. Burkill, M.A., Reporter on Economic Products. In connection with the preparation of the Dictionary there had been established in that office what have come to be officially known as the "Ledgers." These consist of books of blank paper assorted within boxes according to the names of the products of India. Into the books had been pasted cuttings from numerous publications, official and otherwise, in sequence of date, passing onward to the Dictionary and subsequently to the present day. It thus became comparatively easy to ascertain all new particulars, and to verify the data and correct the mistakes of the older work. In a similar manner, though perhaps not on so elaborate a scale, cuttings had been preserved for many years past both in the Revenue and Statistical Department of the India Office and in the Office of the Director of Kew. In addition, therefore, to the material amassed in India, I had placed at my disposal the papers brought together in England in the manner indicated, and the work as issued may, I trust, be found a useful digest, within the previously assigned limits, of all available information. Lastly, I
must take the opportunity to acknowledge my great indebtedness to the Librarians of the India Office and of the Kew Herbarium for the limitless facilities afforded me in consulting the numerous works, not recorded in the official ledgers, and for thus having greatly enhanced the value of the historic details. The primary objects kept in view have been to restrict observation to what concerns India, and to make the work of practical value to the Commerce and Industry of that country.

GEORGE WATT.

*Kew Gardens, July 1908.*
THE COMMERCIAL PRODUCTS OF INDIA

ABROMA AUGUSTA, Linn.; Roxb., Trans. Soc. Arts, 1804, xxii., 382; 1806, xxiv., 151; Fl. Br. Ind., i., 375; Gamble, Man. Ind. Timbs., 1902, 104; Sterculiaceæ. Perennial Indian Hemp or Devil's Cotton, ulatkambal, kumal, olak-tambol, sanu-kapashi, etc. A large open bush, widely distributed throughout the hot moist tracts of India and readily propagated by cuttings.

The bark affords a strong white bast fibre, first discovered by Roxburgh in 1801 (Substitutes for Hemp and Flax); it is easily separated by retting in water or by decoction. It may be made to yield annually two or three crops of shoots, from 4 to 8 feet long, but according to Gamble requires rich land and plenty of moisture. The root-bark is held in high esteem by Nativo practitioners as a medicine for dysmenorrhoea. [Cf. Cross, Chem. Exam. in Imp. Inst. Tech. Repts., 68; Pharmacog. Ind., i., 233; Kanny Lall Dey, Indig. Drugs Ind., 1896, 2; Agri. Ledg., 1896, 6; etc., etc.]

ABRUS PRECATORIUS, Linn.; Fl. Br. Ind., ii., 175; Gamble, Man. Ind. Timbs., 1902, 240; Leguminosæ. Crab's-eye, Joquity, the so-called Indian Liquorice; a plant more or less sacred, and known by the following names—rahi, gaunghaí, gunjha, guri-gijnja, etc., mostly traceable to gunjha in the Sanskrit. A beautiful climbing shrub found throughout the plains of India and Burma, and on the Himalaya and other hills up to altitudes of 3,000 feet—cosmopolitan in the tropics.

The small shining red seeds are almost universally used by Indian goldsmiths as weights: they average 1.75 grains. The Koh-i-nur diamond was weighed with rahi seeds. The chief interest turns, however, on the criminal use to which they are put. Ground down to a paste with a little cold water, they are made up into small pointed cylinders (suis or sutaries), which if inserted below the skin of a bullock, or even of a human being, cause death in a few hours. There were, for example, 20 cases of abrus-poisoning in animals reported from the N.-W. and C. Provinces in 1897-9; from the Panjáb (1897-1903) 16 cases of animal and one of human poisoning; and from Bengal, 5 animal and 3 human cases. The lethal dose (according to Kober) is only 0.0001 grm. per kilo of the animal's weight. The toxic property is due to two proteids—a globulin and an albumose—and is thus closely analogous to the venom of snakes. When boiled, the seeds may be eaten, since their poisonous property is then destroyed. The roots are sold as an indifferent substitute for liquorice. [The names of a few only of the more important writers need be quoted:—Warden, Waddell, Sidney Martin, Weir-Mitchell, Reichert, Klein, etc.; also Pharmacog. Ind., iii. (app.), 151-2; Thevenot, Travels in Levant, Indostan, etc., 1687, pt. iii., 98.]
ACACIA ARABICA

ACACIA, Willd.; Fl. Br. Ind., ii., 299-8; Agr. Ledg., 1902, No. 2; LEGUMINOSE. A genus of spinose or prickly climbing shrubs or trees, which constitutes the most characteristic group of plants in the Sub-order Mimose. There are in all 450 species, of which two-thirds are peculiar to Australia. India possesses only some 22, and these are distributed throughout the plains, two ascending to altitudes of nearly 5,000 feet. [Cf. Prain, Some Additional Leguminosae, Journ. As. Soc., Beng., 1897, lxvi., 506-11; Gamble, Man. Ind. Timbs., 291-302; Brandis, Ind. Trees, 263-9; Duthie, Fl. Upp. Gang. Plain, i., 312-9; Cooke, Fl. Pres. Bomb., i., 443-51.] It might almost be said that every Indian species is of some economic value. Three are of commercial importance, viz. Acacia arabica, A. Catechu, and A. Senegal, while the remainder are mainly of local interest. The bushy and arborescent forms, as a rule, afford astringent barks, leaves, or pods, and are appreciated as Medicines, as TANS or as DYE AUXILIARIES. Many of them afford useful GUMS that are more or less soluble and edible. Interesting particulars regarding the fungi that appear to be instrumental in the formation of these gums will be found in a paper written by Mr. J. B. Prooble, and published in the Pharmacographia Indica (i., 544-55). The barks of some species yield coarse cordage Fibres. The majority of the trees are of the greatest value to the inhabitants of the tracts where they are at all prevalent, both as sources of Timber and Fuel. With regard to the timber, Mr. Gamble observes that the Indian species have sharp prominent medullary rays, which are short in A. Catechu, ferruginea, and modesta, but long in the others. As a rule they are not well marked in a radial section, but A. teucophleba and arabica are exceptional in this respect, the former being beautifully marked. All the species of species are recognised as of the utmost importance in Agriculture, as for example in the reclamation of waste lands. Indeed, in certain arid regions, they are the chief trees and shrubs met with. And lastly, either as living hedges or as dead thorny fences their spinose property is much appreciated for the protection of cultivated lands, and the leaves beaten from the twigs afford a much-valued FODDER to the cattle of the regions in which they are plentiful.

ACACIA, Willd.; Fl. Br. Ind., i., 326-7; MALVACE. The Indian Mallow or American Jute. A small bush met with in North-West India, Sind, Kashmir, etc.

The bark yields a Fibre, spoken of as superior to Jute (Dodge, Useful Fibre Plants of the World, 55). According to Duthie, the fibre is much valued in Kashmir. A. indicaum, Sweet, and A. asiaticum, C. Des—two species that from the industrial standpoint cannot be separated from each other. The former is distributed throughout India, in fact the tropics, and the latter is met with chiefly in Western India. They are often spoken of as Country Mallow, kangu, jhampi, potari, etc., the seeds being balbhi. They yield beautiful white bast fibres, and the leaves, roots and seeds are rich in mucilage, hence used as demulcents, emollients, and diuretics, and prescribed in fevers as cooling Medicines.

ABUTILON AVICENNÆ, Gaurin.; Fl. Br. Ind., i., 326-7; MALVACE. The Indian Mallow or American Jute. A small bush met with in North-West India, Sind, Kashmir, etc.

The bark yields a Fibre, spoken of as superior to Jute (Dodge, Useful Fibre Plants of the World, 55). According to Duthie, the fibre is much valued in Kashmir. A. indicaum, Sweet, and A. asiaticum, C. Des—two species that from the industrial standpoint cannot be separated from each other. The former is distributed throughout India, in fact the tropics, and the latter is met with chiefly in Western India. They are often spoken of as Country Mallow, kangu, jhampi, potari, etc., the seeds being balbhi. A. arbica, Willd.; Fl. Br. Ind., ii., 293. This is the Indian Gum Arabic Tree, the babul or kikar, babola, gabur, bakar, etc.

Dutt (Mat. Med. Hind., 160) gives it the Sanskrit name of vavvula, while babula is a word which according to Rice is only Sanskritised, and
CULTIVATION OF THE BABUL

Sir Walter Elliot (Fl. Andh.) says it is the Barbúramu of Sanskrit. In South India it is known as karú (or karuvellam), gobhi, jadi, tuma, etc. Habitat.—This is one of the most widely distributed and prevalent of small trees in India, but chiefly on village sites, borders of fields or waste lands, where it is usually seen to be gregarious. It prefers a dry to a moist climate and accordingly is, as a rule, absent from the coast tracts; it disappears gradually from Bengal, Behar and Oudh, on the Terai of these provinces being approached; is absent from the warm moist tracts of Assam, Manipur and Burma; is most prevalent from the North-West Provinces, through the Central Provinces to Berar, Central India, Bombay and Sind; and might be said to attain its greatest development in the lower and middle Sind, where it is probably truly indigenous. It does not appear to be a native of many parts of India, where it is nevertheless common, e.g. the Panjáb, Oudh, Bengal and Madras. In the Panjáb it is mainly grown on canal embankments, and in the United Provinces by roadsides and on islands in the Ganges. [Cf. Rept. Arboricult. in Pb., 1890-3, 6.]

Varieties.—Some short time ago Sir Dietrich Brandis (Ind. For., Sept. 1897, 23, 359) raised the question of the varieties of this species. He referred to the kauśa babul of Berar (the kowri, kauria, and vedi—see the Deccan) as a small tree with deeply cracked and exfoliated bark, broad marginate pods, and stout spines than the ordinary form which in Akola is distinguished as telia babul (the godi (sweet) babul, according to Fagan, Shuttleworth, etc.). Another variety is the cylindrical babul known as ram-kanta (possibly the Kabul or cypress babul of certain writers. [Cf. Panjab Gaz. (Sialkot), 1894, 11; Gamble, Man. Ind. Timbs., 292; Cooke, Pl. Pres. Bomb., i, 444.] The kauśa or kauria is a smaller tree, grows on poorer soil, and affords much less valuable timber than the ordinary or telia babul (Brandis, Ind. Trees, 264). It would seem that the well-known variability of Acacia arabica in merit of gum-ten and timber afforded, may to a large extent be dependent on this question of the varieties or climatic conditions of the species, hence the subject is well worthy of careful consideration.

Cultivation.—The babul is raised from seed, bears transplanting indifferently, and according to some writers may be propagated by cuttings. It can be sown by drill or by being broadcasted, and in either case just before the rains or, say, in June and July. The seeds germinate slowly, for they are exceedingly hard, and it is customary to soften them by steeping for a day or so in water or in liquid cow-manure. The seed is generally gathered in April, and by the native cultivator is often coated with cow-dung and kept in that condition till July, then sown on the spot where intended to be grown. Most writers affirm that germination is best effected by making goats or sheep first eat the seeds. This, however, would seem to be a mistake, for these animals will not eat shell ed seeds and do not care much for ripe pods; they prefer green pods with immature seeds. When mature the animals eject them from the mouth during rumination, and the seeds thus never actually pass through the alimentary system. If, however, they chance to be retained for some hours in the first stomach of a ruminant the seeds would no doubt be found to germinate freely.

The plants have to be thinned out about the third year until the healthiest occupy distances of from 10 to 20 feet apart. In the third year they will flower and bear fruit; and according to the exports of the tanning industry in Cawnpore, the bark is in its most perfect condition when the trees are from 4 to 6 years old. Curiously enough, however, many Natives affirm that the older the trees are the stronger the tanning property. This does not appear to be the case, for according to European tanners the colouring principle develops but the tanning value decreases with age. If, therefore, babul plantations be raised with a view to returns from tanning-bark and fuel, the trees should be uprooted after from 6 to 10 years, in order to secure the best financial results. At one time it was supposed that a system of pollarding plantations might be the most remunerative, but plants so treated have been observed to grow so very slowly afterwards that it has proved preferable to uproot and replant. The bark is sometimes stripped off the living plants, but the wounds heal so very badly that this is by no means an approved method of procedure. [Cf. Fagan, Ind. For., x., 393, 441; Washington, Ind. For., xxii., 252.]

Cost of Production and Profit.—Mr. Ozanne (Letter No. 607, dated July 1884, para. 16) furnishes returns given by a Parsi gentleman of Gujarat. Briefly these may be said to give the cost of cultivation and rent of land for 10 years

as Rs. 24, and the gross proceeds for grazing and fuel as Rs. 231, thus leaving a net profit of Rs. 227. Dr. Leather (Agri. Ledg., 1896, No. 18, 158) shows the working expenses for an acre of land in Agra under babul as Rs. 146 and the gross receipts Rs. 440, so that the net profit in 10 years came to Rs. 294. But in neither of these cases does allowance appear to have been made for the sale of bark, the plantations having been undertaken simply for fuel purposes. In conclusion it may be observed that on good soil the tree is much less gregarious, is allowed to grow to a fairly large size, and is accordingly valued more as a timber tree than as a source of fuel. A tree is considered full-grown in from 20 to 40 years, and may then fetch from Rs. 40 to Rs. 100 according to the size of the timber afforded.

The variety (mentioned above) as kaulia or vedi is that usually grown in Berar and Western India, when fuel only is desired. The telia or gudi is ordinarily allowed to run to timber. Success in cultivation would seem to depend upon several circumstances, such as the scarcity and consequent high price of fuel, a good market for the bark, the existence of suitable land at low rents, etc., etc. But it must never be forgotten that, to be successful, production of babul fuel and babul bark must be in close proximity to the markets, since neither product could bear heavy railway freight.

Soil.—According to most observers the babul prefers a sandy light loam or black cotton soil to heavy clay, but appears to be somewhat indifferent to the presence of a fairly large percentage of rék or shor (efflorescent salts—see Alkalies, pp. 51–6). But it does not succeed either on rocky and hilly ground or on low-lying and submerged tracts, hence plantations to be made profitable must be on fairly good soils. The yield and quality of the gum, of the tanning bark and of the timber—its three chief products—greatly depend on the condition of the plant.

Enemies.—The life of the tree is generally said to be about 20 to 30 years; at all events after that age it seems to become a ready victim to the ravages of various pests, among which the grubs of one or two longicorn beetles may be specially mentioned. Mr. Stebbing (Injurious Insects of Forest Trees, 67, 69) describes these as Coleosterna splinctor and Pachydiscus holosericeus. Its greatest enemy, however (especially during the first 3 or 5 years of its existence), is probably the goat.

The commercial products and utilisation of babul may be dealt with under the following headings:

1. The Gum.—This exudes in March, April and May, according to the vast majority of reports, but in connection with Amritsar it is said to ooze from the trees in the months of October, November and December. A tree yields a maximum of about 2 lb. a year, but the average might be more safely put at a few ounces. In certain localities little or no gum is given by the trees, and seasonal variations in yield are also well known and are said to be dependent on abnormal climatic conditions. Tapping the trees is generally believed to accelerate the flow, but this is not often practised, and may be detected by the presence of long stalactiform masses.

The gum occurs in the form of irregular and broken tears agglutinated, each tear being half an inch in size and of a pale straw-colour to red, brown or almost black, according to the age of the tree. The quantity yielded varies directly, but the lightness of colour and quality, inversely to the age of the tree. Such, at least, is the general opinion, although the Amritsar report states that old trees do not yield any gum at all. Long exposure to atmospheric influences, more especially to damp and rain, darkens the colour and lowers the value of the gum, besides making it astringent owing to the quantity of tannin (from the bark, doubtless) with which it becomes charged. [Cf. Vilbouchevitch, Journ. d'Agri. Trop., 1901, i., 49.] Observers have also noted that gum exuding from gnarled stems or diseased portions is dark; moreover, that it varies in colour and becomes brittle by exposure to the sun or artificial heat. [Cf. Goetz in Pharm. Zeit., 18, 119; Journ. Chem. Indust., 1903, xxii., 429.] The purer and paler-coloured gums
Uses—Indian gum arabic is used in Calico-Printing and in all other industries where a mucilage is necessary and in which the peculiar properties of this particular gum are recognised as specially suitable. Amongst other minor purposes it is, for example, employed as an ingredient in whetwash and in paints used for wall-distempering. It is added to certain Mortars and to paints that are used for clay toys. As a Medicine it is an indifferent substitute for the true gum arabic of European pharmacy. It is often used as a vehicle for castor oil, and has the merit of absorbing the offensive smell. One drachm of gum dissolved in \( \frac{1}{2} \) oz. of water will carry 1 oz. of castor oil. Its use in lozenge-form is diminished by the fact that it is less soluble than the true Gum Arabic. [Cf. Taleef Shereef (Playfair, transl.), 1833, 142–3.]

At one time the gum was said to form an important item of human Food in times of scarcity, but recent inquiry has brought out a flat contradiction of that statement from almost every district in India. The gum at all seasons is several times as expensive as the grains eaten by the poor; preferably, therefore, they would purchase grain with it. It is nowhere so abundant as to become a famine food. It is, however, unquestionably edible, and fried with ghi, sugar and spices, is employed in the preparation of certain Native sweetmeats which are very generally eaten after child-birth.

So far as they have proceeded, the investigations into the Indian gums suitable for the European confectionery trade have revealed several very surprising circumstances connected with this gum. There are, for example, great variations in quality, which are not alone to be explained by adulteration with inferior gums. Not only does the quality depend largely on the age and variety of tree, but on the locality of production. Thus two samples, one said to have been the best quality from Nagpur, the other from Cawnapore (both believed to have been authentic samples of *Acacia arabica* gum), were forwarded to Messrs. Rowntree & Co. for examination and report. The reply which came in due course was—“They gave exceedingly dark solutions of medium strength, but both are quite useless to us on account of the colour.” A third consignment procured from the Panjâb was said to give “a pale solution, very thin and probably of little value for any purpose.” The best Indian edible gum, from Messrs. Rowntree & Co.’s standpoint, would appear to be that referred to under *A. Jacqumontii*. It would thus seem that, far from *Acacia arabica* affording the best edible gum arabic of India, it might almost be described as the least important of all the Indian edible gums. It seems, however, probable that babul gum from Sind may be of a much superior quality to that from other parts of India. As met with in trade this gum comes mainly from the Central Provinces and Berar and is known in Bombay as Umrawalti and Amrad. But attention may here be called to the circumstance often discussed (e.g. by Vilbouchevitch, *l.c.* 48), that all gum from the same species and even
from the same tree is not of equal quality. The variation is doubtless due to bacillic action, and ants have been spoken of as facilitating the ingress and dispersion of the bacilli.

Price.—The information available regarding the price at which the gum can be procured is so conflicting as to render the returns practically worthless. They range from Rs. 12 to Rs. 50 per 100 lb.

2. The Tanning and Dyeing Bark.—Babul-bark is perhaps one of the most extensively used and most highly valued of the crude tanning materials of India. It is in fact, with many of the Native tanners, the chief TANNING SUBSTANCE in practically all provinces except South India, where its place is to a large extent taken by the tanner’s Cassia (Cassia auriculata). It is also very extensively employed by the dyers because of the rich colours it affords. In a work such as the present, space cannot be afforded to deal with the methods of dyeing and tanning pursued, nor to furnish the formulæ of the special preparations employed. The reader must consult the Dictionary and other such works for all details.

Source.—The introductory paragraphs of the present article have already set forth some of the practical considerations regarding production of babul-bark. It is commonly obtained from trees felled for fuel, and the bark very often becomes the woodman’s wages. So again the observation has been made that the bark from old trees is not so valuable as that from trees 6 to 10 years of age. In order, however, to obtain perfectly trustworthy information on this point an extensive series of barks from a selected number of districts was procured from trees of various known ages and during certain fixed seasons of the year. [Cf. Agri. Ledg., 1896, No. 9, 42, 54–5.] Apparently no report has as yet been published of the results arrived at by the examination of the barks, thus specially brought together for that purpose. Hooper, however, affirms that “the tanning content undoubtedly increases with the age of the tree” (Agri. Ledg., 1902, No. 1, 23), and he cites a report of Mr. J. Toil of date 1845 in support of that opinion which is exactly the opposite of the modern view held by the European tanners of India. Recent inquiry has, however, been prosecuted sufficiently far to reveal the circumstance that babul-bark is hardly likely to compete successfully with the tanning materials already procurable in Europe, and that very possibly it will never even pay to manufacture for export a tanning extract from this bark or from the bark and pods combined. Much has been written on this theme, but it may be said that the chief claims of babul-bark turn on its cheapness and abundance. It is bulky and the percentage of tannin is small, hence it cannot be profitably carried for more than short distances. Accordingly the conclusion must be that babul-bark is a tanning material of great local value, but one that stands a poor chance of being exported to any appreciable extent. It contains 18–95 per cent. of catechol tannin, which takes a beautiful cream colour when precipitated with gelatin. Martin says that 3 lb. of the bark suffices for each maund of hides. [Cf. Monographs, Tanning, and Working in Leather:—Walton, U. Prov., 23; Martin, Bomb., 7; Chatterton, Madras, 26; Rowland N. L. Chandra, Bengal, 11–2; C. G. Chenevix Trench, C. Prov., 7.]

Price and Supply.—Very little of a definite nature can be published on these subjects. It has been reported recently that the annual consumption in Cawnpore alone is over 200,000 mdaunds, valued at eight annas a maund. But Cawnpore is the great tanning centre of India, and, therefore, its transactions represent a very large slice of the total traffic in the bark. Quotations have been obtained from Dumraon, Bandelkhand, the Central Provinces, Shahpura (in Rajputana), Delhi, Poona, etc., etc., which show that the bark fetches from 8 annas to as much as Rs. 2–4 per 100 lb. These and such as these are the returns that have come to hand, and they afford very little trustworthy information other than that the bark is a local product which in point of price is, like most
BABUL PODS AS A TAN

other commodities, influenced very greatly by the laws of supply and demand.

Babul-bark is extensively employed in India as an astringent medicine, and the ashes as a dentifrice.

3. Tanning Pod.—Roxburgh (Trans. Soc. Arts, 1805, xxiii., 408–10) was apparently the first person to draw the attention of Europe to the large and valuable supply of these pods that might be procured from India. This subject did not, however, seem to attract much attention until 1884, when an absurdly high valuation as a tanning material was attributed to the pods. It was then affirmed that when crushed and freed from seed, they would fetch £40 a ton, or 50 per cent. more than was then being paid for oak-bark. This naturally led to numerous experiments to test the yield per acre, the cost of production and methods of crushing and baling the material. When the desired report finally came to hand from England, babul-pods ceased to attract attention; they had been found to contain at most 91 per cent. of tannin, and could not bring more than £10 a ton. All interest in the subject died as quickly as it had arisen. A more hopeful result seems, however, to have been obtained by Mr. Chatterton. The Agricultural Ledger, (1896, No. 9, 46) may be consulted for further particulars. But crushed babul-pods impart a beautiful colour to leather, and mainly on that account enjoy a certain local reputation as a weak tanning and dyeing material, useful in conjunction with other substances. At the Cawnpore Tanneries the pods are employed almost exclusively for the purpose of removing the lime from skins and hides, before tanning the latter with babul-bark or other substances. The dyers of India often utilise babul-pods to obtain certain shades that are admired in calico printing.

An extract may be prepared from the immature pods by inspissation. This was known to the Ancients, and through the Greeks reached the Arabs, to whom it was known as akakia. To this day a Drug comes to India under that name from Turkey and Persia, and is sold by most Muhammadan druggists. The unripe pods reduced to a powder are used as a domestic medicine in all cases where an astringent is indicated. They are employed in the manufacture of Tooth-powder, and along with sulphate of iron in the preparation of ink. The tender young pods are eaten as a vegetable, especially in times of scarcity. They are often pickled (achar) and viewed as a luxury, especially by the Marwaris. The green pods with their seeds are regularly given as fodder to goats, sheep, cows, and camels. In Sind the green pods are much appreciated, and in the early part of the hot weather, during April and May, the sale of green pods forms an important item in the forest revenue of that Province. In the Annual Reports of the Forest Department for Bombay (including Sind) the amounts credited as realised on this heading average from Rs. 12,000 to Rs. 30,206.

4. Tanning Leaves.—Most of the older writers speak of the leaves of this tree being also used as a tan, but according to voluminous opinions recently to hand this would appear to be a mistake. They are sometimes employed in dyeing, and are also often utilised in the manufacture of ink, so that they do possess tannin but in such small quantity as to be useless as a tan. The chief value of the leaves is as fodder, especially in times of scarcity or famine. Beaten from the lopped and dried spinose branches, they are regularly given to cattle. Although the tree is never leafless, fresh foliage appears from February to April. The value of this source of fodder when rain fails cannot be overstated, as the tree is thereby little, if at all, affected in the production of foliage.
THE INDIAN GUM ARABIC TREE

ACACIA CATECHU Timber

The leaves constitute an ingredient in the intoxicating drug of Indian hemp known as madak, and it is said that in a similar way they are also made up with opium.

5. Minor Industrial and Agricultural Uses. — One of the most widely known of the minor uses of the plant is for tooth-brushes. Short twigs are made up into small bundles of about 100 each and in that form are exported as a regular article of trade from Karachi to Bombay and practically all over India. They are very extensively in demand by the Marwaris; on being used the end is chewed until it forms a sort of brush. Very strong and durable baskets are also made of young green babul-twigs. In fact, they are the base of the agricultural and industrial classes of many localities (see Basket and Wickerwork, etc., pp. 114–6). In some parts of the country fishing-traps are similarly constructed of the young shoots and the spines are occasionally employed as fishing-hooks or as pins to fasten together the leaves used as platters. Crude ropes are sometimes made of the bark fibre.

In Sind (and to some extent also in the Panjâb) babul is one of the important trees on which the Lac insect is reared. The reader will find full particulars on this subject in The Agricultural Ledger (1901, No. 9). To the Indian cultivator babul is of the greatest possible value. It does not afford much shade, and yet curiously enough very little except grass will grow underneath it. On this account it is rarely, if ever, allowed to get established in the middle of fields. For avenue purposes, where shade is required, it is not a desirable tree. But in the Reclamation of waste lands babul is invaluable, especially where reh effluence gives cause for anxiety (see Alkalis and Alkaline Earths, p. 55). Grass rapidly becomes associated with it, so that grazing affords a distinct source of revenue in babul plantations. [Cf. Ribbentrop, Ind. For., April 1900, xxvi.; Moreland, Director of Agriculture in the United Provinces. Official Reports regarding the Abbaspur (Oudh) Experiments.] Sown thickly as a HEDGE, babul forms a great protection both against animals and the parching, dust-laden winds. As dead fences, the spiny boughs are universally employed to afford temporary protection to valued crops. For these and similar reasons extended cultivation of this tree should invariably be commended in all suitable localities.

6. The Timber. — This Timber is highly appreciated for all forms of agricultural implements, because of its hardness and durability. It is especially valued for cart-wheels. In Bengal, the United Provinces and the Central Provinces the timber is rarely, if ever, employed in house construction or for furniture, as it is supposed to be very unlucky. But in the Panjâb, Sind and Bombay no such superstition exists, and accordingly it is frequently utilised in house-building and is much appreciated where great strength is desired. In Bijapur it is in demand for the construction of the carts for which that town is famous. When used for furniture, especially wood-carving, the timber is previously carefully seasoned in water. Recently it has been suggested that babul-wood might be employed for wood-paving. A writer in Capital (March 5, 1903) believes that this would be found cheaper in the long run than the present method of metalling. The wood when seasoned is very durable and much easier to cut and shape than the timbers most largely used for paving-blocks.

As a source of Fuel or Charcoal babul justly holds a high position in popular favour. Its cultivation in the vicinity of all large towns would seem highly profitable. An average-sized tree will give 5 maunds of fuel, besides branches and bark that bring in additional returns. Some few years ago a scare was started by the Madras Railway that babul fuel injured the boilers. This point has been freely discussed since then. The practical result may be said to be the conclusion that, as compared with coal, all forms of wood fuel are injurious. Babul is not more injurious than other timbers, and moreover it has so high a calorific value that it is not only extensively used at the cotton and other mills and on the railways of Upper India, but would be even more extensively employed were it procurable in sufficient abundance.

A. Catechu, Willd.; Fl. Br. Ind., ii., 295; Heuzé, Les Pl. Indist., 1895, iv., 288–92; Prain, Some Additional Leguminosae, Journ. As. Soc., Beng., 1897, lxvi., pt. ii., 508–9; Gamble, Man. Ind. Timbs., 296–8. This is the Cutch or Catechu tree, the khair or katha. Prain has rendered valuable service by establishing the
characteristics and respective areas of distribution of the three forms of this plant. These are briefly as follows:

**Varieties of the Species: Var. (a) Catechu.** Calyx, petals and rachis with spreading hairs.—This is the most northern form, having been recorded as met with in Hazara, Kashmir, Simla, Kangra, Garhwal, Mussoorie, and the Konkan, and has been recorded so far to the north-west as in Kathiawar and Rajputana, and on the north-east in Burma, at Segaiy, Mandalay, and the Shan hills. It is the *lat-khair* (red Catechu), the *nallasandra* (or simply *sandra* or, as Sir Walter Elliot renders it, *chandra*), also *kuti, kute, kach*, *kagi, kempu, shemi, karangali, baga, banni*, etc. [Cf. Cooke, *Fl. Pres. Bomb.*, i., 448; Hooper, *Rept. Lab. Ind. Mus.* 1903-4, 28.]

**Chief Products.—** These three forms of var. *A. Catechu* are said to be practically identical in their properties and uses. They all yield a Gum, an astrin gent Extract and a useful Timber.

The Gum is of a pale yellow colour and often occurs in tears one inch in diameter. It is sweet to the taste, soluble in water, forms a strong pale-coloured mucilage and is not precipitated by neutral acetate of lead, but gelatinises with basic acetate of lead, ferric chloride and borax. It freely reduces Fehling's solution. It is a better substitute for the True Gum Arabic than is babul gum. Most of the superior qualities of Indian Gum Arabic, especially those of South India, are very possibly obtained from this species of Acacia.

**The Timber.—** Sapwood yellowish-white, heartwood either dark or light red, extremely hard. It seasons well, takes a fine polish and is extremely durable. It is used for all kinds of agricultural implements, wheelwrights' work, etc. In Burma it is employed for house posts and very largely as fuel for the steamers of the Irrawaddy Flotilla. The Fuel of dead *khair* is much valued by goldsmiths. In Northern India cutch wood is made into *charcoal*, and is regarded as one of the best woods for that purpose. It has been pronounced good for railway sleepers. A cubic foot of *variety* (a) weighs from 50 to 60 lb.; of *(b)* about 60 to 70 lb., and of *(γ)* slightly more. But it is as the material from which Cutch extract is prepared that the wood of this plant attains its greatest value.

**THE EXTRACT CUTCH OR CATECHU.**

It is not proposed to deal with this substance very elaborately in the present work. The article in the *Dictionary*, amplified as it has been by *The Agricultural Ledger* (1895, No. 1; 1896, Nos. 2, 35; 1902, Nos. 1, 2; 1906, No. 3) contains practically all that is known. The reader is referred to these publications, and the remarks that follow must, therefore, be accepted as an abstract intended alone to set forth the aspects of commercial interest:—

**Commercial Qualities of the Extract and Methods of Manufacture.—** How far the peculiarities of the above-mentioned trees account for the different properties
ACACIA
CATECHU
Pegu Cutch

Exported from Cambay.

Origin of Name.

Terra Japonica and Gambier.

The extract, appears never to have been ascertained. It may be mentioned as a curious circumstance, very possibly connected with A. Sundra, that one of the earliest European writers, Barboza (1514 A.D.) speaks of cacho as exported from Cambay to Malacca. The name cacho would seem to be simply the Kanarese kachu, and very possibly gave origin to the modern Latin name Catechu. In 1574 Garcia de Orta (Coll., xxxi.) gave a complete account of the plant, and of the manufacture of the extract under its Tamil name of kati (cate), a word which by some authors gave the first half of the name Catechu, the second being derived from chuena, to distil. It is probable, however, that although the earliest European authors saw the extract being prepared from A. Sundra, the Pegu form is quite as ancient if not more so. It was not, however, until the seventeenth century that catechu attracted the attention of Europe. It was then supposed to be a natural earth, and as it reached Europe by way of Japan it received the name of Terra Japonica. About the same time Gambier also found its way to Europe, and was designated Terra Japonica indiscriminately with catechu. Cleger exploded the mineral notion of these substances, by republishing in 1685 Garcia de Orta's account of the preparation of the extract. He affirmed that the best quality came from Pegu, other sorts from Surat, Malabar, Bengal and Ceylon.

There are said to be three forms of this substance: (1) Dark Catechu or Cutch, chiefly used for industrial purposes; (2) Indian Pale Catechu or kath—a crystalline substance eaten in pan or used medicinally; and (3) Keersal (kirsch), a crystalline substance found embedded in the wood, much after the same fashion as Barus camphor. To obtain the cutch the trees have to be felled, but the destruction is conducted in so ruthless a fashion, and so widespread is the demand, that many officers affirm the total extinction of the tree is threatened [Cf. Upper Burma Gaz. Shan States, 1900, ii., pt. i., 314; For. Admin. Rept. Pegu Circ., 1900–1, 10: Summary Sett. Operations, Lower Chinwin Dist., 1901–3, 3; Hooper, Rept. Labor. Ind. Mus., 1901–5, 26–7; 1906–7, 10.]

The following particulars may be given regarding the manufacture of the two first-mentioned extracts:

1. Dark Catechu or Pegu Cutch.—Three men generally work together: one cuts down the trees and drives the cattle that drag the logs to the site of the furnace; the second clears off the sapwood and cuts the heartwood up into the little chips required by the third man, who attends to the furnaces and boilers. The chips are packed into earthen pots holding three to four gallons of water, and the whole is boiled down to one-half; the chips are then taken out, and the liquid of 20 to 25 parts is gradually poured into a large iron pan or cauldron, and again boiled and stirred and fresh liquid added from the earthen pots until the fluid attains the consistency of syrup. The cauldron is then taken off the fire and the contents stirred continuously with a wooden paddle for four hours or more, till the mass cools and can be handled. It is then taken out and spread on leaves arranged within a wooden frame, like a brick mould. It is left over-night, and in the morning the extract is dry and ready to be cut up into pieces for the market. It might then be described as a brick of cutch weighing 36 to 44 lb. A picturesque and illustrated account of the work is given by a correspondent in The Empress (July 1903).

The chips are sometimes boiled down a second time, but as a rule very little is extracted by this further boiling. Much difference of opinion prevails as to the necessity of beating the liquid after the cauldron is taken off the fire. Some manufacturers are satisfied with half an hour, others give it as much as four or five hours.

Cutch manufacture takes place from June 1 to March 31, but the
months of December to March inclusive are those of most energetic operations. The produce of each cauldron is approximately 36 to 44 lb. a day, but the total yield during the season cannot be accurately determined since much depends on the quality of the trees, their proximity to the boiling place and, above all, the working days of the season. The proceeds of one cauldron may be 2,000 lb., or it may exceed 6,000 lb. As to the yield of cutch per given weight of heartwood, it is believed that a ton of wood might be taken as yielding 250 to 300 lb. of cutch.

In the western and northern tracts of India, such as Kanara, Dharwar, Khandesh, Surat and Baroda, and to some extent Chota Nagpur in Bengal, Dehra Dun and Gonda in Oudh, dark-coloured cutch is also prepared by a process that only differs in minor details from that briefly described in connection with Pegu. The industry in these regions is on a much smaller scale and the appliances are correspondingly less perfect, but the principle involved is the same. In Gujarat, as a rule, the trees are not felled, but the larger branches are simply lopped off, and these are cut and boiled down into cutch. The article from these localities as met with in the market differs, however, materially in external appearance and shape from Pegu cutch. It occurs in small cubes, flat cakes or rounded balls, and is of a redder colour and more opaque fracture. The influence of the method of manufacture, more especially the use of iron cauldrons, will be discussed in a further paragraph.

2. **Pale Catechu** or the crystalline substance known as **Kath**.—This is the restricted name, given in Northern India to a grey crystalline substance prepared from a concentrated decoction of *A. Catechu* wood by placing in it a few twigs and allowing the decoction to cool. The twigs are removed and the crystalline substance found adhering to them is collected and pressed into large irregular cubes. Whether the liquid is rejected or is afterwards boiled down to produce a poor quality of dark catechu or cutch has curiously enough not been recorded. The cubes of grey crystalline substance are the *kath*, which is eaten by the Natives in their *pan* and which imparts with lime the red colour to the lips. It is, apparently, hardly ever exported to Europe, and the name *kath*, while chiefly applied to it, is in some parts of India unfortunately also given to cutch. *Kath* and cutch have by Europeans been mistaken for the same substance, but the former is much purer chemically than the latter, and it may be owing to the fact of cutch being the form exported to Europe that catechu has lost the former position it held as an astringent *Medicine*. It seems probable that the preparation of *kath* may be a secondary process from the cutch, since its direct preparation from the original decoction has only been observed at Kumaon, although the substance is universally used in *pan* all over India. This subject deserves to be thoroughly investigated, and the merits of *kath* and its process of preparation made better known. In a further paragraph will be found an abstract of recent investigations that have a bearing on the issue here raised. [Cf. Madden, *Journ. As. Soc. Beng.*, 1848, 565.]

3. **Keersal or Khersal**.—From the wood of *Acacia Catechu* is occasionally obtained a pale crystalline substance known as *khersal*. The woodmen, when cutting up the timber for fuel, sometimes come across this substance and carefully collect it, since it is much valued as a medicine by the Hindus, and fetches a high price. [Cf. Dymock, *Mat. Med. Western Ind.*, 232; *Bomb. Gaz.*, vi., 13.]
Improvements in Manufacture.—The Agricultural Ledger (1895, No. 1) records Dr. Warth’s experiments in the manufacture of cutch, with the results obtained and the correspondence that ensued on his recommendation for the establishment of central factories under Government control. Warth showed that the Native system was wasteful and destructive, more especially through the use of iron cauldrons. He explained that the active principle of cutch was the tannin known as Catechu-tannin. This forms a greenish-brown compound with ferric salts. There is also present, however, another substance known as Catechin, and this is the active principle in kath, or the edible form of cutch. Catechin is, however, easily changed into tannin. It is soluble in hot water but practically insoluble in cold water, while catechu-tannin is completely soluble in cold water. From this simple fact Warth proposed that catechin should be invariably separated from the catechu-tannin and sold by itself, but he showed that it was essential that this should be accomplished by a rapid process and in concentrated solutions. Etti had previously pointed out these peculiarities, but Warth gave them a practical value. The concentrated decoction is by him recommended to be set aside for five days, to allow of the formation of the crystalline catechin. Cold water is then added and the solution filtered, and the filtrate again boiled down to form catech free from catechin. As already suggested, it seems probable that by some such process kath may be regularly manufactured by the drug dealers of India, since the Kumaon supply could hardly suffice to meet the Indian consumption.

Warth then demonstrated the injurious action of iron on catechin, and urged that the cauldrons used should invariably be copper. His observation that wood spotted with white deposits is richest in catechin, and that such wood is more prevalent in Oudh than in Burma, confirms a widespread Native opinion, and probably points to something peculiar in the variety of plant grown in Oudh (var. α, Catechu, above), as compared with that of Burma (var. β, Catechuoides).

The inquiry was next prosecuted by Dr. Leather, Agricultural Chemist to the Government of India. His assistant, Mr. Collins, furnished a most instructive table of analysis, in which he showed that commercial valuations rarely coincided with percentage of catechu-tannin and catechin (more especially of the latter), but were dependent mainly upon the appearance of the extract. So far as the tanner is concerned the complete absence of catechin might be said to be a recommendation. Leather dealt in a most interesting manner with the best methods of cutting up the timber, with the effect of different kinds of water, the quantity of water required, and the time which was essential to boil the wood. He showed that it would be more economical to reduce the wood to shavings by the carpenter’s plane than to cut it into chips as at present. When reduced to shavings the yield of catechu-tannin and of catechin was much higher than with chips; the proportion of water to weight of wood could be reduced from 20 to 10 or even less; and the duration of boiling might be reduced from twelve hours to half an hour. All these circumstances indicate not only vast financial economies, but the production of a superior quality of extract, owing to the smaller amount of boiling that is necessary. The separation of white catechu (or catechin) from cutch (or catechu-tannin), might be made a commercial success if accomplished from an extract prepared in the manner indicated by Leather.
PRODUCTION AND TRADE

In The Agricultural Ledger (1896, No. 35) will be found the results of Professor J. J. Hummel’s and Mr. Reginald B. Brown’s chemical investigations into the dyeing properties of catechu-tannin and catechin. Briefly, they have demonstrated that both these substances may under certain circumstances be used as dyes. [Cf. Journ. Soc. Chem. Indus., March 31, 1901, xx., 246.] The present purpose has been to convey the facts of commercial importance and the bearings of recent research (both botanical and chemical) on possible developments of the cutch industry.

Production and Trade in Cutch.—Trustworthy returns are not available regarding the production of cutch in India. The trade is very largely in the hands of small manufacturers and dealers. As a rule the right to work the cutch forests belonging to Government is granted by license and sold by auction or tender. The period for which the licenses hold good is usually four months. Commercial Circular (1896, No. 11) gives certain particulars of interest regarding the Burma trade. It is calculated that on the average 80 cutch trees are used per cauldron, and as the average price paid for the cauldrons comes to Rs. 225, the average price obtained per tree comes to Rs. 2-13. But each tree would yield about 25 cubic feet, say half a ton, so that the price obtained is equivalent to Rs. 5-10 per ton, or nearly as much as is usually got from the local traders for undersized teak logs.

It would seem that the Burma production averages from 130,000 to 150,000 cwt. a year; the South Indian perhaps 1,000 cwt.; the Bombay perhaps half that quantity; and it is probable that Bengal and the United Provinces yield between them about 20,000 cwt. This conception of the probable annual production is inferred very largely from the returns of Foreign, Coasting and Internal Trade, rather than from actual statistics, and consequently it ignores local consumption. Thus the total exports to foreign countries were 183,729 cwt., valued at Rs. 36,96,106, in 1895-6; 122,082 cwt. in 1896-7; 97,187 cwt. in 1897-8; 61,669 cwt. in 1898-9; but they rose again to 127,815 cwt., valued at Rs. 24,70,422, in 1899-1900; sank to 101,995 cwt. in 1900-1; and further to 66,162 cwt. in the year following. In 1902-3 there was a slight improvement to 70,305 cwt., valued at Rs. 13,42,583, and a still further improvement in 1903-4, viz. to 112,936 cwt., valued at Rs. 19,71,896. In 1904-5, however, they again fell to 62,562 cwt., valued at Rs. 9,71,041, and in 1906-7 to 97,269 cwt., valued at Rs. 15,92,561. The traffic thus fluctuates greatly, but would seem on the whole to be declining. Usually Burma contributes about 98 per cent. of the total. For example, taking the total export for 1906-7, Burma furnished 95,451 cwt., Bengal 1,687 cwt., Madras 124 cwt., and Bombay, 7 cwt. The Bengal trade seems for some years to have declined and direct shipments from Burma to have increased. The United Kingdom is the country to which by far the largest consignments are usually made. The next in order are, as a rule, Egypt and either France, Germany or Holland. The trade with the Straits Settlements has steadily declined from 6,585 cwt. in 1898-9 to 1,796 cwt. in 1901-2, 104 cwt. in 1905-6, but rose to 854 in 1906-7. The United Kingdom takes from 70 to 80 per cent. of the total annual supply. Of the coastwise traffic Bengal (Calcutta) is the most important receiving centre and Burma the most important exporting. In 1895-6, Bengal received 35,079 cwt., but that traffic seems to have declined seriously, and in 1902-3 was only
ACACIA
JACQUEMONTII
Gum

13,557 cwt., and in 1905–6, 10,678 cwt. The Rail and River-borne trade returns show Bengal as the most important receiving province, and mainly from the town of Calcutta, hence doubtless Burmese. The United Provinces might be called the most important exporting centre, the major portion of the supply going to Bombay town and Presidency.

**A. concinna**, DC.; Fl. Br. Ind., ii., 296. A common prickly scabdent bush met with in tropical jungles throughout India.

Since the pods of this bush are extensively used as a detergent, they are often confused with the Soar Nuz (Sapium Makarossi), and, indeed, they bear, as a rule, the same vernacular names—viz. rita or ritha, but are sometimes separately distinguished as the ban (wild), ritha, sikakai, aulah, etc. These detergent pods are largely employed in washing silk and woollen goods. Some of the best tinctorial results are believed to be obtained only with yarn washed with this form of soap previous to being dyed. They are extensively used in washing the hair, and with much advantage in cleansing tarnished silver plate.

In Northern Bengal they are utilised in poisoning fish. The trade in detergent pods must be very considerable in India as a whole. Collective returns are, however, not available, but we read of from 10 to 135 tons being imported into Bombay annually, and mainly from South Kanara. The Madras Mail (Jan. 1898) speaks of the local supply coming from Palghat and Vaniambaby, and urges that an effort should be made to place these pods on the European market.

The bark of this bush is to some extent used as a Tan for fishing-lines, and is imported for this purpose into Bombay from Kanara. [Cf. Gamble, Man. Ind. Timbs., 1902, 291; Cooke, Fl. Pres. Bomhs., i., 450.]

**A. Farnesiana**, Willd.; Fl. Br. Ind., ii., 292. A small tree best known in Europe as the Cassie Flower, and curiously enough is in India denoted by comparative or descriptive names such as *wileyati* (English) babul or kikar, pissi-babul, gu-kikar, kankar, veda vala, gaya-babul, murki tumma, naga tumma, kusturi, jali, nanlongying, etc. It is indigenous in America and possibly cosmopolitan in the tropics, is cultivated or naturalised all over India and Burma.

It is largely grown in France on account of the rich perfume obtained from the flowers. Although it yields a Gum and other products similar to most species, the chief interest centres in its "Cassie Flowers." The late Sir E. Abel, in a letter to the Government of India, dated July 16, 1894, gives certain interesting particulars regarding the success obtained by a tea-planter in Naini Tal, in producing Cassie Pomade. Although a good deal of attention has been given to this subject, little progress has as yet been made towards establishing a trade in the perfume. It is probable that in India a difficulty might be found to exist in preventing the lard or sweet oil, employed in the manufacture of the pomade, from becoming rancid. But in the lower hills or terai where this tree abounds, or might easily be cultivated, it seems possible that a useful auxiliary crop to tea, coffee or even indigo planting, might be found in Cassie Pomade. [Cf. J. C. Sawer, Odorography, 114–6.]

**A. Jacquemontii**, Benth.; Fl. Br. Ind., ii., 293. A small handsome shrub with polished stems and thorns, and flowers sweetly scented. It is met with in the North-West Himalaya up to 3,000 feet. In the Panjāb plains, in Sind, in Rajputana and in North Gujarat it is often very abundant, especially within watercourses.

Known in Afghanistan as the hanz, in the Panjāb it appears to bear, as a rule, the same vernacular names as *A. arabica*, but a sample recently received from Amritsar, by the Reporter on Economic Products, bore the vernacular names of dhakki and chota-kikar. In Rajputana it is called baoni or guli bonti; in Gujarat it is the rita-biwal; in Baluchistan harbarbara; and in Sind khunbut. Captain M. A. Tighe, Political Agent, Southern Baluchistan, speaks of the gum of this tree as one of the spurious gum arabics which are known in that country as *khorikhor*. [Cf. Rept., dated March 14, 1898.]

For some years past a considerable trade from Baluchistan and Sind has
been done in the Gum of this species, exported from Karachi. Stokes (speaking of Sind many years ago) says that it is inferior to gum arabic, but is used in medicine, calico-printing, and in paper-making. Captain Tichie has much to say as to the difference between this and the true gum arabic (the khor-ka-khor) which see under A. senegal. But it may be added in conclusion that Messrs. Rowntree & Co., Ltd., of York, have pronounced the Amritsar samples (mentioned above) as the best of the series of Indian gums examined by them, for the confectioner’s requirements. “It is strongly mucilaginous and forms a thin jelly on standing with ten proportions of water. The solution is brownish, but fairly free from sediment, and the flavour is sweet.” It has been ascertained that about 35 cwt. of this are annually procurable in Amritsar.

A. leucophloea, Willd.; Fl. Br. Ind., ii., 294; Gamble, Man. Ind. Timbs., 295; Brandis, Ind. Trees, 265. The safed kikar, arinj, rinj, ruru, nimbar, goira, kewar, haribaual, vel-veilam, tella-tuma, tanaung. This large deciduous fast-growing tree is found in the plains of the Panjáb and Rajputana, the forests of Central and South India and Burma. It prefers a low-lying situation, and in the Panjáb its presence is regarded as significant of a rich soil. Its branches are often disfigured by large excrescences.

According to Mr. J. G. Prebble, it yields a Gum readily soluble in water, which forms a good thick pale-coloured mucilage, possessed of the somewhat peculiar property of being gelatinised by borax but unaffected by ether, neutral or basic acetate of lead or perchloride of iron. It seems probable that, owing to its close chemical affinity, this gum is often largely used to adulterate the better qualities of “Gum Ghati” (see p. 17) of commerce. According to Mr. Hooper (Agr. Ledg., 1992, No. 1, 26) a specimen of the bark sent from the Province of Mysore was found to contain 20·8 per cent. tannin, being equal to the best babul-bark; but this seems to have been an exceptional case, as he adds that a sample examined at Dehra Dun yielded only 9·33 per cent. Its use as a TAN is therefore doubtful. The bark affords a strong Finn said to be much valued for fishing-nets. Ground to a powder it is sometimes eaten with bajra, especially in times of scarcity. But it has obtained a considerable reputation as an astringent used in alcoholic Distillation. On this account it is often called sharak-kī-kikar (spirit Acacia). The tannin precipitates the albuminous substances present in the saccharine juices, and thus facilitates fermentation, but is also said to give a pleasant astringent flavour to the beverage. In the Southern Maráthá country the trees are farmed out by Government, in consequence of the value of the bark. A distiller in South India recently informed me that he would use this bark more extensively than at present, were it possible to obtain a guarantee of quality. He held that while most Acacia barks might be used in neutral fermentation, that of the present species was so much superior to all others as to justify its being called “The Distiller’s Acacia.” [Cf. Cooke, Fl. Pres. Bomb., i., 447.]

A. modesta, ‘Wall.; Fl. Br. Ind., ii., 296; Gamble, Man. Ind. Timbs., 299; Brandis, Ind. Trees, 266. The phula, phulāi, bhamburi, kantosirayo, palosa. A moderate-sized tree found in the Suliman and Salt Ranges, the Sub-Himalaya—between the Indus and Sutlej—and is one of the characteristic trees of the Northern Panjáb plains. It grows readily in poor sandy or rocky soils, but curiously enough is also found occasionally in very damp situations. It is a slow grower, and in consequence is not often planted to any extent as a fence, for which it is peculiarly suited.

It yields sparingly a very useful Gum which occurs in small round tears or angular fragments, with a few vermiform pieces marked with waved transverse lines. Prebble says, “It is translucent and of a yellowish colour; very soluble in water, forming a good pale-coloured mucilage. With basic acetate of lead and ferric chloride it forms a jelly, but not with borax; with neutral acetate of lead a faint precipitate or cloudiness, and a slight reduction with Fehling’s solution.” The gum is sent to Bombay from Northern India, and is classed by the merchants as “Amritsar Gum.” The Panjáb supply comes mainly from the Rawapindi and Jhelum districts. In Northern India it is largely
THE TRUE GUM ARABIC TREE

ACACIA SENEVAL
Gum Arabic

employed in medicine. The tree affords also a very beautiful, strong and durable timber which is largely employed for cart-wheels, sugar-cane crushers, agricultural implements, etc. The soft delicate twigs are employed as tooth-brushes, especially in the Panjab. [Cf. Pharmacog. Ind., i., 552.]

The bark is an article of commerce, being exported from the Konkan, and employed in Bombay to Tan fishing-nets. Hooper (Agri. Ledg., 1902, No. 1, 26) says that a sample from Bombay was found to possess only 8-8 per cent. of tannin. In the Annual Reports of the Forest Department, Bombay Southern Circle, an entry occurs of the amounts realised by the sale of shemba bark. These range from Rs. 25 to Rs. 394. In Bombay it fetches about Rs. 14 per 700 lb.

A. Senegal, Willd.; Fl. Br. Ind., ii., 295; Gamble, Man. Ind. Timbs., 299; Brandis, Ind. Trees, 266; Cooke, Fl. Pres. Bomb., i., 449. It yields the True Gum Arabic of European commerce, and is the khor (Sind), khor-ka-khor (Lus Bela), kumta (Rajputana). A low tree with grey bark and flexuose branches, met with, so far as India is concerned, on the dry, rocky hills of Sind and Rajputana, more particularly in the Lus Bela country.

Commercial Qualities.—It seems desirable to bring together in this place a few of the more important facts regarding India's participation in the world's supply of Gum Arabic. There may be said to be three chief forms of the gum: 1st, True Gum Arabic of European Commerce; 2nd, The East India Gum Arabic; 3rd, The Gum Arabic of India, often collectively called "Gum Ghati." The True Gum Arabic is obtained from A. senegal, Willd., and there may be said to be two or three grades of it:

1. (a) Gum Senegal, the verek of the Negroes.—This comes from the French Colony of Senegal (on the West Coast of Africa).

(b) Kordofan or Turkey Gum.—This is known in East Central Africa by the name hashab. It comes from the mountainous tracts of Kordofan on the Upper Nile and almost in the same latitude as Senegal, though across the vast continent of Africa from west to east. It occurs in round lumps, often as large as a walnut, or in irregular broken pieces, pure white, very much fissured, especially on the surface. This gum is most frequently used for medicinal purposes, and may, in fact, be regarded as the true official Gum Arabic of England, India and America.

(c) Inferior qualities known in trade, such as Suakim Gum, Sennaar, Blue Nile, Barbary or Morocco and Mogador Gums. These are most probably mainly derived from A. arabica. Reference has already been made to the variability of gum due to climate, soil, seasons, etc., and to the part possibly played by bacilli (see above, p. 2), but physical changes also take place subsequent to its collection, and these doubtless produce variations in quality. [Cf. Journ. Soc. Chem. Indust., 1903, xxii., 429; Goetz, Pharm. Zeit., 18, 119; Pharm. Journ., 1903, 70, 417; Muriel, Ind. For., 1902, xxviii., 45-58.]

Attention may now be directed to The East India Gum Arabic. This is imported into Bombay, in the first instance, from Aden and the Red Sea ports—no part of it being produced in India. There are two qualities, viz. maklai and maswai. The former exists in large round tears or vermicular pieces, white, yellow or reddish. It is much like Gum Senegal, but more fissured. It derives its name from Makalia, the port from which it is mainly shipped. The latter exists in angular fragments and vermicular pieces very similar to the former and obtains its name
from the port of Massowa. Both of these are good soluble gums, very little inferior to true Gum Arabic. They are picked and assorted, then re-exported from Bombay as EAST INDIA GUM ARABIC, the traffic being by no means unimportant. Within recent years, however, that traffic has given distinct evidence of decline, due very possibly to direct shipments to Europe in place of to Bombay—the historic emporium of distribution.

Lastly, we come now to the INDIAN GUM ARABIC or GUM GHATI. It would seem that, in contradistinction to the gums that reach Bombay by sea, those that come by train, down the Ghats to Bombay, are collectively designated GUM GHATI. But it may be here mentioned that Clusius in 1605 speaks of Gunmi Gutti as brought from China to Europe: hence it may be asked, is it the Malay getah? [Cf. Kew Mus. Guide, 1907, 150.] Accepting the modern usage, "Gum Ghati" would embrace very possibly a wide range of gums, and very often, it is feared, degrees of quality denote the extent of admixture rather than the nature of specific variation. Gum when detected is gathered casually by women and children, or by the shepherds, and sold in small quantity to the nearest shopkeeper. It is next conveyed to the dealers and so on through many hands until diversified gums, the produce of a wide area, get hopelessly intermixed. Nowhere in India is gum systematically produced, and indeed hardly anywhere is arborescent vegetation so exclusively of one gum-yielding tree as to admit of a large uniform and constant supply of any particular gum.

Prebble (in the paper to which reference has already been made) describes 27 gums as met with by him in Bombay. These include A. arabica, A. Catechu, A. Farnesiana, A. leucophaea and A. modesta. Some short time ago Captain M. A. Tighe, Political Agent, Southern Baluchistan, was induced to give attention to this subject. In consequence he furnished admirable samples of the gums of Baluchistan, as also corresponding botanical specimens of the plants from which these had been procured. The two most important were thus definitely determined, namely, khör (or khor-ka-khor)—Acacia senegal, and harbarbara—A. Jacquinomontii. Tighe's description of the country, of the season of flow of gum, and the dependence on rain, will recall the conditions that prevail in the regions where the True Gum Arabic is produced. [Cf. Agri. Ledi., 1903, No. 2, for further particulars.] Far to the south, at Tuticorin, a modern trade in gum has been organised. Considerably different prices are being paid for the various grades of it, and at least one firm employs a staff of persons to hand-pick and assort the gums as procured. I was unable to ascertain all the species of plants that afford these South Indian gums, but the most important would doubtless be A. Sundra, which is the South Indian variety of A. Catechu and an abundant tree from Coimbatore northwards to the Deccan and Gujarat. [Cf. Heuzé, Les Pl. Industr., 1895, iv., 258-66.]

TRADE IN GUM ARABIC.—As already stated, one of the features of this trade is the supply drawn by India from Africa, Arabia, etc., by sea, and from certain tracts of country by land routes across the frontier. There are thus exports from India in both Indian and foreign gums, the latter being usually designated re-exports. The following statement shows the total transactions under these headings:

(a) Imports by sea 1898–9, 2,841 cwt., Rs. 59,531; 1902–3, 1,146
A CONITUM
Monk's-hood

TRADE IN GUM ARABIC

cwt., Rs. 21,494; 1906-7, 10,127 cwt., Rs. 1,54,270: (b) by LAND
1898-9, 18,093 cwt., Rs. 282,877; 1902-3, 12,800 cwt., Rs. 1,66,066;
1906-7, 11,969 cwt., Rs. 1,56,932: (c) RE-EXPORTS 1898-9, 7,297 cwt.,
Rs. 1,05,801; 1902-3, 10,704 cwt., Rs. 1,47,044; 1906-7, 2,684 cwt.,
Rs. 57,417: (d) EXPORTS 1898-9, 41,469 cwt., Rs. 7,14,632; in 1902-3, 38,019
cwt., Rs. 4,54,659; and in 1906-7, 39,202 cwt., Rs. 6,69,263.

Decline in Price.

If there be any meaning in averages of declared official values in a traffic
that for some years has been obviously changing its main characteristics,
it may be affirmed that a marked depreciation in price has taken place.
The traffic in Indian-produced gum for 1906-7 may now be analysed
thus—exports from Bombay 35,044 cwt. and from Sind 51 cwt. The
re-exports take place almost entirely from Bombay, and they are far in
excess of the recorded imports, both by sea and land routes. It is not
known to what extent the Trans-frontier traffic could be accepted as being
gum arabic, but the chief items of the "gums and resins" carried across
the frontier, drain from Nepal and Lus Bela. The latter seems a modern
trade, and doubtless mainly in the gum here dealt with. The discrep-
cancies between the returns of imports and of re-exports are seemingly
due to the Trans-frontier land supply not being fully accounted for;
to the varying extent to which stocks are drawn upon or withheld; and
lastly very possibly to admixture with Indian gum arabic. The re-
export trade fluctuates both in quantity and value very considerably,
having undoubtedly in the past been greatly disturbed through war and
plague. But on this subject Wordhoff (Journ. d'Agri. Trop., 1901, i.,
46) affirms that the advance in price of the gum called "Soudan" only
lasted into 1892, and that since 1894 the price has been almost the same
as in 1880. Vilbouchevitch believes that the only effect of the Soudan
troubles has been to bring into notice, for subsidiary purposes, certain gums
not previously known or indifferentely appreciated. There seems no doubt,
however, that so far as India is concerned, a decline has taken place in
the imports from Red Sea ports, but an expansion of Indian supply, more
especially through the organisation of the Sind and Madras contribution.
The figures discussed above are mainly those given for Gum Arabic,
not the "other Gums" nor the "Resins." Moreover an error is ever present in
that it is not always possible to isolate returns of gums from those of resins. The "other gums" may also be to some extent "gum
arabic," and thus the figures quoted may not represent the total trade.

A. Suma, Buch.-Ham. ; Fl. Br. Ind., ii., 294; Gamble, Man. Ind.
Timbs., 295; Brandis, Ind. Trees, 268.

This medium-sized tree has a white bark (a circumstance that gives origin
to most of its vernacular names); it is common in Bengal, Bihar, Assam and
South India, from the Karnatak to Mysore. It is known as the sai-kanta, kumtia,
dhauila (white) khejra, etc. Through being confused with var. SINDRA (which
see under A. Catechu, p. 9) it has by some writers been incorrectly spoken
of as a cutch-yielding species.

Recent Researches.

D.E.P.
1. 91-4.
Atis.

A. heterophyllum Wall.; Stapf, l.c. 151-4; Fl. Br. Ind., i., 29; Royle, Illust. Him. Bot., 1834, 56, t. 15; The Bover Manuscript (Hoernle, trans.), many passages. A common plant on the sub-alpine and occasionally alpine Himalaya from the Indus to Kumaon.

This is the atis, atiwa, patis, etc. (Sanskrit ativisha, which might be rendered "antidote"), but in the more eastern section of its area it receives the name nirbisi—a name more correctly indicative of A. palmatum. Atis root, if of good quality, should break with a short starchy fracture and present a uniform milky white surface. The fresh fully grown root is about 1 to 1½ inches long,
ACONITUM
ROTUNDIFOLIUM
Jadvar

and perhaps half an inch thick at its upper extremity. In structure it is of a uniform white farinaceous substance within; transverse sections seem to consist of four, or sometimes five, isolated cambium strands, the vessels of which show prominently the radiating wedge-shaped formation.

The discovery made by Dr. H. A. D. Jowett that the alkaloid exists in very small proportions, destroys any chance for the drug in the future; and the still more recent opinion that it is inert, has no antiperiodic virtue (arrived at by the expert Committee appointed by the Government to investigate the Indigenous Drugs of India), renders it necessary to remove the root from consideration as a drug, except as a mild bitter tonic. Several European and Native merchants and chemists furnished me with parcels of the roots of A. palmatum under the name atis, and others of the true atis largely adulterated with A. palmatum. These facts may be accepted as showing that in Indian pharmacy the two roots are regarded as similar, if not identical in properties. [Cf. Taleef Shereef (Playfair, transl.), 1833, 8.]

A. palmatum, D. Don.; Stapf, l.c. 156-8; Fl. Br. Ind., i., 28 (excl. syn.); Agri. Ledq., 1902, No. 3, 89. A species met with in the alpine Himalaya of Nepal, Sikkim, and South Tibet, at altitudes of from 10,000 to 15,000 feet.

This is best known by the names bikma, bijsha, wakhma, wakhma, and nirbisi. In Sikkim (according to Mr. C. Gilbert Rogers) it is the seto-bikhuma (or white bikhuma, the black bikhuma being A. inclinatum). The word bikhuma or bikma might be translated “resembling-bikh,” but also has the meaning of non-poisonous bikh. So also nir-bish means free from poison (bish). It seems probable that while that is the meaning of nirvisha, the word often confused with it—nirvisha—denotes an antidote to poison. The nirvisha most quoted by writers is the substance separately designated jadvar. The late Dr. Moodeen Sheriff paid much attention to the subject of the jadvars of modern Indian pharmacy, and one at least of those he described would seem to be the root of A. palmatum. It has come to me from all parts of India broken into short lengths and often bearing the name jadvar. What the nirvisha or jadvar of the Ancients may have been is a subject beyond the scope of this work.

As met with in commerce bikhuma root is pale-brown; it exists for the most part in long straight pieces, sometimes twisted together, but is never completely pyramidal. The fragments range from 1 to 3 inches in length and ¼ to ¾ inch thick. In structure they are almost pure white, are of a starchy consistence and, on transverse section, show a double ring of large though inconspicuous cambium strands in the form of circular or horseshoe-shaped patches. It is perhaps the most easily recognised of all the Indian commercial aconite roots.

The alkaloid present in this root has been found identical with that of A. heterophyllum, and it is thus impossible to put faith in its reputation as an antidote for poison. But according to Dutt, the Sanskrit name for A. heterophyllum is ativisha or atisiva, a circumstance if correct that would confirm the identical properties of atis and bikhuma.

A. rotundifolium, Kar. et Kır.; Stapf, l.c. 149-51; Fl. Br. Ind., i., 29; also A. violaceum, Jacq.; Stapf, l.c. 144; A. multifidum, Royle, Illust. Him. Bot., 45, 56; A. dissectum, Madden, Journ. As. Soc., Beng., 1846, xv., 95 (non D. Don); A. Napellus, var. multifidum and also rigidum, Fl. Br. Ind., i. 29.

These pretty little Alpine aconites are characteristic of the Western Himalaya (along with A. heterophyllum) between the area of the poisonous forms of the East and Central Himalaya and that of the poisonous forms which reappear on the extreme West. They have no commercial value, though in the Panjáb these roots are occasionally seen in the drug-shops, and appear to be known as tīkī ka'chāng or du'ūshā. They can with difficulty be distinguished from the roots of A. heterophyllum.

II. Poisonous Aconites that contain bikhaconitine (in one species) and pseudoaconitine (in some at least of the others). These roots are in India traded in under the names “Nepal Aconite,” bish, bikh, etc. [Cf. Herbert; Travels, 1677, 369.] They can very appropriately, therefore,
be collectively designated as the East Himalayan Aconites, for although one species exists in Kunawar and two in the mountains of Assam and Manipur, their headquarters commercially are Sikkim and Nepal. They are the Nepal Aconites of the shops of Calcutta. The important forms of the series are:

This plant occurs in the sub-alpine and alpine Himalaya of Garhwal, and a well-marked variety of it (which Stapf calls latitobum) was collected by Mr. Minniken in Nagli, Bashahr, where it is known as kalamohra (or the very poisonous mohra).

A. laciniatum, Stapf, l.c. 168-9; A. ferox, var. laciniata, Brühl, l.c. v., pt. ii., 11 (in part); Agri. Ledg., 1902, No. 3, 96.

This plant comes from the sub-alpine and alpine Sikkim, where it is called (so Rogers informs us) kalo-bikhuma—a name that doubtless would mean the poisonous bikhuma, in contrast with the non-poisonous bikhuma (A. palinum above). This isolation of A. laciniatum from the true bikh is interesting and important. It shows that it is recognised locally as only a substitute or adulterant for the true root, and in fact it would seem to be exclusively so used. Apparently it is the kalabachnag of Moodoon Sheriff, and very possibly the kalakut of other writers. The root is if anything larger than the most prevalent "Nepal Aconite" of Sikkim (A. spicatum below) and has numerous circular scars, indicating fallen lateral roots, so abundant and regular as to resemble nodes or joints. In transverse section the tuber seems to differ from that of A. spicatum by the absence of the so-called inner ring of vascular strands enclosing the pith.

A. lethale, Griffith; Stapf, l.c. 175-6 (the Mishmi Aconite); and A. nagarum, Stapf, l.c. 176-7 (the Naga hills and Manipur Aconite). It is probably safe to regard these as the most eastern members of the series.

A. spicatum, Stapf, l.c. 165-8; A. ferox, var. spicata, also var. crassicaulis, Brühl, l.c. v., pt. ii., 110; A. ferox, Fl. Br. Ind., i., 28 (in part); Agri. Ledg., 1902, No. 3, 94-6 (in part); and later by Dunstan and Andrews, Trans. Chem. Soc., 1905, ix., 138, 1636-50. This is the most abundant, most robust, and most characteristic species of alpine Sikkim and Chumbi.

The chief "Nepal Aconite" of Indian commerce, the bhik, bhish, the ativasa (very poisonous bhish) of Sir Walter Elliot; the mitha-bhish, singi-bhish, daugr, bachnag, or talka of Indian writers, and the singia jur or singia khar of Taleef Shereef (Playfair, transl.), 1833, 107. Its poisonous principle has been called bhikaconitine by Dunstan and Andrews, and described as closely related to psuedaconitine both in its chemical properties and physiological action.

The roots are very large, and when fresh are soft, flexible and pale-coloured, but when quite dry they are hard, dark brown or black externally, and of a brownish-red internally. The half-dry root when cut resembles horn (hence the name singyi or singya-bis), but as it matures and dries it becomes hard and has darker-coloured portions developed as embedded irregular patches within the tissue. These patches often appear like resin in consistence. In transverse section Stapf says the tubers are seen to possess cambium strands, continuous and forming a more or less sinuous ring. The secondary sieve-strands of the mother tubers are not encased in sclerenchymatic sheaths. The samples examined by me might perhaps be properly described as having the vascular strands in the form of an irregular sharply pointed star, enclosing a small central pith surrounded by a secondary ring of bundles. To protect the roots from...
ACONITUM BALFOURIII
Mohra
Method of Preservation.

being weevil-eaten they are often preserved in cow-urine. This may account for the dark colour of some parcels, and may perhaps explain the name kala (black) often given to these, though most writers seem to prefer to translate kala when given to an aconite as meaning deadly. This is the root exported from both Nepal and Sikkim to Calcutta. It has been pointed out that Nepalese traders have been in the habit of draining their supplies from the Sikkim as well as the Nepal side of the Singaleelah range, but that recently the facilities of the Himalayan Railway at Darjeeling have begun to make the Sikkim supply by far the most important. As indicative of the very poisonous nature of this plant, mention may be made of the fact that the sheep have often to be muzzled in the Sikkim Terai. [Cf. Kew Mus. Guide, 1907, 9.]

III. Poisonous Aconites, one at least of which contains pseudaconitine; they are in Northern and Western India traded in as “White Bith,” safed-bikh, safed-bachnag or some derivative of the word mohra (a word which like bikh denotes a deadly poison). They also constitute grades of the so-called “Nepal Aconite” of Indian commerce, and are the Central Himalayan Aconites, those found in the shops of Upper and Western India.

A. deinorrhizum, Stapf, l.c. 158-60; A. ferox, var. atrox, Watt, Agri. Ledg., 1902, No. 3, 97 (in part).

This interesting plant was collected in Bashahr (Jani Kanda) by Mr. Minniken and said to bear the local name of mohra, but it is believed by Stapf to have been very possibly the maura bikh of Cleghorn, the mitha-didya of Aitchison (Trade Prod. Leb., 175), and the plant referred to by Madden (Journ. As. Soc. Beng., 1846, xv., 95). It is thus very possibly met with throughout the Central Himalaya from Kunawar to Nepal, and has been collected by Mr. Duthie in many parts of Kumaon. Moirocroft spoke of the abundance of aconite (possibly this species) in Kumaon, and supposed the stupefiant effects of the honey from certain localities to be due to the bees feeding on aconite. Dunstan and Andrews, on the examination of fresh, more accurately determined roots, have arrived at the conclusion that the present species is that which should be regarded as affording the alkaloid pseudaconitine of previous reports. The existence of that alkaloid in certain forms of Indian aconite appears to have been first made known by Schott (1857), elaborated by Hübsehmann (1868), and worked out in every detail by Dunstan and Carr (Trans. Chem. Soc., 1897, reprinted in Agri. Ledg., 1897, No. 19; 1898, No. 3). These distinguished chemists give full particulars of the properties of the alkaloid and its decomposition products. It would appear that pseudaconitine may physiologically be regarded as identical with aconitine, though very much more active. The chief objection to its extended use is the difficulty of obtaining a continuous supply of the root of uniform quality. It seems, moreover, probable that this plant is not separately recognised by the collectors of and dealers in drugs, but is confused with the following:—

This corresponds with a large portion of the A. ferox, var. atrox, Watt (Agri. Ledg., 1902, No. 3, 97-8), and includes also A. ferox var. polyactis, Bikh. It is met with in the sub-alpine and alpine Himalaya of Garhwal to Nepal, and seems to be known by the vernacular names gobriya and banwa or bhanwa. At present it is doubtful how far the following names belong to this species or to A. deinorrhizum: phatkia, kauiriya, diliya, dhanla, dhumuriya, jhirina, etc. Mr. Duthie observes that every valley has its own names for its aconites, and even different names for the same plant when of a different shade of colour.

The difference between the roots of A. deinorrhizum and A. Balfourii is not very great. The latter is shorter and thicker than the former, and has always hardened sharp rootlets attached. The former is that which comes most largely into the markets of India as White Aconite, safed-bikh, safed-bachnag. According to Native opinion it is the most valuable and certainly the most expensive form in the bazars. It was furnished to me under the name of

22
IV. Poisonous Aconites that contain indaconite. This may be accepted as a series that corresponds botanically with the most valuable medicinal aconite of Europe and America—viz. *A. Napellus*. Stapf has shown that the true *A. Napellus* nowhere exists in India. The world’s supply of medicinal aconite is, in fact, derived mainly from the cultivated plant, and comes very largely from Germany. But there are one or possibly two indigenous aconites met with in the extreme western division of the Himalaya and adjacent hills of the Panjab that seem worthy of a place in this section:—

This very beautiful species occurs on the sub-alpine and alpine Himalaya from Chitralt to Kashmir, and also on the mountains of Hazara, between altitudes of 7,000 and 12,000 feet. It is the *mohri* of Hazara; *tilia*, kachang, dudhia, pisin of the Himalaya, and ban-bai-nag of Kashmir. According to Dunstan and Andrews its roots contain *indaconite*, an alkaloid which represents a compound intermediate between *aconitine* and *pseudaconitine*. Cash and Dunstan (Proc. Roy. Soc., 1905, 468) have pointed out that its physiological action differs in degree only, and not in kind, from the two alkaloids just named. Samples have been furnished by Indian chemists and druggists as "True Aconitum Napellus." One contributor sent it under the name of *mitha zaher*. Davies (Trade Report) alludes to 20 seers of *mitha tilia* as annually exported from Peshawar to Kabul.oodeen Sherif mentions the circumstance that a very small and highly poisonous root is sold in Northern India but never seen in the south. It differs from that of *A. Napellus* by being smaller, shorter but comparatively thicker. The tubers are seen in cross-section to have the cambium continuous, forming a more or less sinuous or star-shaped ring. The remains
of the stem are nearly always found on its upper extremity. It is not more than one inch or an inch and a quarter long. It is of a black colour; curved, densely coated with short sharp thorns (lateral rootlets), and is terminated by a short, hard, smooth and pointed bead. In the dry state it has a horny or cartilaginous fracture.

A. soongaricum, Stapf, l.c. 141–2; found in Gilgit.

An Indian form of the genus this comes nearest botanically to

A. Nupellus, Linn. The root does not appear to find its way to the bazaars of India. This species has not as yet been chemically investigated, and it is just possible that it may be found to contain aconitine.

ACORUS CALAMUS, Linn.; Fl. Br. Ind., vi., 555; Aroideae. The Sweet-flag, bacha, shadgrantha, vashambu, etc. The imported Persian rhizome is known as bāl-vāch or bāl-vekhānd. The medical treatise which constitutes The Bower Manuscript (Hoernle, transl.) makes repeated mention of this drug.

It is the Calamus aromaticus of medieval writers, and possibly the Acoron of the Greeks. It is a semi-aquatic herb occurring wild and sometimes cultivated, from Kashmir to Assam, Manipur and Burma, and to the mountains of Central, Western, and Southern India. It is most abundant between altitudes of 2,000 and 6,000 feet. An essential Oil prepared from the leaves is used in England in the preparation of a hair-powder, and from 1:3 to 2:6 per cent. of a yellow neutral essential oil may be extracted from the rhizomes, which like the other parts of the plant owe their property to the glucoside acorin. Gilde- meister and Hoffmann (Volatile Oils (written under the auspices of Schimmel & Co.), 302) say that though the oil has been repeatedly examined no satisfactory insight into its chemical nature has been obtained. It is used in "the manufacture of liquors and of snuff," but is less in demand than formerly for medicinal purposes. Native medical practitioners consider the rhizome in large doses an emetic, in small doses tonic or stomachic and carminative. It is prescribed in cases of fever, rheumatism and dyspepsia, as well as for flatulence, even in infants. It is also a pleasant adjunct to tonic or purgative medicines, and as an aromatic stimulant is recommended for catarrh and distressing coughs. Dr. Child, Second Physician to the Sir Jamsudji Jijibhai Hospital, Bombay, tried an authentic tincture for malaria, dyspepsia, dysentery and chronic bronchitis, and after careful experiment pronounced it inert. Linschoten, who studied the cultivation of sweet-flag in Gujarat and the Deccan (A.D. 1598), mentions a preparation called arata (a mixture of the rhizome of sweet-flag with garlic, cumin seeds, salt, sugar and butter) which was used as a strengthening medicine for horses. Nicholson (Man. Coimbatore, 247) refers to its use in the treatment of foot and mouth disease. [Of. also Taleef Shereef (Playfair, transl.), 1853, 34.]

It is generally stated that a considerable demand exists for sweet-flag spirit as a Flavouring for gin, beer, etc., and that the supply is obtained from the Broads district in Norfolk. In India it is said to be similarly employed in the manufacture of aromatic vinegar. The rhizomes of the bazaars come mostly from the lower hills of Northern and Eastern India, but the imported Persian root is the most expensive. As an illustration of local Trade, it may be observed that Mr. Coldstream mentions an export duty charged on sweet-flag in Sarmor State, but the root can be purchased there at the rate of 12 seers per rupee. No particulars are available as to the total Indian trade or the foreign exports, if such exist, but a large supply is obtainable. Sir W. Lawrence (Valley of Kashmir, 72) speaks of it as an abundant wild plant in Kashmir, and the same is true of most if not all of the warm temperate tracts. INSECTICIDE AND ANTISEPTIC

ADHATODA VASICA, Nees; Fl. Br. Ind., iv., 540; ACANTHACEAE.

ADHATODA VASICA, Nees; Fl. Br. Ind., iv., 540; ACANTHACEAE.

Red-wood (occasionally called Red Sandal-wood or Coral Wood), the *rukta kunchan, rukta kambal, ranjana, mandukaich, thorlagunj, val, bari-punchi*, etc., etc. Sometimes incorrectly called *rukta-chandan* (*Pterocarpus santalinus*). A large deciduous tree met with in the moist forests of Bengal, Assam, Bombay, Madras and Burma, and readily propagated by seed. A Gum (*madatia*) is said to be afforded by it. The wood is powdered and used as a Dye, and is the red paste (*tilak*) with which the Brahmins colour their foreheads after bathing. Taylor (*Topog. Stat. Dacca*, 1840, 53) says a decoction of both the seeds and wood is used in pulmonary affections, and as an external application in chronic ophthalmia. The Timber is much employed for house-building and cabinet-making. The seeds, which are sometimes eaten, are bright red and therefore used for rosaries and as weights (about 4 grains). Ground to a paste with borax they form a useful cement.

**ADHATODA VASICA, Nees; Fl. Br. Ind., iv., 540; ACANTHACEAE.**

A sub-herbaceous bush, found throughout the warmer tracts of India up to altitudes of 4,000 feet, and usually very abundant on the Sub-Himalayan tracts but much less common in Western and Southern than in Eastern India. Gregarious and found in large patches, but where it does not grow as a weed it is often semi-cultivated in hedgerows, and under these latter circumstances often attains the proportions of a large bush.

Hooper (*Handbook Imp. Inst., 1897*, ser. No. 10) incorporates all the information available up to that date and should be consulted. Subsequent investigation has mainly consisted in careful therapeutic tests, with the object of ascertaining the medicinal value of the plant. The results of the inquiries will be found in the *Report of the Indigenous Drugs Committee of India* (i.e., 38, 68, 183, 385-418, 497). It may be observed here that the verdicts of recent trials in Indian hospitals may be said to confirm belief in the plant as affording relief in chronic bronchitis and asthma, but to preclude acceptance of its reputed virtue in cases of phthisis. The medicinal properties of this plant are mentioned in *The Bower Manuscript*, recently translated by Dr. Hoernle. It is there called *vrisha* (85, etc.).

The leaves are sometimes boiled with the sawdust of jack-wood to make a yellow Dye. They seem to be most frequently employed, however, as or with Manure, being either put on to the fields just before the rains and ploughed in, or scattered over rice-fields recently flooded. It does not seem established whether this agricultural utilisation is as a preventive against noxious insects (see below), or in recognition of the quantity of potash which they contain. At all events it is one of the principal plants employed in India for the preparation of pearl-ash. It appears also to be used not infrequently for gunpowder Charcoal, and in Bengal the wood is turned into Beads. In the Naga hills the stems are used in a kind of augury.

Considerable difference of opinion prevails regarding the use of *Adhatoda* as an insecticide and antiseptic. In *The Journal of the Pharmaceutical Society* (April 7, 1888), Hooper announced that he had discovered the active principle of the plant to be an alkaloid, which he called *vasicine*, but seven years later Prof. Giacosa of Turin (at the instance of Sir Lauder Brunton) threw some doubt on this discovery, by stating that though he had found the leaves rich in potassium nitrate (and therefore a valuable green manure), he had found no alkaloid. In 1897, however, Hooper's discovery was fully confirmed by Dr. W. G. Boorsma of Java, who added interesting suggestions as to the use of *vasicine* both as a drug and as an insecticide. Although the insecticide property would thus seem established, it has been found by practical experiment that *vasicine* cannot be used, as at present available. A Tartrate is on the market, but cheaper and equally efficacious insecticides already exist. The use of the leaves, both as a green manure and as a poison to pests, especially on inundated ground (originally pointed out by me in 1887), might with advantage be further investigated and recommended to cultivators in localities where the plant abounds. [Cf. Paleef Shereef (Playfair, transl.), 1833, 12; Voelcker, *Improv. Ind. Agri.*, 1893, 107.]
THE BAEI TREE

History.

A small tree found here and there both wild and cultivated throughout India and Burmah. It is sacred with the Hindoos, the leaves being specially suited for the worship of Siva (Jones, As. Res., 1790, ii., 349-50). It is all but universally known by its Sanskrit name bīva, a word which appears in some form, such as bel or bael, in most modern languages. The fruit is generally called sriphal. By the early European writers it was called Cydonia Bengalensis or Bengal Quince, and by others was confused with Curae'va religiosa (which see, p. 429). Garcia de Orta, followed by his reviewer Ciusius (Arom. Hist., in Hist. Exot. Pl., 1605, 233) early in the 16th century, called it Marmelos de Bengala, and he and other writers make special mention of the value of the fruit in the treatment of dysentery. Jacobus Bontius (Hist. Nat. et Med. Ind. Or., 1629, in Piso, Ind. Utri. re Nat. et Med., 1658, 98) terms the fruit Malum cydonium. Rheede (Hort. Mal., 1686, iii., t. 37) calls it coovalam... but Rumphius, who wrote in 1750, makes no mention of it. Turning now to the Arab authors: Serapion describes three drugs under the names bel, jel and sel, but does not sufficiently distinguish these one from the other. Avicenna treats jel and bel as synonymous, and tells us that it is a drug with virtues very similar to the “Apples of Mandragora.” [Cf. Paulus Aegineta (Adams, transl.), iii., 448.] The Makhzan-el-Adwiya describes the fruit as cardiac, tonic and astringent. In ancient Sanskrit poems this tree is frequently alluded to, and by Hindu physicians it is much extolled. [Cf. The Bower Manuscript (Hoernle, transl.), p. 14, etc.; Pharmacog. Ind., i., 277.]

Varieties.

There are believed to be several varieties, distinguished by the size and shape of the leaflets when taken in conjunction with the size, shape and texture of the fruit. The main distinction may be said to be into the wild state, with small, hard, round, very astringent fruits having numerous seeds, and the cultivated conditions with large, often oblong fruits, having frequently a comparatively soft rind, a richly flavoured and copious pulp with only few seeds. It has been observed that whilst in Northern, Western and Central India the wild fruits are very intoxicating and are often used as a fish poison, no such character attaches to the cultivated fruit. This curious observation deserves further inquiry. From the Panjab comes the statement that a form known as kagzi has a conically shaped fruit, while the cultivated plant generally met with is known as bil, and further that the wild condition (with small round fruits) is distinguished as the bilian—a name given in other provinces of India to Feronia. [Cf. Joret, Les Pl. dans L’Antiq., 1904, ii., 285.]

The bael is usually grown from seed, but in Burmah advantage has been taken of the fact that it frequently sends up shoots from the roots, to propagate the approved races by root cuttings. It is generally stated that in from 5 to 8 years the plants will begin to fruit, and that when about 25 to 30 years old, the trees may be regarded as in full bearing. When grown for medicinal purposes only, a small round fruited form, much like the wild plant, is preferred, and it is maintained by the Burmans that the best results are secured when that plant is grown on dry, open, rich soil.

Bael takes ten months to ripen, and it may be said to come into season usually during March and April. In some cases it can be had in December, January and February, but in such instances the fruit has most probably been forced. On the other hand, fresh fruit may be procured as late as June, having been simply left on the trees until required.

A reddish-brown Gum is sparingly obtained from the stem. A gummy or mucous substance is secreted within the cells of the fruit, and thus around the seeds. This is universally used as a CEMENT, and if carefully mixed with lime will be found a clean and useful article that will set rapidly and firmly. It is reported to be obtained more copiously from the wild than the cultivated fruits. In Northern and Central India it is in special demand for the construction of wells, since it sets firmly, takes a fine polish, and is not affected by water. The pure mucus is spoken of as a valuable VARNISH for pictures and as a gum or glue of...
PROPERTIES AND USES

AEGLE
MARMELOS
Bael Fruit

special merit, where extra security and, at the same time, neatness are desired. It is reported to give brilliancy when added to water-colour paints. In Burma it is commonly mixed with paint as a dryer and to give a glossy surface. But perhaps the most remarkable use of this substance is that recorded in connection with the Madras Presidency. In Madura it would appear that the yogis (Hindu devotees) employ the pulp of the fruit as a kalpam or substitute for oil. For this purpose a ripe fruit is placed on the hearth until it bursts. The pulp is then removed from the shell, and a little water worked up with it until a glutinous material has been produced. After being purified, the pulp is rubbed over the body. A bath is then taken, when the pulp acts as a detergent and imparts a refreshing and cooling sensation. Of South Arcot it is stated that the mucous fluid only is used for the above purpose, and that it is rubbed on the hair in place of oil by the poorer classes or is employed as soap in washing garments. The Dutch in Ceylon used formerly to prepare an Essential Oil (or attar) from the rind, known as Marmelle Oil (Journ. Agri.-Hort. Soc. Ind. (Proc.), 1857, ix., 134). A Perfume is also distilled from the flowers.

The Medicinal properties of bael fruit are so well known that they need hardly be detailed. The fresh ripe fruit is eaten as an article of Food by the poorer classes only, more especially the aboriginal hill tribes. By others it is mainly consumed as pickles or preserves or as a refreshing and mildly laxative drink or sherbet. Most writers say that the half-ripe fruit is extensively employed in India as an astringent, digestive and stomachic, and is prescribed in diarrhoea and dysentery, and often proves effectual in chronic cases when all other remedies have failed. For these purposes, however, according to some writers, the wild fruit is preferable to the cultivated. It is certainly much more astringent, contains a larger amount of the gummy substance already mentioned, but has an objectionable quantity of seeds and only a very small amount of pulp. On the other hand, Colonel J. Parker (Medical Storekeeper to Government, Bombay Command) writes (Rept. Cent. Indig. Drugs Comm., i.c. 138), "Natives do not use the unripe fruits for medicinal purposes, but the pickle prepared therefrom is considered to be admissible in illness when other forms of pickle are said to be contra-indicated. The half-ripe fruit is adopted by the British Pharmacopoeia, but the rind only of the ripe fruit is used at this Depot in the manufacture of Extractum Belae Liquidum." Mooden Sheriff recommends for medicinal use a syrup made of the pulp of the ripe fruit, as more especially serviceable for chronic affections, and a powder of the pulp of the half-ripe fruit for acute diseases. He says of the last preparation that it is specially useful in altering the nature of dysenteric motions rather than in reducing their frequency.

The sun-dried slices of bael (generally known as belgiri) may be seen in every drug shop of India. They are not supposed to be injured by time, if kept perfectly dry, but in Europe the same beneficial results have not been attained with this drug as in India, a circumstance explained by European physicians by the theory that the dry slices deteriorate when kept for more than one season. Dymock says, "The best preparation of bael-fruit is a MARMALADE made from the full-grown but still tender fruit, cut in thin slices; it keeps well, which is not the case with the conserve made from the pulp of the ripe fruit that is usually met with in the shops."
THE BAFL TREE

In addition to the fruit, the root-bark is viewed as medicinal and employed in the treatment of intermittent fevers. The former is one of the chief ingredients in the much-talked-of dasamula of Hindu medicine—a preparation from ten roots. The leaves when fresh are made into a poultice and used in ophthalmia and maggot-infested wounds. The juice expressed from the leaves is bitter and pungent. Diluted with water it is highly spoken of as a remedy in catarrh, fever and biliousness. It may be preserved by being boiled in oil. The leaves are eaten in order to destroy the desire for food, and are so employed by sadhus. Bael fruit is employed in the treatment of scum in vinegar manufacture (see p. 1110).

The timber, yellowish-white, mottled, close-grained, hard, has no heart-wood, is not very durable and is readily attacked by insects. It weighs from 40 to 50 lb. per cubic foot. When freshly cut it has an aromatic smell. According to certain Hindus it is sacrilege to cut this tree down, but chiefly when cultivated and more especially when near temples. In the wild state, or when the tree has been neglected or has been killed, it may be felled and the timber utilised even for fuel or charcoal. It is used in the construction of sugar and oil mills, carts, agricultural implements, and, according to some writers, in the construction of idols, combs, and beads for certain rosaries. In the Institutes of Manu (ii., 45) the wood is given as an alternative with that of Butea frondosa, whence the Brahman sticks may be made.

Although there must be a very large local trade in bael, nothing in the way of actual returns can be quoted. The dry fruits sell at about Rs. 1 per 100 and the green fruits at less than half that figure. The dry pulp (belgiri) can be purchased at about Rs. 20 per cwt. Although several firms, such as the Great Eastern Hotel Company, Ltd., in Calcutta, regularly manufacture the marmalade, the article does not appear to be exported to any appreciable extent. In the London "price-current," quotations are given of dried and sliced fruit fetching from 1d. to 4d. per lb. It is often observed, however, that the market is neglected and the demand very limited.

The dried fruits, with pulp excavated, are largely employed as boxes in which to store medicines, sacred ashes, etc. Small ones are beautifully carved, and made into snuff-boxes. A considerable trade is done all over India in these ornate boxes, but it is feared that the majority may in reality be made from the small hard fruits of Feronia, rather than of Aspera. In the snuff-boxes made at Peshawar there is a considerable export to Kabul and Lower India. Ganjam, far to the south, is famed for its charmingly carved snuff-boxes—these show the 10 incarnations of Vishnu. Charged with gunpowder, the small dry fruits are also employed as bombs in firework exhibitions. Very young fruits (about half an inch in diameter) are used as beads and are arranged alternately in necklaces with the seeds of Elaeocarpus Ganitrus (the rudak). These are specially worn by religious men of the Siva sect. The wood ground down on a stone to a paste, with a little water, is often employed alone or in combination with sandal-wood to give the white transverse caste markings on the forehead of the Sivites.

MANUFACTURES OF SOLA PITH

ÆSCHYNOMÉNÆ

Æ. indicæ, Linn.; the kat or kath (hard)-sola, kuhila, kathiahedor, etc. The chirmilli or sirmilli is Sessbania and not Æschynomene—a plant often used as a substitute for sola.

The former species is a floating bush, with sensitive leaves, found on land annually inundated or within the margins of tanks or lakes throughout Bengal and the greater part of Assam; is frequent in Burmah and also present in South India. The latter, a taller more bushy plant and much less aquatic in habit, represents the genus in the other provinces, is found in Bengal, Assam and Burmah only above water-level, or on land temporarily flooded. Neither species is systematically cultivated, but in November and December the upper portions of Æ. asperæ bearing pods are severed and thrown on the water and the seeds thus become self-sown. The roots also are perennial. By February-March the pods are ripe and the pith-yielding shoots over-ripe; the stem then becomes dry, shrunken and discoloured, whilst a large cavern forms along the centre. The plant usually grows in from 2 to 4 or 6 feet of water, and when found living above water-level it appears to be unhealthy. It is often seen in the corners of rice-fields, but as a rule is viewed as a pernicious weed, and accordingly uprooted.

Roxburgh would appear to have been the first person to draw attention to this plant and its economic uses. He recommended its adoption as a substitute for cork in the manufacture of swimming-jackets and life-boats. But it is curious that he makes no mention of its use in the construction of hats (sola-topis). In Bengal and Assam the workers in Pithi usually belong to the Malakar or Mali caste of Hindus, who as a rule acquire the hereditary and exclusive privilege of manufacturing garlands for ceremonial use in certain districts. The thicker portions of the stems only are cut into lengths of 2–3 feet. These are tied into bundles and stored until dry, when the brown bark is removed and the pith cut up as required. If intended for the manufacture of hats, caps, or frames of puggries, it is split into thin sheets. For this purpose the stem is held in front of the operator and with a long thin, sharp knife is stripped spirally, the knife being made to travel round and round within the thickness until the whole stem is reduced to a sheet not much thicker than note-paper. Hats, etc., are worked up on wooden or clay moulds, and, if honestly made, are built up layer upon layer of sola sheets pasted one on the top of the other. By dishonest makers a large proportion of paper is intermixed with the pith, thus adding greatly to the weight of the hat and lessening very materially its insulating power (to the rays of the sun) wherein lies the superiority of the pith hats (sola-topis) over all others used in the East.

In the Roorki district the pith from Æ. indicæ is very largely used for sola-topis with a surface-dressing of Bengal pith. Owing to its hardness, this form of pith cannot be split into the very thin sheets needed for flower manufacture. If pith be required for this purpose, or for weaving into mats, the debarked stalks of Æ. asperæ are drawn between bamboo fastened upright in the ground at various distances apart, or are flattened by means of smooth stones. By either of these methods the pith is compressed, and will retain the form thus given it until moistened, when it again expands. To make a flower, the strips of sola are compressed in such a manner that in transverse section they are more or less triangular in shape, and along the surface, corresponding to the base of the triangle, parallel lines are cut. The strips are then sliced transversely with a sharp knife into very thin pieces. The pointed ends of the triangles are inserted into slits made on another stick of sola, intended as the stalk of the flower. When the required parts have been thus inserted into their places a brush, moistened in green-coloured water, is made to touch the outer whorl of triangles. These instantly expand and become the sepals of the rose or other flower. A brush, moistened in pink or other coloured water, next touches the inner whorls, and these, obeying the magician's wand, expand into petals, and are bent while still flaccid into the desired positions. The slits cut lengthwise along the compressed sticks of sola are now seen to open out into petaloid teeth. Stamens are formed of thin strips of pith, upon the extremities of which, particles of sugar (from a coloured saccharine fluid) have been made to crystallise, thus forming glistening anthers. Floral buds are

**SOLA AND SOLA SUBSTITUTES**

constructed of stained grains of rice fastened within green leaflets of sola. [Cf. *Ind. Art at Delhi*, 1903, 169.]

The three great centres of this art may be said to be Dacca and Mandalay for small and large flowers respectively, and Tanjore for models; but the ceremonial craft of the Malakars is practised all over India. The introduction of matches has practically rendered obsolete the domestic use of sola as a tinder with flint, but the pith is now made into covers for water-bottles, stoppers for medicine-bottles, and plugs to widen earing holes in the ears. It is also employed as a lining for the tops of palanquins and for seats and cushions, as also for the ornate Muhammadan *tazias* used at the Muharram. The cheaper pith of *A. indica* is usually employed for fishing-floats, fishing-baskets, rafts and swimming-belts, as it is supposed to be specially durable in water. Where procurable in abundance it is said to be especially useful in firing pottery, and the charcoal made from it is highly prized in the manufacture of gunpowder.

The soft sola (*A. aspera*) is used in surgery for insertion into the opening of a sinus or abscess since it rapidly absorbs moisture, expands, and thus widens the opening. A long article on the *Chemistry of Sola* by Hanneock and Dahl will be found in *The Chemical News* (July 12, 1895). 'The leaves of the sola plant are sometimes used as a *Pot-herb*, and an *Oil* is extracted from the seeds. [Cf. also Hanausek, *Micro. Tech. Prod.* (Winton and Barber, transl.), 1907, 253–5.]

There is practically only a local demand for sola-pith, and in its unmanufactured condition it is hardly ever exported. The best quality is obtainable in Bengal, and is carried thence all over India. To this day the centre of the Trade may be said to be in Calcutta, where the manufacture of sola-topis appears to have originated. No information is available as to the trade in the harder pith of *A. indica*, but it may be recognised by the circumstance that the stem is curiously striated on the thin bark and has wart-like formations along the striations. A central pith is always present in the form of a hollow surrounded by a slightly hardened layer. In *A. aspera* the bark is not striated; the stem unless over-ripe is quite solid, very soft and of a pure white colour. [Cf. Acosta, *Tract. de las Drogas*, 1578, 241; *Journ. Soc. Chem. Indust.*, 1903, xxii., 198; *Der Tropenpflanzer*, v., 598.]

**Sola Substitutes.**—The following are the chief substitutes:

- Aralia armata.
- Cassia mimosoides.
- Cephalanthus occidentalis.
- Heptapleurum hypoleucum.
- Mimosa pudica.
- Pentapetes phœnicica.
- Sesbania paludos a.
- Sonneratia acida.
- Trevesia palmata.

**D.E.P., iil., 18.**

It is in Burma known as *theet-men* and is generally spoken of as the Amboyna or White Pine. It affords a large quantity of transparent resin known as **DAMMAR**, which is used like that of the New Zealand *cowdie* or *kauri dammar* (*Agathis australis*, *Salisb.*) in the manufacture of varnish similar to Copal and for waxing and polishing fabrics. [Cf. Roxb., *Trans. Soc. Arts*, 1805, xxiii., 412–3.]

**D.E.P., i., 183–44.**

Drummond and Prain, the most recent authors on the Indian Agaves, review the various botanical opinions that have been advanced, give a complete history of the useful species, and also furnish a record of publications so exhaustive as to render further treatment in this work almost undesirable. The citation of publications below is intended therefore to amplify the enumeration given by these authors in so far as works, mainly of practical and commercial interest, are concerned.

Distribution.—The species of *Agave* are indigenous to tropical South America, Mexico and the Southern States of North America. By cultivation (chiefly during the 16th to 18th centuries) the forms of industrial and horticultural interest have been distributed throughout the greater part of the warm temperate and tropical regions of the globe. Several have even become acclimatised (or have run wild) in South Europe, Africa, India, the West Indies and some portions of the American Continent where they are believed not to have been indigenous. While completely naturalised in the warmer tracts of India, one of the species has become equally at home on the hills up to an altitude of 6,000 feet, provided the soil be dry and rocky, and the atmosphere not too moist. They are best known under the following names—American Aloe, Century Plant, Carata, Pita, Sisal Hemp, White Rope Fibre, and the like.

History.—One of the earliest detailed accounts of the economic properties of these plants was that given by Gomara (*Hist. Gen. de las Indias*, 1554, 334). Writing of the Spanish West Indies including Mexico, he speaks of a plant known to the Natives as *mell* or *maquey* (= tree of wonders) and to the Spaniards as *cardon* (the thistle). He gives a statement of its use for textile purposes, and explains the name *jil-y-agulla* as referring to the use of the spine as a needle and the fibre as thread. Frangousus (*Hist. Med. Ind.*, 1600, 88) mentions the wine obtained from the plant (*pactire*—the *pulque* of later writers). Dodoneus (*Purgantium*, 1574, 115) publishes a plate borrowed from Clusius who had it prepared from a plant seen by him near Valencia (*Rar. Stirp. Hist. Obs.*, 1676, 442). The same plate did duty in some form with later writers for the next two hundred years, though it usually appeared side by side with the plate of Camerarius (*Hort. Med.*, 1588, 10–11, t. v.). In 1727 Trew published an excellent monograph on the subject with a careful drawing of the flower. As regards India the first authentic reference would appear to be that of Roxburgh (*Obs. on Substitutes for Hemp and Flax*, 1801). In *The Journal of the Society of Arts* (1804, xxii.) he speaks of Agave as wild and beautiful, and in his *Hortus Bengalensis* (1814, 25) he mentions three species, *A. cantala*, *A. Fruvata*, and *A. tenebrosa*. The first he tells us had been introduced into the Royal Botanic Gardens, Calcutta, before 1794 (from India, locality not stated), and further he affirms that it possessed a Sanskrit name—*kantala*; the second he speaks of as a native of America; and the third he says had been procured from Kew but turned out to be the plant called “Yucca Superba” of the Calcutta Gardens—a plant which had been procured direct from America in 1799. Subsequently Roxburgh (*Fl. Ind.*, ii., 167) was induced to think it wild. But neither the name *kantala* (nor any other) has been accepted by other writers as being Sanskrit. Roxburgh doubtless obtained it from Sir W. Jones (*As. Res.*, iv., 230). It is possibly a gloss on *katevall*, Rheede’s name for the medicinal aloe. The names that exist are mostly descriptive or comparative and thus modern, for example, *banskeora* (= the bamboo *Pandanus*) or *bara kannar* (= the large aloe). From Vasco da Gama (1498) down to Hedges (1683) none of the Indian travellers seem to mention agave. It is not referred to in the *Memoirs of Baber* nor the *Administration of Akbar* (the *Amī-Askari*), though the pine-apple appears in the latter work. It is perhaps referred to by Hove in 1787, and twenty years later Buchanan-Hamilton speaks of its being much planted as a hedge. There is reason to believe that it was introduced into Northern India by Rohillas from the south on purpose to be employed as an impenetrable hedge around forts. The name *kethi* (usually restricted to *Pandanus*) is the most general name for agave in Central India. But it is significant that Rheede should say nothing of agave in his account of the

Acclimatisation

SISAL HEMP IN INDIA

plants of the West Coast of India (1678), while Rumphius (Herb. Amb., 1750, v., 273, pl. 94) should describe and figure a plant which is certainly agave and possibly A. Cantala. It seems then to have been a very recent discovery, and it probably reached India from America by the trade-route, vii the East Indian Archipelago.

Brief History of the Efforts to acclimatisé Sisal Fibre in India.—The several Governments of the West Indies (more especially of the Bahamas) have made strenuous efforts to participate in the sisal hemp trade, and the Blue Books that have appeared from time to time contain much of great value. It is perhaps safe to say of India that by far the most important contribution to the existing knowledge of cultivated agaves has been the direct outcome of the great personal interest taken by the former Director of the Royal Gardens, Kew, Sir William Thistleton-Dyer. Live plants of all the more highly approved species and races of agave were procured and the more interesting of these distributed to the Colomes and India. Reports have at the same time been obtained from the indigenous habitats of the various species as also from the regions of most successful production, and these have from time to time been published in the Kew Bulletin. Still later the information thus collected has most considerately been brought together and republished in one volume (Bull., add. ser., 1898), thus forming a convenient book of reference that gives full particulars of the results attained within recent times. The Director of Kew, at the suggestion of Sir George King, and subsequently of the Revenue and Agricultural Department of the Government of India, procured and forwarded to India three consignments of live plants of sisal hemp. The first reached India on July 9, 1890, but the plants were found to be dead on arrival at the Royal Botanic Gardens, Sibpur, Calcutta. The second consignment of 1,000 plants came to hand on October 28, 1891, and it was then found that 943 were alive. The third consignment of 4,900 plants reached Sibpur on October 14, 1892, and of these 2,984 were alive. Prior to these consignments, however, the Botanic Gardens, Saharapur, had received by post in 1886, direct from Florida, a few live suckers. One of these had been successfully grown and had yielded many young plants, of which a limited distribution was made. Recently a report was called for as to the success attained with the 1892 consignment of plants. The preparation of that report was entrusted to Lt.-Col. D. Pain, at that time Curator of the Calcutta Herbarium. The recipients of the plants issued from the Royal Botanic Gardens were invited to furnish information on eleven separate subjects of inquiry, such as the nature of soil on which the plants had been grown; distance planted apart; percentage of deaths; the date on which they afforded suckers; date at which the plants were cut; the length of fibre obtained; the method adopted in preparation of fibre, etc., etc. It may be here explained that the Agricultural Society of India having a small supply of plants from the Superintendent of the Royal Botanic Gardens, Calcutta, issued these to the members of that Society, and the answers furnished to the series of questions were published in the Journal (1898, xi., n.s., 804–8). The replies received by Pain were incorporated in his report. This was republished in The Agricultural Ledger (1900, No. 6), and may therefore be regarded as a most important practical contribution to our knowledge of the sisal hemp fibre in India. It will be there found that Pain concludes a letter to the Hon. Secretary of the Agricultural Society of Madras as follows: "I may add, for your information, that since preparing my Note I have learned that two private importations from Florida of Sisal Hemp plants, one in the Tirhut (indigo) area, and one in Assam (tea) area, have taken place, the parties concerned having said nothing about these importations, and all that I am able to say regarding them is that the efforts of the various Indian Governments, detailed in my note on Sisal plants, those of your Society and of the Government of Madras are, when put together, insignificant as compared with either of those private ventures." Of Dauracherre, in South Sylhet (the Assam instance doubtless in the above quotation), it is said that 10,000 plants were imported from Florida in 1894. In 1901 most of the original stock were poling and each yielding 2,000 to 3,000 bulbils. Mr. J. Cameron in his address to the United Planters' Association of South India in 1900 stated that the Mysore Government had imported over 4,000 plants direct from Florida about seven years previous. These had taken kindly to the climate and now afforded material for an extensive propagation. Carrying the Indian records to more recent dates, two exceedingly important

32
Species and Varieties.—The necessity for a complete revision of the species of this genus, more especially the cultivated forms, has long been felt as very urgent. Much has been done by systematic botanists for the wild forms in their native habitats, but much still requires to be accomplished before we possess the accurate knowledge essential to industrial progress. Cultivators have not always gone to botanists to secure their original supplies. There have in consequence been carried here and there throughout the tropics a multiplicity of forms, some at least of which in their new homes seem to have made confusion confused by modifying the colour, shape and spinosity of their leaves until they have greatly obscured their botanical characteristics. And these have also brought with them incorrect or even quasi-scientific names that have passed unchallenged for many years. Hence it is no matter for surprise that the Agave furida of one high authority is not the Agave furida of "certain practical men." The blame for this state of affairs cannot, however, be cast at the one or the other: errors and misconceptions are unavoidable in the early stages of most discoveries. The necessity for a common basis of knowledge is now, however, the more urgently demanded. Drummond and Prain (L.c. Agri. Legd., 1906, No. 7) have taken a most valuable step in the direction of the elimination of ambiguity. They have reduced the Indian cultivated and acclimatised forms to some ten species, and of these five or six are of industrial merit. It would be presumptuous for any one who has not specially studied this perplexing genus to venture on a critical review of the conclusions arrived at by these distinguished botanists. I shall accordingly content myself with an effort to transcribe into one place what appears to me of special value to practical men, and in so doing endeavour to focus my abstract alphabetically under the scientific names given in the Notes for the chief forms:

Agave americana, "Linna., Sp. Pl., 1753, l. 323.—This plant (to which alone that trivial name should be restricted) exists in India as an ornamental garden plant only. It is extremely constant in its characteristics, and except as horticultural sports (in which the leaves become parti-coloured) it has no authentic varieties. Although a fibre can be and has been extracted from its leaves, this plant is of no value as a textile and does not exist anywhere in India in such abundance as to be of importance. The cultivated stock probably originated in the West Indies. [Cf. Drummond and Prain, Lc. 84-5, 121-2, 126, 136, 151.]

A. Cantala, "Roeb.; A. vivipara, Dalz. & Gbds. (non Linna.), Fl. Bomb. (suppl.), 1861, 93.—This would appear (as indicated above) to have been the species that first reached India. It had taken such a firm hold of the country by 1804 that Roxburgh, when led to suppose that it had a Sanskrit name, was induced to regard the plant as indigenous. It is common in hedges and one of the two species most widely spread and most plentiful in India. Frequent near Bombay, in the northern portions of Madras Presidency, in Central India, and in the Gangetic plain generally, as far north as the sub-mountain districts of the provinces of Agra and the Panjab, ascending the hills to close on 6,000 feet, but is absent from the arid strip between Gwalior and Delhi. Fibre is extracted from its leaves in considerable quantity, but opinions on its quality are conflicting. It is the chief source of the Bombay Aloe Fibre of commerce. [Cf. Drummond and Prain, Lc. 87-8, 100, 105, 133-4, 135, 138-9, etc.]

A. sp. (? A. elongata, Jacob.)—Drummond and Prain (Lc. 88, 101, 105, etc.) show that the plant here indicated cannot be identified as A. mexicana, Lamb. Further they observe that it approaches A. sisalana and is intermediate between that and A. Cantala. It seems very close to the species cultivated at Kew as A. rigida, var. elongata. It has been met with in the Upper Gangetic plain, as for instance at Dehra Dun and the Panjab Siwaliks; it is somewhat extensively planted along railways in N.W. India, and is the most prevalent form in the dry arid tract from Gwalior to Delhi, being there, as it were, obtruded into the area of A. Cantala. The fibre has not been sufficiently investigated, but it seems good and would probably be found valuable. The plant has been grown on a marketable scale in the dry tract between the Chambal and the Jumna.

Cultivated Sisal.

A sisalana, Perrine.—The True Sisal Hemp Plant of India, Australia, the Pacific Islands, etc. This was introduced on various occasions between 1835 and 1892. It is cultivated in Burma, Cachar, Sylkhet, Assam, Bengal, N.W. India (as far as Lahore), Central India, Bombay, the Deccan (Poona), Mysore and Madras (Bellary). Original stock, obtained from cultivation in Yucatan, conveyed in 1834 to Florida and other parts of America, thence to the West Indies and finally to India. There are forms with the leaves having the margins spinose and others naked, but these conditions may be found on the same plant, so that they are not varietal in value. The seedlings and bulbs of both forms are spinose. There is but one form of sisal in all India. Mr. Cameron fixes its introduction into Mysore in the year 1892. He mentions that the Lal Bagh of Bangalore had recently sold from its stock 45,000 plants. [Cf. Drummond and Prain, i.e. 83, 89–90, 96, 99, 103, 117, 135, 143–7; also Proc. Agri.-Hort. Soc. Mad., 1903, 44–6.]

A. Vera Cruz, Miller, Dict. Gard. (ed. 8), 1768, No. 7.—Possibly this plant came originally from Mexico. It is naturalised throughout Southern Europe, in most of the Mediterranean Islands and in N.W. Africa, but has not been recorded from S.E. Europe or the Orient, etc. This would seem to be the A. americana of Clusius, and of most writers prior to the time when Linnaeus restricted that name to the special ornamental garden plant. It has been called A. turrita by some writers (but is not A. turrita, Jacquin). Introduced into India from the Chelsea Physic Garden by Lord Auckland during 1836, and looked on by Wallich as doubtfullly distinct from A. "turrita." Recorded as met with here and there practically all over India, but more especially in the Eastern Peninsula. Is spoken of as frequent in the Gangetic plains north to Cawnpore, used for hedging and luxuriantes in Calcutta gardens, but rapidly disappears from all localities subject to occasional frosts. It stands a moist atmosphere more successfully than do most other species, and has become naturalised in Mysore. The fibre has not been separately reported on, so that its special properties, if any, are not at present known. [Cf. Drummond and Prain, i.e. 80, 83, 85–7, 99, 105, 121, 126, 131, 140, etc.] The above may be given as a conspectus of the opinions held regarding this species. Compiling from an extensive correspondence and comprehensive series of practical (not botanical) opinions, it would appear highly probable that the fibre of this plant has given origin to the low valuations of the so-called Aloe Fibre of India.

A. Wightii, Prain: A. vivipara, Wight, Ic. Pl. Ind. Or., vi., n. 2024; Baker, Gard. Chron., n.s. 1877, viii., 780 (non Linn.). The Bastardi Aloe.—This is a well-known naturalised form in Southern, Central, Northern and Western India. It is strongly regarded by some as being A. Cantala, Roxb., and is often spoken as of 'desi' or "Native" owing to its being self-sown. It is easily recognised by its round, compact rosette of pale-coloured rather stiff leaves. It is widely spread in the drier tracts of India from Mysore to the Panjib. It extends to the extreme south and to the east of Bengal and Assam, but does not thrive in damp countries. The fibre has been reported as good but shorter than A. sisalana, and on that account is not so much in demand as formerly. [Cf. Drummond and Prain, i.e. 91, 101–3, 123, 139, etc.; Greengrass, Letter in Madras Mail, 1903.]

A. ? longisepala, Tod.—This is species (H.) of Drummond and Prain (i.e. 90). It is naturalised at Saharanpur, met near Calcutta, and also in Southern India and N.E. Burma, though nowhere on a large scale. It is distinguished in Saharanpur as rambans keora, and is understood to be most probably the plant that furnished the fibre favourably reported on so many years ago. It has an acrid juice.

PROPERTIES AND USES

Synopsis of the Properties and Uses.

The Fibre.—The leaves yield a fibre, the ALOE FIBRE, SISAL HEMP or VEGETABLE SILK, which in common with most fibres of this class is often designated Pita.

Medicine.—The large, moist, fleshy leaves are sometimes used as a poultice. The expressed juice of the leaves is administered by American doctors as a resolvent and alterative, especially in syphilis (Ponder and Hooper, Mat. Med. Ind., 165). The roots are diuretic and anti-syphilitic, and are said to find their way to Europe mixed with Sarsaparilla. Prescott (Hist. Mexico) says that when properly cooked, the root affords a "palatable and nutritious food."

Food and Fodder.—In its young green state the stem is regularly used as an article of Food, as for example during the famine of North Arcot (Lisbon, Useful Pl. Bomb., 205). In The Agricultural Ledger (1893, No. 3) Mr. J. O. Miller gives the results of the experiments made in the United Provinces to test the value of these plants as articles of food, and the conclusion may be said to have been unfavourable. The leaves are occasionally utilised as Fodder, especially for ostriches. [Cf. Agri. Journ., Dept. Agri. Cape Colony, July 1896, 252, 386.]

The Sap.—If the central bud be lopped off at the flowering season, the cut stem discharges freely a sour-sweet liquid which ferments rapidly and forms the Pulque beer of the Spaniards, or by distillation a kind of brandy known as Mescal. The putrid odour of the pulque is said to be due to the vats in which it is fermented being made of hides (Century Dict., 1899, vi., 484). The species specially cultivated for pulque is probably A. Salmiana, Otto, never A. americana, Linn. [Cf. Journ. d'Agri. Trop., 1901, 42; Drummond and Prain, l.c. 98; Bull. Un. Agri. Calied., 1903, ix, 11.] Sugar and vinegar may also be prepared from the sap.

Industrial.—The juice may be used as a SUBSTITUTE for SOAP. Wall-plaster impregnated with the expressed juice is said to be proof against the ravages of white ants. (This same statement of the use in Cement has, it will be found, been made under Aloe, p. 59.) A writer in The Madras Mail (Oct. 1901) says that the juice rubbed on the hands and feet protects them from injury by fire, hence the "fire-walking" of the Saniyasis. The flowering stem, dried and cut into slices, may be employed as a natural razor-strop or as a substitute for cork. The pulp after removal of the fibre is a valuable manure for the land on which the plant has been cultivated. It is rich in lime, magnesia and potash.

Fibre.—If possible, it would seem the most useful course to refer the observations that follow to two sections: (I.) THE PRODUCTION OF THE ALOE FIBRES and (II.) THE PRODUCTION OF SISAL HEMP. The former practically means the fibre from stock acclimatised in India many years ago, and the latter the fibre of more recently introduced plants. There are, however, only two or three localities in India where Agaves are systematically cultivated, and in these plantations, both old and new stock doubtless exist. But so much ambiguity and disappointment have resulted from not separately recognising the merits of the old stock that it seems desirable to endeavour to separate the Indian fibre into the two groups indicated, viz. American Aloe Fibre (old stock) and Sisal Hemp (new stock), (pp. 39-43).

Aloe fibres

THE ALOE FIBRE PLANT

I. ALOE FIBRES.

From the remarks made under the paragraph above on the botany of these plants it may be learned that the Indian fibres of this kind are derived from A. Cantala, A. Vera Cruz, A. elongata and A. longisepala. The assumption that the varying qualities of the Indian fibre were exclusively due to diversity in climate, season, age of collection, and methods of separation, etc., has been completely upset by Drummond and Prain's recent paper (already briefly reviewed). We now know that there are several distinct species and that the A. americana proper is the most inferior and least important of all.

The necessity for a full knowledge of the plant being or proposed to be cultivated in any locality cannot be disputed. Prain (Ann. Rept. Roy. Bot. Gard., Calc., 1903–4) says:—"The Sisal Agave does not thrive equally well or give equally remunerative results in all parts of India, and in certain districts species of Agave other than sisalana, already so completely naturalised as to appear indigenous, thrive so much better than Sisal and yield fibres commercially so little inferior to the best Sisal fibre that their systematic cultivation offers a hopeful field for investment." "It seems that, while, as a rule, more or less well-defined areas have particular species well established, the prevailing species in one area often differs from that most plentiful in another area. Moreover, it is found, when attempts are made to utilise the fibre of these local Agaves, that somewhat diverse results are obtained: at times the fibre extracted is reported to be nearly up to the standard of Sisal, at other times it proves too weak to be worth extracting. The explanation of these facts appears to be that other species of Agave share with A. sisalana the peculiarity of adapting themselves readily to certain localities and thriving less vigorously in others. The original object of the introduction of all the species was to provide secondary lines of defence round stockades, forts and strong villages; in more settled times they have been chiefly used as hedges bordering highways and lines of railway. Vigour of growth therefore has been the only quality considered in selecting plants within any particular area; the nature of the fibre has not till recently attracted attention." In selecting stock there would seem to be every likelihood that it may be possible to discover two plants with equally (or nearly equally) good fibres, the one of which would poll in seven to twelve years, the other not till much later, say twenty-five years. There would be an obvious advantage in the latter, namely the greater number of years before the estate would have to be completely renewed.

Technical Reports on Indian Samples of Fibre.—Two samples of Indian so-called American Aloe Fibre (or what were believed at the time to have been such) were in 1893 examined and reported on by the Director of the Imperial Institute, London. These had been procured in 1891 by the Government of India from Saharanpur in the United Provinces, and by Thurston (Off. Reporter on Economic Products) from Coimbatore in the Madras Presidency. [Cf. Agri. Bull., Mad., 1894, No. 30.] Mr. Collyer of Messrs. Ide & Christie (the expert consulted) reported very favourably on both samples, and in consequence a series of questions were asked by the home authorities which were circulated to persons known to be interested in Agave fibre. The late Mr. Gollan, among others, replied to the questions and thereby afforded more direct and personal
knowledge regarding the Saharanpur sample and the cultivation of the plant, than will be found in the other Indian reports which have as yet appeared. [Cf. Agri. Ledg., 1894, No. 18.] Some doubt, however, may be admitted to overshadow most of the published statements regarding the so-called Agave americana of India from the exact species experimented with not having been accurately determined. But Mr. Gollan, who actually supplied the Saharanpur sample (along with his letter of February 3, 1891), wrote in reply to a special reference on this point, that at the time in question he furnished two consignments, one of the so-called A. americana (much of which very possibly should now be called A. ?longisepala), the other of A. vivipara (or rather A. Wightii) fibre, but none of A. sisalana, for the very good reason that no plants of the last-named species had reached Saharanpur until fully a year later, and no fibre from the Sisal plants had been cut until four years later. [Cf. Agri. Ledg., 1900, No. 6, 63.] The point is of importance chiefly in support of the contention that certain forms of Indian-grown Aloe fibre are little if at all inferior to the true Sisal of Commerce. The fibre that Mr. Collyer viewed with so much favour was thus procured from two of the long-acclimatised plants prevalent in North India. Subsequently Mr. Gollan furnished samples of Sisal fibre grown at Saharanpur, and these were also sent to the Imperial Institute for opinion and valuation. [Cf. Agri. Ledg., 1896, No. 34; Imp. Inst. Tech. Repts., 1903, 81-5.]

A sample of Agave fibre from Gwalior (possibly the plant indicated above as A. ?elongata) has been highly commended (Imp. Inst., l.c. 84), and a sample from South Sylhet, said to have been that of A. sisalana, is in the same publication reported on most favourably. Coventry gives a brief account of the Agaves in the Panjáb. [Cf. Agri. Journ. Ind., 1906, i., pt. 3, 265.]

CULTIVATION.—Indian-grown fibre has, however, been more frequently condemned than approved, but as already indicated this may have proceeded from the fibre of a worthless form having been supplied. It is true also that the condemnation may have arisen through the ignorance of the planters as to the best seasons and methods of preparation. It follows accordingly that the abundance of a species of Agave in a particular locality is no proof of commercial possibilities. The experts have, however, usually reported that the inferiority of many of the samples examined may have been due to either of two causes: (1) The leaves having been too old, thus causing the fibre to become hard, coarse and brittle; (2) The very defective method of cleaning that seems invariably practised by the Natives of India. The leaves while resting on a flat stone are cruelly scraped by a knife and violently beaten every now and again in order to shake off adhering particles of cellular tissue. As a not unnatural result the fibres are broken, torn and cut short. But what is even still worse, before being scraped the leaves have often been retted for weeks, or the fibre after being separated has been soaked in water for days. As a result fermentation has been set up and the fibre discoloured, deprived of its natural polish and rendered harsh. The leaves as they near maturity, but not later, should be simply scraped by hand or by machine, then sun-dried and baled. Retting is not necessary and is distinctly injurious, but washing in a stream of water during the process of scraping is often recommended as advantageous.
In Bengal.—The late Mr. N. G. Mukerji (Handbook Ind. Agri., 1901, 325–8) furnishes an abstract of the currently accepted views on Agave cultivation in Bengal. In the Dictionary will also be found a detailed report on the cultivation of this plant by Col. R. Cobb (at that time Superintendent of the Hazaribagh Jail), and since recent information regarding Bengal does not materially alter the conclusions there advanced, the original article should be consulted.

It may in fact be said that the chief exception recent investigation would suggest to Col. Cobb's report, concerns the season when the fibre reaches maturity. Most writers affirm that when the pole has arisen from the middle of the rosette of leaves, the fibre is practically useless. It becomes too hard and brittle for manufacturing purposes. The fibre which has fetched the best prices would appear to have been obtained from fully grown leaves, but from plants that have shown no signs of producing the "candelabra-like" inflorescence. The plant grown at Hazaribagh seems to have been mainly A. Cantala, but the inferior samples of Bengal fibre have evidently been chiefly procured from A. Vera Cruz (the A. havida of some writers).

In Bombay.—The Bombay Aloe Fibre has recently attained an assured position in commerce and is being pushed with much success. It is chiefly obtained from A. Cantala, and apparently to some extent also from A. Wightii and more recently from A. sisalana and Furcraea gigantea.

On the heavy clay soils of Bengal and Assam, as also some portions of the Central Provinces and of Madras, A. Vera Cruz might be regarded as a fairly abundant species, but on sandy loams and stony laterite soils of some parts of Bengal, the United Provinces, Sind, Rajputana, Central India and Bombay, A. Cantala becomes the most characteristic form, and is indeed met with in a state of more or less complete acclimatisation. [Cf. Madras Mail, Oct. 1904.] In the Panjâb its place is taken by A. Wightii, of which Stewart makes the very observation regarding its prevalence in that province which Roxburgh made of A. Cantala in Bengal, viz. that it might be regarded as indigenous.

One of the earliest descriptions of this fibre, as far as India is concerned, will be found in the Journal of the Agri-Horticultural Society of India for 1854 (viii., 148 et seq.) where Mr. A. R. C. Hamilton, then Resident at Indore, furnished a sample which was examined by Capt. A. Thomson at his rope-factory at Calcutta and found equal to the best Russian hemp. Capt. Thomson adds that a considerable quantity of a fibre exactly similar had lately been imported from the Malabar Coast and that he had had some made into rope which very much resembled Manila rope. Mr. Blackburn forwarded from Agra about the same time samples of fibre and rope made from "the Common Aloe," and Dr. Falconer identified the plant from which these had been prepared as A. Cantala—a plant with which he had been familiar as common at Saharanpur.

In 1889 the Bombay Government forwarded to the Secretary of State for India a report that had been drawn up by the Director of Land Records and Agriculture on "the aloe fibre shipped under the name of 'hemp' from Bombay." This fibre, it is there stated, comes chiefly from the Bombay Karnatak and the Central Provinces. "The plant grows wild but nowhere in abundance, nor is it anywhere cultivated specially for extracting fibre." "In the Bombay Karnatak it is the chief hedge plant along railway lines. For fencing it is planted one to three feet apart according to the quality of the soil." The Director then describes the crude method adopted to separate the fibre, namely by burying the leaves in running water or amongst the sand near streams where water percolates. When sufficiently decomposed the leaves are taken out and washed clean of the pulp by beating.

Sir D. Morris, at that time Assistant Director of Kew, identified the specimens of plants that accompanied the Bombay report as confirming the fact that the "Bombay aloe fibre" was prepared from the leaves of A. vivipara. It would now seem that it was A. vivipara, Doniz. & Gilb. (non Linn), i.e. A. Cantala, Roxb., according to Drummond and Prain. Sir Daniel, after suggesting
SISAL HEMP

that the quality of the fibre might be improved by cultivation and that it was possible A. sisalana might be introduced on a large scale on the waste lands of Bombay, added, "The value of the machine-cleaned fibre ranges, according to length, from £25 to £30 per ton. The ordinary Bombay aloe fibre, cleaned by hand, is worth only from £5 to £12 per ton. These figures fully bear out the opinion offered in my letter of February 21, 1887, that the Bombay aloe fibre industry was capable of being greatly improved." The subsequent history will be found in the Kew Bulletin. (add. ser., ii., 1898, 194-200).

Plantations of Bombay.—The Englishman (June 10, 1899) gave a long and most instructive description of Dr. E. Suter's endeavours to establish successfully the plantation owned by the Fibre Company of Powai. Another equally admirable account of the Powai plantation and factory will be found in The Textile Journal (Jan. 1901). We learn that Dr. Suter has obtained a 30 years' lease of 3,000 acres of land, on a rent of Rs. 14 an acre, and that he is in treaty for a further tract of land of some 20,000 acres. He employs about 500 workmen for the greater part of the year. The plantation consists mainly of A. Cantala, but he has put out a large number of A. Wightii, also of A. sisalana and Furcraea gigantea.

There are apparently two operations pursued in separating the fibre at his factory, during each of which a liberal supply of water is utilised. The sharp, thin extremity of each leaf is first dealt with, and when the fibre has been freed from the pulp, etc., it is washed before the lower half of the leaf is treated. The fibre of the apex of one leaf (or of several leaves treated at one and the same time) are then twisted round a small brass handle, by which means the operator is enabled to submit the lower and thicker ends of the leaves to be scraped without any risk of injury to himself. The fibre having been washed in the plentiful supply of water procured by the factory from the Powai lake, is then sun-dried. By the next process it is scotched or combed and thus turned into beautiful white threads which are assorted according to length into two qualities. Finally it is baled and is thus ready for the market. The men employed in the factory are dressed in woollen garments and gloves (supplied by the owners) in order to protect them against the acrid juice that would otherwise cause painful blisters on the skin. But Suter has also patented and is daily using a semi-automatic machine of which full particulars and photographic illustrations will be found in Mann and Hunter's pamphlet on Sisal-Hemp Culture in India, published by the Indian Tea Association, 1904 (22, pl. vi.). The fibre from Dr. Suter's plantation is said to fetch £36 a ton.

II. SISAL HEMP.

It was customary until quite recently to read of the Sisal hemp being botanically a form of the species known as A. rigida, Miller, and of there being two industrial forms of the species, viz. (1) var. longifolia, the Henqueen Hemp of Yucatan, the Sacqui or Sacci (a name denoting light colour); this has the leaves spinose on the margin; (2) var. sisalana, the Sisal and Bahma Hemp, the Yashqui or Yaxqui (dark green); this has the margins of the leaves almost destitute of spines, but the apex ends in a conspicuous black spine. Mann and Hunter tell us that plants of the former introduced direct from Yucatan have not been very luxuriant in Sylhet, while the latter succeeds splendidly (l.c. 5). Drummond and Prain (l.c. 135) are of opinion that "there is one Sisal Hemp in this country and one only," and they add, "Leaves with and without prickles may be found on the same individual." That plant,

Association with Tea.

Assam.

Propagation by Seed, Suckers, Bulbils.

The SISAL HEMP PLANT

they are further of opinion, is A. sisalana, Perrine, a good species and not a form of A. rigida, Miller.

Mann and Hunter have dealt so fully and satisfactorily with its cultivation as an associated crop with tea that it seems almost undesirable to attempt to set forth as a separate chapter their main conclusions. Persons interested in the subject of Sisal cultivation in India should most certainly procure the pamphlet mentioned. But as experience gained by others differs slightly from that in Sylhet, it may be useful to give a combined review of the practical results hitherto attained in India as a whole.

CULTIVATION.—In Sylhet.—It would seem fairly certain that A. sisalana is an even more tropical form than most of the Agaves and will not live if liable to seasons of frost. It may be propagated (1) by seed, (2) by suckers from the base of the stem, or (3) by “pole plants or bulbils.” The last mentioned are produced from the flowering spike or “pole,” and are buds formed within the bracts of the individual flower stalks. Suckers are preferred in America, and “pole plants” are largely used (if not preferred) in the Bahamas. From 1,500 to 4,000 are formed on each pole, and they do not fall to the ground until they are six inches or more in length. They root at once, and if left alone form a grass-like vegetation around the perishing parent-plant. Seeds are not so often resorted to, owing to the great delay. Morris seems to doubt the advisability of propagation from bulbils, and Mann and Hunter only recommend that course until such time as a continuous supply of suckers has been established on the estate. [Cf. Sly, Agave Fibre in Assam, in Agri. Journ. Ind., 1906, i., pt. iii., 247–9.]

Nursery and Plantation.—The young plants, whichever way obtained, are first raised in a nursery until they attain a height of about 15 to 20 inches—Mann and Hunter say 8 to 12 inches. Shade-trees in the nursery are injurious. According to the most generally approved plan in America the young plants are transplanted into the estate, in rows 12 feet apart, the individual plants being from 6 to 8 feet apart in the rows. This will give about 650 plants to the acre, but in some estates they are planted much closer, viz. 9 to 10 × 4 to 6 feet, thus giving about 1,000 plants or more to the acre. The danger of close planting lies in the fact that during wind storms, the leaves may stab each other and thus injure the subsequent growth of the leaf and discolour the fibre. Fermentation, set up within the growing leaf or in the leaves after separation from the plant, will ruin the fibre by staining it a red colour. A writer in Capital (March 1901) would seem to think that the Dauracherra Estate in South Sylhet has “made no provision for a permanent crop. The plants have been planted 8 feet between in the row and 10 feet between the rows. These distances have always been recommended hitherto. When the plants got to be about four years old a young sucker ought to have been planted in between, so that when a plant poles and dies, which they almost invariably do within ten years of planting, the plant placed between would be ready to take the other’s place and keep the constant supply of fibre going. But after seeing the Dauracherra plantation the writer is convinced that 8 feet by 10 feet is far too wide apart and would say 4 feet by 6 feet an ample distance.” Mann and Hunter think that 5 feet between the plants and 9 to 10 feet between the rows are suitable distances for general use. Thus it may be said that overcrowding is condemned in most parts of the world where sisal planting prevails. The best time for planting is from February...
INDIAN PLANTATIONS

AGAVE

Cultivation

Sylhet

to June, and it is essential that the plants be pitted (not dibbled in) and that they should not be buried in the ground above the base of the leaves. They lay great stress on the latter condition; earth within the leaves, they say, causes them to rot. During the first two years the plantation requires to be hoed to such extent as found necessary to keep weeds in check.

Diseases and Pests.—Protection from cows, deer, etc., is necessary, since if the central bud be injured the plant dies. By the third and fourth years the plants are able to defend themselves. I am informed by Mr. G. Massee that at least one fungus is known to kill the leaves, namely, Coniothyrium concentricum, Sacc., and that this may often appear as discoloured patches without fructification. It would seem probable that "the discoloured spots on some of the older leaves of even very young plants" alluded to by Mann and Hunter are due to the fungus named. [Butler, Sisal Hemp Disease, in Agri. Journ. Ind., 1906, i., pt. ii., 261.]

Cropping Season.—Much depends on the size, age and vigour of the young plants when transplanted, but they attain as a rule the condition of being able to afford a first crop of leaves in the third year, and come into full bearing in the fourth or, it may be, only in the fifth year. Leaves as a rule are ripe when they extend at right angles to the stem. Mann and Hunter say that half a right angle to the stem will suffice but none before that should be cut. The plants continue to give an annual supply of leaves till about the twelfth year, when they show signs of forming the inflorescence or "pole." Having given their crop of seed or "pole bulbils" the parent plants die and should then be uprooted. If the outer large leaves be not systematically removed year by year the plants will attain maturity at a much earlier date, say about the sixth year. Experience so far would seem to support belief that the plant will pole slightly earlier in Sylhet than in Yucatan. Mr. Woodrow reports that the sisal planted in Poona in 1892 began in 1898 to show signs of producing flowering-stems. On the other hand, it is recorded that under certain circumstances the plants may continue to yield for 15, 20 or even 25 years before the "pole" forms. In the Kew Bulletin (1898, add. ser., ii., 178) will be found a most interesting correspondence on the methods that might be adopted to retard polling. Sir D. Morris recommends the systematic removal of all suckers not required. It transpired (in the correspondence referred to) that the Bahamas hemp plant flowers earlier than the Yucatan hemp, a distinctly unfavourable circumstance if it be the case. As soon as the "pole" appears it has to be cut out, the remaining leaves harvested and the old plant removed. But it is customary long before this takes place to plant a seedling or sucker close by or within the interspace, so as to have a fresh plant nearing the bearing stage before the period of removal of the exhausted one has been reached. In Sylhet it has been found that the best time for cutting leaves is from October to June. This is mainly on account of the necessity for drying the fibre. The leaves are moreover less heavy at that season, an obvious advantage seeing that they have to be carried to the factory. This arrangement fits in admirably with the associated tea industry, which calls for most labour from June to October. In laying out an estate Mann and Hunter say that owing to the enormous weight of the leaves the factory should be central and have good roads in every direction. On a small estate pack bullocks, and on a large one a slight railway may be used.
AGAVE
Cultivation
Mysore

In South India and Mysore.—It seems that an effort is being made to organise an Agave or Sisal fibre industry of South India. We read of the South Indian Fibre Company having taken this matter up energetically. Particulars of actual plantations, however, are not available, though Mr. Tytler seems to have made a start in Anantapur district. [Cf. Madras Mail, Dec. 1901; Ind. Planters’ Gaz., Feb. 1902.] Travancore is also mentioned as a locality where the plant is being cultivated. Reference has been made to the large importation of sisal plants by the Mysore Government. Mr. J. Cameron and others (recent Proc. Agri.-Hort. Soc. Mad.) describe the progress accomplished. Mr. Cameron seems moreover confident that in Mysore there are many tracts of comparatively useless jungle that possess the requisite soil for Sisal cultivation. He also tells us of having sold sufficient young plants to cover the cost of importation of the original stock. The experience gained he summarises thus:

1. Land of a gravelly soil and stony nature is most suitable.
2. When it is planted, cultivation practically ceases for a period of four years or until the matured leaves are ready for cutting.
3. On suitable land, failure of crop has never been heard of.
4. The profit of a cropped acre is estimated at £4 to £5 per annum—that is, 60 to 70 rupees.

On this subject Mann and Hunter observe that the Sisal does not require a rich soil. It must have a soil well drained, moderately light and not too rich since that leads to luxuriance but loss of fibre, nor too poor since the fibre will then become short. The presence of lime in the soil is advantageous. In a word, much of that culturable land in tea districts which is not suited for tea will do well enough for Sisal. But it would appear these authors may have been led into the expression of a too emphatic opinion as to Sisal being not only the best but the only species suited to the tea districts (Mann and Hunter, l.c. 4, 9). It seems highly probable that the liability to frost, to which not a few tea districts are subject, might preclude the cultivation of Sisal and point to A. Cantala, for example, as preferable. Of course where it is found possible to grow A. sisalana that would be the best species, but there seems no doubt that for the whole of the tea districts, and still more so for the whole of India, one and the same species is not universally suited. [Cf. Ann. Rept., Bot. Gard. Sibpur, 1903-4.]

Bombay.

In Tirhut and Bombay.—Although a good deal has been written in a general way regarding the Tirhut and Bihar ventures, little definite knowledge is available such as to justify the formation of opinions regarding either the methods pursued or the success obtained. It is known that large shipments of plants have been secured, and it is understood that they have taken kindly to the climate and soil of Bihar. Frequent mention has also been made of Mr. Woodrow’s experiments and results and of his endeavours to establish plantations at Nasik and Nandgaon. In the prospectus of the Bombay Sisal Hemp Co., Ltd. (issued in April 1899), Mr. Woodrow says, “I introduced a few sisal hemp plants seven years ago; they have grown remarkably well and have given 10,000 young plants.” Further on he adds, “One million aloe fibre plants are at hand, enough for 500 acres, and about 10 millions are procurable this year.” In the same way it is known that Dr. E. Suter is growing Sisal at Powai, near Bombay.
INDIAN PLANTATIONS

But as already shown, the plant cultivated on that estate is chiefly A. Cantalau.

While these brief references denote what might be called the more important centres of the new Indian Sisal hemp enterprise, particulars of small experimental plots are to hand from every province of India and Burma. The reader should consult Prain's Report for additional particulars (Agri. Ledg., 1900, No. 6).

Yield of Fibre.—Of Yucatan it is said that from 1,000 to 1,500 lb. per acre of cleaned fibre are obtained and that 50 to 70 lb. are derived from 1,000 leaves of plant. This would come to an average of about 30 leaves yielded by each plant, in order to give the amount of clean fibre stated; but most reports place the produce at a much lower figure, namely from 10 to 20 leaves a year for each plant. We read that in Lucknow, grown on a poor soil, the plants are said to have had 30 leaves; 50 in Saharanpur, Cashar, Tirhut; 60-70 in Port Blair; 73 in Assam; and 80 in Poona. Doubtless these numbers have reference to the total leaves on each plant, not to the number of mature leaves annually available for fibre extraction.

Harvest and Fibre Extraction.—The leaves are cut off from the stem from below upwards by means of a heavy-bladed long knife, and the spine on the apex is also severed by a blow of the same before the leaves are thrown on the ground. In America and the West Indies the operators are paid as a rule by contract, but a day's labour would be regarded as from 2,000 to 2,500 leaves. According to Indian experience the leaves are approximately 4 feet 6 inches long and 5 inches wide with a weight of 2 lb. Some are recorded as only 2 feet long by 3 inches and weight 5 ounces; others 6 feet 6 inches long by 5 inches wide and 2½ lb. in weight. The Sylhet experience would be about the mean of the figures given. "True Sisal hemp, grown on suitable and not too rich land, should yield for instance, 3 per cent. of fibre (and often much more) on the weight of leaf: careful tests of the large blue Aloe in India have given 2½ per cent. only of fibre. Furcraea gigantea (Mauritius hemp) gives a still more yield on the weight of leaf, the amount being in Sylhet from 1½ to 2 per cent., but in this case the difference is more than counterbalanced by the larger weight of leaf obtained per acre."

Machinery.—The most generally used fibre-cleaning machine in Yucatan is called the "Raspador," although others are employed, such as the "Solas," "Preito," "Torrusola" [cf. photograph in Mann and Hunter, Lc. 24, pl. vii.] and "Villamore." The "Raspador" [cf. Mann and Hunter, Lc. 21, fig. 2] consists of a drum with brass knives fastened across the face. It is so geared as to revolve about 110 times a minute. The leaf is held by a clamp and crushed as it moves forward, while the pulp is scraped off by the knives as they dash across it. When little more than one-half the leaf has been reduced to pulp it is withdrawn and reversed so that the other half may be similarly cleaned. The fibre is then dried in the sun and baled for export. Though crude in construction the "Raspador" has the advantages of cheapness and simplicity. It is typical of most of the modern machines that have been brought out, each with special claims to superiority over the others. With Furcraea gigantea the "Gratto" machine is in a position of supreme favour. But in addition to the machines already mentioned, the following may be said to have been specially designed to deal with the aloe fibres:—the "Death," the "Barraclough," the "Van Buren," the "T. Abe Smith," and the "Weicher" machines. Then there is the "Silburn" machine of which so much has been said in the Indian Press recently, and lastly the "Suter" machine, which makes 500 revolutions a minute.

Properties and Uses of Sisal and Aloe Fibres.—I have not thought it necessary or desirable to devote space to the discussion of these subjects. Briefly the fibres are used for ropes and cordage; for carpets, mats and matting; for brush-making; and the waste for papermaking. To a limited extent the shorter and finer fibres are carded, spun and woven. [Cf. Royle, Fibrous Pl., 1855, 41-50; Agri. Ledg., 1896, No. 34; Dodge, Useful Fibre Pl. of the World, 1897; Stuhlmann, in Der Pflanzer, 1907, Nos. 15, 16, 229-43; Hanausk, Micro. Tech. Prod. (Winton and Barber, trans.), 1907, 96-8.]
TRADE IN HEMP.—Mann and Hunter give interesting particulars regarding the prospects of a Sisal Fibre Industry: the capital required, the world's markets for the fibre, prices ruling, etc., etc.; their work should be consulted for such particulars. One of the earliest records of this fibre refers to the imports into England from Yucatan from 1750 to 1780. Although high expectations were then raised, the fibre did not assume a position of importance until fully a century later, when the first plantation of some 50 acres was laid out. The exports from Yucatan were 243,968 bales in 1889 and 418,972 bales in 1898. It is said that in the latter year there were 1,200 plantations in Yucatan alone. It seems probable that in the Bahamas there are over 20,000 acres under the crop. According to Sir W. Robinson (lecture in March 1900 before the Royal Colonial Institute of London), so long as the fibre fetches even £20 to £25 a ton the prospects would be distinctly favourable for the investor in the West Indies. Were it not necessary to provide for heavy charges in supervision, for rent of land (as a rule too valuable for the crop), for freight charges in many instances over long distances to the seaboard, the cheap labour of India might be a factor of no small importance. But it cannot be denied that there are large tracts of India highly suited for this plant which are at present practically waste. As an auxiliary crop with tea and when grown on land near the seaboard, it is very probable that success would be attained. But the industrial developments possible for this fibre seem to be comparatively limited. Moreover, indications are not wanting that the increasing production is at a higher rate than the expansion of the demand. But that a limited Indian cultivation might be successful seems fully demonstrated by the results already attained. It may be of interest to add that the first public sales of Sylhet Sisal fibre show that it fetched £36 10s. per ton in London or approximately the same price as realised for the Bombay Aloe fibre, so that the difference in species grown does not appear materially to have affected the value of the fibre produced. [Cf. Ind. Plant. and Gard., Feb. 21, 1901.]

Indian Market. To what extent production is meeting the existing Indian demand cannot at present be discovered, but there would seem to be no doubt that steadily the Indian supply will improve, and the most recent information goes to show that most encouraging results have been attained in Assam (Sylhet). It is known that there is a regular import trade in "white fibre" to be used by the rope-makers in place of or in mixture with the more expensive Manila Hemp. Certain qualities of sisal or other aloe fibres are also used by the brush-makers. For brushes the larger, thicker, more elastic and more highly polished fibres are required, since these approximate most nearly to pig's-bristle. In the Calcutta market a specially selected fibre for the brush-making trade is reported to be sold under the name of reju and to be imported from England. But here it may be added that the Izte or Tampico fibre (Agave heteracanthia) is a Mexican fibre which might be said to be specially produced for the brush-maker. How far this may be the reju fibre of India cannot at present be ascertained. Nor can definite returns of the Indian trade in sisal fibre be given, since both the import and export traffic is recorded under the collective heading of "Hemp." Out of the total imports of "Raw Hemp" from foreign countries received by India in 1906-7 (viz. 22,513 cwt., valued at Rs. 6,94,623), China supplied 14,815 cwt., the Philippines 4,891 cwt., the
United States 1,635 cwt., New Zealand 756 cwt., and the United Kingdom 209 cwt. The nature of the fibres classified as "Hemp" in these returns can be judged of only by the countries from whence derived. Thus the Philippine Hemp may in all probability have been Manila Hemp: the supply from that country was renewed in 1899-1900. Perhaps the most striking feature of these imports of hemp is the decline in the supply from the Straits, which in 1896-7 fell from 6,624 cwt., valued at Rs. 1,01,831, to 370 cwt., valued at Rs. 10,796, in 1905-6, and in 1906-7 nil. The Exports from India are mainly, if not entirely, of "Sunn Hemp" and other allied fibres, and thus quite distinct from the "Sisal Hemp" here dealt with, so that the returns of exports need not be further considered. But it is believed that about 25 per cent. of the exports of Raw Hemp from Bombay are at the present time Aloe (Agave) fibre. In 1906-7 Bombay exported 255,375 cwt. of Hemp, valued at Rs. 28,74,499. And a striking feature of the exports of raw hemp is the fact that the Bengal section appears to have given an indication of expansion, a consequence, doubtless, of the Sylhet production of Sisal. In 1899-1900 Calcutta exported 63,433 cwt., valued at Rs. 4,66,603, in 1900-1 an expansion to double the quantity and three times the value was recorded, viz. 128,634 cwt., valued at Rs. 12,20,351, and in 1906-7 to 261,867 cwt., valued at Rs. 29,76,541.

There are in India 14 species of this genus, all trees except one. Lt.-Col. D. Prain in his revision of the genus has added four species not hitherto separately recognised and has removed much of the ambiguity that previously prevailed. He has shown that Indian authors have been in error in thinking that *A. Julibrissin* is met with in India: he has restored *A. mollis, Balf.* to specific importance, and separated from *A. Lebbek* (under the name *A. Gambicèri*) an important East Himalayan form. Generically the species of *Albizzia* bear the vernacular names of *siris*, *sirisha*, *sirin*, *turanti*, *chirigu*, *baghi*, *vaghe*, *koko*, etc. *A. Lebbek* seems to be the true *siris*, a tree, according to Sir Monier Williams, that is sacred to the Buddhists. The other species are distinguished as the sweetly scented *siris*, the white *siris*, etc.

They all afford Gum, more or less copiously, from wounds on the stem, and though little is known for certain of the specific differences of these gums, that of *A. stipulata* is reputed to be specially valued as a size in the manufacture of Nepali paper. The barks of most species are astringent and used as Dyes, Tans and Medicines. That of *A. Lebbek* is employed in Madras to tan fishing nets, and that of *A. myrtophylla* (kanka-*siris*) is utilised as a substitute for *A. leucophlora* in distillation, and those of *A. stipulata* and *A. procera* are said to be fish poisons. The leaves of most species are regarded as useful Fodders and in some instances the trees are specially grown on that account, but according to Mr. Hartless the stipules and young leaves of *A. stipulata* are poisonous to cattle. The most curious discovery regarding the leaves of this genus may be however to be the determination made by me of the so-called *Jyre Tea*, which consists of ordinary tea mixed with specially prepared leaves of *A. amara* (the *lalai* or *unjei*). [Cf. Journ. Agri.-Hort. Soc. Ind., 1898, xi., 838-42; 1899, 982-3; Kew Bull., 1899, 82.] Mr. Chandra Bhushan Bhaduri, Officiating Chemist to the Industrial Section, Indian Museum, analysed *A. amara* leaves (hand-picked from a sample of *jyre tea*) and found that they possessed no special properties worthy of notice. [Cf. Ann. Rept. Ind. Mus., 1899-1900, 52; Pharm. Journ. Gl. Brit., Dec. 16, 1905, 833.]

The Timber of these trees varies greatly, being very soft in *A. stipulata*, hard in *A. odoratissima, lucida* and *amara*; sapwood large and white; the heartwood light to dark-brown, streaked, shining; pores usually scanty and often

Timber.
Subdivided, showing up prominently as dark streaks on vertical section; lastly the medullary rays are fine, short-distant and shallow. Recently A. Lobbek has found its way to Europe under the name of "East Indian Walnut," being exported mainly from the Andaman Islands. [Cf. Handbook Imp. Inst.] It grows rapidly, seasons, works and polishes well, and is fairly durable. It is said to be taxed in Burma at a higher rate than teak-wood, a circumstance which indicates the local value put on this timber. It is used for agricultural and industrial instruments and appliances, for furniture and picture frames, and cartwrights' work, etc. The timber of A. amara is very much like that of the Siris only that it is purplish-brown with concentric light and dark bands. [Cf. For. Adm. Rept. Mad., 1897–8, app. i., 31.] The timber of A. odoratissimum turns almost black with age, is largely employed for cart-wheels, etc. Lisbon says that the wood of A. procera has darker patches, but that it takes a fine polish and is recommended for furniture. [Cf. Useful Pl. Bomb., 1884, 70, etc.]

As Avenue and Shade-trees most of the species are much admired.

A. tophanthus is a rapid-growing tree, introduced from Australia and completely naturalised in the Nilgiri hills. A. moluccana is another introduced species, and one of the most stately and beautiful members of the genus. It was at one time much cultivated by the coffee-planters of South India, but has got into disfavour for that purpose because of the immense size it ultimately attains.

A. procera has been specially commended for cultivation on saline soils. [Cf. Ind. For., 1887, xiii., 339; 1888, xiv., 142; Ann. Rept. Dept. Land Rec. and Agri., Beng., 1891–2, 23.] It is the species that first appears on the sandy beds of rivers. But by far the greatest interest in the species of Albizia centres in A. stipulata, which is now very extensively grown as a shade-tree for tea, both in Assam and Darjeeling. It is known as the sau in the former province and the kala-siris in the latter. Its chief value turns on the nitrating warts formed on its roots. [Cf. Watt and Mann, The Pests and Blights of the Tea Plant, 140; Der Tropenpflanzer, 1901, v., 244.]

ALEURITES FORDII, Hemsl., Kew Bull., 1906, 117, 120; Hooker, Ic. Pl., tt. 2801, 2802 (confused with A. cordata by most authors); Euphorbiaceæ or Spurge-worts. A small tree, native of China but successfully acclimatised in the Southern Shan States (between 1,500 and 3,000 feet in altitude) and to some extent also in Burma, Assam, Sikkim and Nepal. Frequently met with near Buddhist monasteries, though in some localities it appears to have escaped into the neighbouring jungles.

A. cordata, R. Br. ex Steud., has a wrinkled fruit and is found in Formosa, Hainain and Tonkin and is cultivated in Japan.

Oil. Trade Names.

A. Fordii yields an Oil known in commerce as Chinese Varnish or Tung Oil and in some books is spoken of as Chinese Wood Oil, the latter name referring to its special adaptability for varnishing wood (see p. 602). In fact the Chinese prefer to coat boats and other work with this oil rather than to paint them. It dries in about four hours. It is chiefly prepared in the provinces of Ichang and Szechuan and is employed in lacquering, varnishing and waterproofing, etc. The drying property of the cold-expression oil exceeds that of any other known oil; in fact it would appear to be an exceedingly valuable substance, the properties of which have been but indifferently appreciated in Europe. Of Japan it is said that the tree flowers at the end of May or beginning of June. The fruit ripens in autumn. Three to five seeds are contained in each fruit; they afford an oil to the extent of 37½ per cent. which is pressed out, in ordinary practice cold, to the extent of two-thirds of the possible yield. This oil, known in Japan by the name of Dokuyenoaburo, serves for filling the pores of wood before it is coated with lac, or it is used when desired to protect wood against moisture. In Japan it is also employed for lacquering machinery.

Drying Property.

Lubricating Oil.

A recent inquiry in India into the species that follows, led to information being procured from the Southern Shan States regarding the present plant. It would appear that in Kengtung the tree is fairly plentiful and the oil regularly prepared, although the demand is but limited. It has been estimated that the nuts of each tree might yield at least 50 ounces of oil. The kernels are first pounded, then steamed in a basket placed over the mouth of a pot in which water is boiled. The basket is next placed within a piece of bullock's skin and

A. triloba, Forst.; Hemsley, l.c. 121; A. moluccana, Wild.; Fl. Br. Ind., v., 384; Gamble, Man. Ind. Timbs., 613. The Indian or Belgaum Walnut, the Candle-nut; the jangli-akrot, jaiphal, etc. It occurs practically throughout India and Burma, but nowhere plentifully except perhaps in the Malay Peninsula. It has been stated to be wild in the Wynnaad, because of its greater abundance in that country, but it is certainly not indigenous to India, and, in fact, usually exists as a garden or roadside curiosity, especially near towns or villages. On the eastern side of India the fruits ripen from June to August (Roxb., Kurz., etc.), and on the western side not until the cold season (Talbot).

The nuts are commonly said to contain 50 per cent. or more of a sweet edible Orr. [Cf. Dymock. Mat. Med. Western Ind., 713.] It is much appreciated for illuminating purposes and is said to be largely exported from Polynesia and used in the candle trade of Europe. The kernels are sometimes strung on thin bamboo sticks and burned as natural candles, a circumstance which has given origin to the name of the Candle-nut tree. Capt. Champion (Agri.-Hort. Soc. Ind., Corresp. and Select., 1843, i., 383 et seq.) described the preparation of the oil from these nuts as then practised in Ceylon, and tells us that it was being exported from that country under the name of Candle-nut oil. During the succeeding half century, the Journals of the above Society, as also the pages of the Indian press generally, have spasmodically urged the importance of this tree on the attention of the Indian people, but with very little practical results.

The inquiry during the past decade has revealed the fact that the tree exists here and there all over the country, but nowhere in such abundance as to admit of any expectations of an immediate Trade in the oil. In fact, with the exception of the Shan States, the oil does not appear to be expressed from the kernels anywhere in India. In some parts of Burma it is employed as a VARNISH with lacquer-ware, but it is usually stated that for that purpose it possesses no special advantage over Sesame or Saron oils.

There are two directions of study that should engage attention in the future: (a) The method of preparation of the oil or oils of these trees, best calculated to bring out their special features of value. (b) The yield and profit, in connection with the regions that give indications of greatest success.

ALKALIS, ALKALINE EARTHS, ALKALOIDS, etc.—It would be beyond the scope of this work to deal with the substances indicated by the heading given to this article with any pretense to completeness, but they could not be omitted since it might almost be said that the industrial progress of a country can be ascertained by the extent to which it produces the Alkalis required by it own industries.

ALKALIS AND ALKALINE EARTHS

In its restricted sense the term *Alkali* might be said to denote Ammonia, Potash, Soda, Lithia—the alkalis proper. But in a wider signification it embraces the Alkaline Earths, viz. the hydrates of the metals Barium, Calcium and Strontium. These all possess to a certain extent the properties usually attributed to the alkalis. In like manner the Alkaline Ashes are very largely crude alkalis obtained by burning certain plants. Lastly the Alkaloids such as Aconitine, Morphin, Quinine, etc., have been described as the Organic Alkalis, but of course have nothing alkaline about them.

The distinctive features of the alkalis compounds may be said to be their solubility in water, their neutralisation of acids, their corrosion of animal and vegetable substances, and lastly their property of changing or inverting vegetable colours, such as litmus.

In all fairness it may be said of India that it does not possess any industry (pursued on modern scientific methods) for the production or refinement of the alkalis, alkaline earths and their salts. Such manufactures as do exist (if common salt be for the moment left out of consideration) are a century behind the times, and consist mainly in the production of saltpetre, pearl-ash, barilla and the like.

It is intended in this place to deal more particularly with the collective aspects of the alkalis and alkaline earths and to discuss, in such detail as may be necessary, the minor products, but with those of commercial value, simply to indicate the positions where separate articles on these will be found.

ALKALIS.——I. Ammonia and its Salts.—This alkali is in Europe and America very largely prepared from “gas liquor” (see Coal, p. 344) or “bone liquor” or from “volcanic salts.” It is not manufactured to any appreciable extent in India, for the simple reason that none of the crude materials named are to be had in sufficient abundance.

The chief preparations and salts are (a) LIQUOR AMMONIA used as medicine, as a chemical and as a solvent for resins and for certain active vegetable principles, thus forming varnish and ammoniated tinctures. Of the latter class may be mentioned the “Essence of Ginger,” employed in the manufacture of gingerade and ginger beer; of the former the Hatters’ Varnish, which consists of shellac dissolved in ammonia and alcohol.

The salts are (b) the CHLORIDE (narasāra or nāussadār), of importance as a material from which to manufacture other salts of ammonia, also essential in galvanising, in galvanic batteries and as an alkaline flux. (c) The SULPHATE, which is largely employed as a manure (see Coal and Coke, p. 346). [Cf. Mollison, *Textbook Ind. Agric.* i., 117.] (d) The CARBONATE, SULPHIDE, OXALATE, NITRATE, PHOSPHATE and BROMIDE, all of which take important places in the arts and industries of every country and may be said to be entirely imported by India.

2. Potassium or Potash and Carbonate of Potash.—J. H. Brough, *Cantor Lectures in Journ. Soc. Arts.*, 1903, lii., 144. This is the chief source of Caustic Potash, and the two compounds may, therefore, be dealt with collectively in this place. The carbonate in its crude form is often called Potashes or Pearl-ashes and in Bengali sarjika, in Hindustani *jon-khar* or *ivāk-chār*, and in Sanskrit *Yavak-shāra*. Of the other provincial names the following may be quoted:—*jhār-ka-namak, jhadichā-mitha, mara-vupp̄u, manu-vupp̄u, būddī-cupp̄u, kāram*, etc.

Sources.—Formerly the European supply of the crude material from which this substance is manufactured was very largely the Pearl-ash of Wood-ash obtained from America, Canada and Russia, etc. While the production of pearl-ash has steadily declined with the advance of traffic in more scientific and less wasteful materials, the imports into Europe of pearl-ash have not been entirely discontinued. Caustic potash is usually manufactured from the carbonate, and
this is procured:—(a) From the ashes of plants. (b) From the soil (due to the disintegration of felspar and other silicates and the ultimate combination of their potash with carbonic acid), also numerous methods patented for the accomplishment of this same result artificially. (c) From the potassium sulphate, produced by the decomposition of the chloride through the agency of sulphuric acid followed by fusion of the resulting sulphates with limestone and charcoal, in other words a process almost identical with the Le Blanc method of treating soda. (d) From suint or the wool of sheep impregnated with the sweat that exudes from the bodies of the animals. (e) Beet-root vinasse.

Roxburgh's statements regarding the production of pearl-ash are amusing and interesting (Fl. Ind., ii., 62). I shall quote his own words. "Our extensive, and I may also say impenetrable forests, which cover such large tracts of the best lands in India might by degrees be cleared and turned into potash, for the same reasons and by the same means" as the saltworts of the coast might yield barilla. "Certainly, labour is as cheap here as in Russia." "In this hot climate we have many advantages, viz; immense tracts of wood of the most solid texture which require little labour to prepare it for the fire, on account of the great drought and heat which prevail at the season this manufacture could be best carried on. The same heat and drought is fully sufficient to evaporate the fly without the least assistance of fire." "Our extensive and impenetrable forests" sounds remarkable when it is borne in mind that one of the reasons assigned at the present day for the recent expansion of the area of carbonate of soda impregnated sterile soils is the absence of forest. We know as a matter of trade history that India never actually burned her forests in the production of pearl-ash. Moreover, Roxburgh's "impenetrable forests" had very possibly no reference to Northern India. Still his remarks are significant since he was one of the best informed and most careful observers and at the same time one of the most accurate writers who ever lived in India. His words cannot, therefore, be placed on one side as unworthy of consideration. They doubtless denote that 100 years ago forest was very much more plentiful than at the present day and was possibly ruthlessly destroyed to make room for temporary cultivation.

Of plants it may in general terms be said that herbaceous annuals contain more pearl-ash than woody arborescent plants, but even of the same plant the succulent young growths are more highly charged than mature tissues. Of different species 1,000 parts of pine contain an average only 0·45 parts of potash, oaks 0·75, vine shoots 5·50, ordinary straw 5·8, ferns from 4·25 to 6·26, Indian cornstalks 17·5, nettles 25·03, wheat straws before earing 47·0, wormwood 73·0, and beet about the same amount. These facts naturally suggest the plants best suited for the preparation of pearl-ash, and the immense development within recent years of the beet-sugar industry at once awakened an interest in carbonate of potash as a by-product that might supplement the returns of beet cultivation. This has been actually turned to account.

**Indian Pearl-ash.**—The following may be given as the principal plants employed in India for the preparation of pearl-ash:

- *Achyranthes aspera.*
- *Adhatoda Vasaica.*
- *Alstonia scholaris.*
- *Amaranthus spinosus.*
- *Bambus app.*
- *Borassus flabellifer.*
- *Butea frondosa.*
- *Cassipinia Bonducella.*
- *Calotropis gigantea.*
- *Cassia Fistula.*
- *Cedrus Deodara.*
- *Erythrina indica.*
- *Euphorbia neriifolia.*
- *Euphorbia Tirucalli.*
- *Gmelina arborea.*

The crude ashes obtained from the above and such-like plants are the chief sources of the potash salts employed by the people of India in their arts, science and medicine.

**Uses.**—In Europe carbonate of potash is largely in demand for the manufacture of certain soaps, after having been converted into the caustic. It is also essential in the formation of potash-glass and enters into many tinctorial and textile processes, such as the dyeing of Turkey red and of Arnotto (*Bixa orellana*).
ALKALI 
SODA

Sodium Carbonate

In Garhwal hemp-fibre is boiled before being bleached (see Cannabis sativa, Fibre, p. 255). In India it would be almost impossible to over-estimate the extent to which a crude carbonate of potash is employed. A better selection of plants or improvements in the methods pursued for the production of pearl-ash are chiefly responsible for the preparation of these products of pearl-ash from wood-moss, after the manner of the common method, is not apparent nor are its plants are not apparently utilised. From the high percentage of carbonate of potash which they contain, the preparation of pearl ash from wood-moss might be conjectured to the poorer inhabitants of the temperate regions of India as a useful new industry.

In Bombay, especially in the rainy tracts, the system prevails of rabing (as it is called) the seed-beds. This consists in burying brushwood, boughs of trees, cow-dung, etc., under a thin layer of soil, then firing the mass. In this way the soil becomes highly charged with wood-ashes, the most important constituent of which is double-dose potash. It is found that the finer qualities of rice can alone be grown when the seed has been previously germinated on rab-beds, and later on transplanted to the fields. It would be well, in connection with the subject of potash as a manure, for the reader to consult Leather's admirable papers on Indian Manures. [Cf. Agri. Ledg., 1897, No. 8; also Indian Soils, 1898, No. 2; Mollison, Textbook Ind. Agric., i., 83-5, 119-21.]

3. Potassium nitrate (see Saltpetre, pp. 972-5).

4. Sodium and its Compounds, Carbonate of Soda; Ball, Man. Econ. Geol. Ind., 1881, 492-7; Holland, Rec. Geol. Surv. Ind., i., 115. The term soda, strictly speaking, denotes the oxides of the metal, but it is also used for the hydroxide and the carbonate. The last mentioned is not only the most important commercially, but it is the compound from which the majority of the other soda salts are made or can be made, and therefore it may be dealt with in greatest detail.

Carbonate of Soda is a valuable salt; it exists in nature and is, as a rule, the most abundant and, from the point of view of the agriculturist, the most objectionable ingredient of the soluble sodium salts found in the soil. This subject will be dealt with in a further paragraph under the heading of Rmh deposits (see below). It may be here observed that from such deposits carbonate of soda can be isolated and purified commercially, or a crude mixed salt can be made that might be utilised in the manufacture of special alkalis or in the glass, soap and other trades. Sodium carbonate in an even purer state may be obtained from the brine of certain lakes, such as the Lonar in Berar.

Manufacture from Kelp.—In Europe some few years ago a large trade used to exist in the separation of sodium carbonate from calcined sea-weeds—Kelp, or salt-worts—Barilla. Indeed to this day it may be said that Salisola Soda is still regularly produced both in France and Spain because of the large amount and fine quality of soda obtained from its ashes. And it was the loss of their regular supplies of barilla, during the wars with Spain, that compelled the French people to seek for new sources of the salt and finally led to Le Blanc taking out a patent in 1792 for the artificial manufacture of carbonate of soda from common salt. Le Blanc's discoveries practically revolutionised the chemical works and industries of Europe (see pp. 50-1). The calcination of sea-weeds is pursued as a rule for the purpose of obtaining potash rather than soda, and at the present day "kelp" is much more frequently spoken of as the source of iodine than of either of the alkali named. [For particulars regarding the manufacture from Sea Salt the reader might consult Agri. Ledg., 1902, No. 5.]

One of the greatest economies in the carbonate of soda industry was effected by the manufacture of Sulphuric Acid from Pyrites, in place of from the expensive Sicilian Sulphur. The extensive deposits of copper pyrites that exist in India, if utilised in the combined production of copper and sulphuric acid, should open a highly lucrative field of enterprise. So also the manufacture of the phosphatic deposits of India and adjacent countries into superphosphates should not be neglected, though so far as at present known the phosphatic deposits of India seem to contain too much iron and alumina to make really good superphosphates. As an exemplification of such results it may be remarked that the production of sulphuric acid from iron pyrites was in Germany 358,149 tons in
Réh Efflorescence

1882, and 754,161 tons in 1898, and of that large quantity only 25,000 tons were exported, the balance being used up in the exceedingly important German chemical industries which within the past three-quarters of a century have expanded from being nominal to a valuation of £50,000,000. The imports of sulphuric acid taken by India have averaged from 1902-7 Rs. 6,58,488 in value.

For the finer sorts of glass, and for many other minor purposes, a Refined Carbonate is required. This is obtained by re-dissolving the ash in hot water, settling, boiling down and re-furnacing—the result being a purer quality of carbonate. Soda Crystals may be said to be a well-known special preparation that contains 10 parts of water in combination with the carbonate. For household purposes of cleaning, bleaching, etc., soda crystals are still sold. The other substances obtained from sodium carbonate that may be here mentioned are the bicarbonate of soda and caustic soda. Before proceeding to deal with the last mentioned, the Indian manufacture and sources of supply of carbonates of soda may be dealt with very briefly. These have already been incidentally mentioned, namely, Réh and Barilla, but to the former must be added the sources of natural carbonate derived from the waters of certain lakes, such as the Lonar in Berar. [Cf. Oldham, Man. Econ. Geol. Ind., 19.]

5. Réh or Sajji-matti; Ironside, Phil. Trans., 1774, lixiv., (ed. xi.), 506; Sleeman, Tour through Oudh, 1858; Agri. Ledt., 1893, Nos. 12, 13; 1896, Nos. I, 33; 1897, Nos. 5, 7, 13; 1901, Nos. 4, 13; 1902, No. 5, 117-24; Oldham, Man. Econ. Geol. Ind., 1893, 447; Mollison, Textbook Ind. Agri., i., 77-80; Wedderburn, Drought-resisting Fodder Plants, in Ind. Famine Union Leaflet, Dec. 1901, No. 2; Jan. 1903, No. 8; Alkalic Land and its Reclam., in Dept. Land Rec. and Agri. Mad., 1905.

This is an efflorescence that occurs on the surface of the ground, in most provinces of India. It may be said to be a mixture of the following salts:—sodium carbonate (sajji), sodium sulphate (khari), and sodium chloride (common salt or namak). In most localities the carbonate predominates but in others the sulphate, and in the latter case it is very often associated with potassium nitrate or even with calcium nitrate. Soils badly impregnated with soluble alkali salts are variously designated as usar, bhādi, réhul, réhār, réh, kalar (kalar), etc., though these terms are employed occasionally to denote the presence of common salt, just as khāri usually indicates a soil containing the sulphate. But it may be here remarked that the earlier investigators of usar lands speak of the sulphate as being the most abundant constituent. Hence apparently Yule and Burnell (Hobson-Jobson, Gloss. of Anglo-Ind. Words) defines réh as an efflorescent sulphate of soda mixed with chloride and occasionally carbonate. On the other hand, Voelcker advanced what is to-day the correct view (Improv. Ind. Agri., 37) when he said of réh, “The salts are principally impure carbonate of soda, but sulphate of soda also occurs largely and with them are found common salt and salts of lime and magnesia.” An efflorescence of the nitrates of potash or soda would oftener be viewed as of value rather than of danger.

Réh frequently occurs in such abundance as to give origin to large tracts of desert—and constantly increasing tracts—the surface being literally encrusted with a white, snow-like deposit (hence the name réh or réj = shining)—or the salt may be invisible and only present to an extent sufficient to greatly lower fertility, or while still hardly visible, may yet render the soil more or less sterile for at least half the year. In passing it may be added that fuller’s-earth is a hydrous silicate of alumina, but is often called, though incorrectly, sajji-matti; it contains no soda.

Formation of Usar.—The opinions advanced regarding alkali deposits vary in consequence of what might be called professional bias. Apparently the earliest mention of such deposits is made by Sleeman. His theory is in essentials not far
ALKALIS

RÉH

from being in accordance with modern views. It is certainly strange that Royle (Prod. Res. Ind., 1840-75) makes no mention of the phenomenon of réh efflorescence. He remarks that Dr. Helenus Scott had sent from Bombay to England a sample of a "mineral alkali" as a substitute for harina, and so closos his account. He was for some time resident in Saharanpur, and if the úsar tracts existed as they do to-day, it is curious that he should not have mentioned them. In 1864 was published (Select. Rec. Gov. Ind., No. xlii.) a correspondence which deals with the deterioration of village lands lying along the W. Jumna Canal and contends that the canal was not responsible for the existence of injurious salts, but that defective drainage in connection with it had led to the accumulation of salt to such an extent as to render cultivation impossible. The inquiry had no practical result. In 1876, however, a committee was appointed to investigate the matter in consequence of a planter's complaint that his land had been spoilt by the mismanagement of canal irrigation. This was the Réh Committee of 1877, of which Mr. H. B. Medlicott was a member. Medlicott (at one time Director of the Geological Survey) began the study of this subject early in the 'sixties. As a member of the committee, he wrote a masterly report which may be said to contain all we know regarding the formation and movement of the soluble alkali salts within the soil. These, he tells us, are formed from normal soil-materials by the disintegration caused through the growth of plants and tillage. The silicates are broken up by the action of heat, air, water and carbonic acid, etc., with the manifestation of the various alkalis that are formed or re-formed during the several changes that ensue. During the production and maintenance of fertile soils, carbonate of soda, for example, is as a rule a transitional compound and is destroyed with the elaboration of other and more essential constituents, especially in the presence of lime. In most fertile soils the percentage of that carbonate is accordingly remarkably low. In fact the total of soluble soda salts in good soils rarely exceeds 0'1, of which ordinarily one-half may be the carbonate. Crops, more especially cereals, may however be grown on soils that contain 0'1 per cent. of carbonate of soda, and 0'2 per cent. is sufficient to cause serious injury if it be not found fatal, except perhaps to the so-called saltworts or saltbush—plants that are actually found to luxuriate on briny soils or littoral swamps. At times, however, as already observed, the surface soil may become encrusted with soluble salts, as much as 2 to 6 per cent., or much more being often present. Normally these soluble alkalis are carried by the rain-water or irrigation to the subsoil, and a certain percentage are detained mechanically, the surplus being carried away by the drainage. Where subsoil drainage is defective, as a purely local and temporary measure surface wash may prove beneficial. For this purpose trenches or pits are dug, and the surface water dissolves the salts and carries these to the trenches, thereby leaving the higher ground less charged with alkali. But the evil consequence of even a temporary cessation of soil-permeation may be exaggerated under certain conditions such as (1) recurring periods of hot, parching winds; (2) absence of soil-covering (i.e. wild herbage or crops and trees); and (3) defective tillage (i.e. superficial ploughing or puddling during flood). These are the very conditions that produce réh efflorescence, aided by (a) the chemical nature of the original soil-materials; (b) the physical attributes (or texture, as it has been called) of the soil (i.e. abundance of clay and the conditions of the clay; abundance of sand or of lime, etc.); and (c) the accidental or irregular distribution of (a) and (b) brought about through countless ages of water action, both during the formation of the alluvial plains and subsequently. For particulars regarding the association of concretionary lime (kankar) with réh, the reader is referred to Limes, p. 711.

Kankar.

Capillary Action.—Dr. Center (then Chemical Examiner to the Panjáb Government) wrote in 1880 a most valuable Note on Réh or Alkali Soils and Saline Well Waters, in which he dealt in great detail with the movement of these salts within the soil and their temporary accumulation on the surface. They may be spoken of as first diffused, then carried to the surface by capillary action. Hilgard and Loughbridge, in connection with the Californian Experimental Station of Tulare, have carried these investigations to their final issue by tracing, in every detail, the actual movement of the salts in sterile soils, before and after irrigation, and have exhibited their results graphically, in direct correspondence with a most critical analysis of practically every inch of soil to a depth of 4 feet. They have also demonstrated beyond dispute that this movement to and from the surface is directly a result of imperfect drainage in conjunction with severe surface evaporation.
TREATMENT OF USAR SOILS

Manuring and Tillage.—Dr. Brown (then Chemical Examiner to the Panjâb) investigated the use of lime salts as manures to be employed in the treatment of Usar soils, and his views were published by Mr. Baden Powell (Pb. Prod., 1868, 149) as follows:—"When the deleterious sulphates and carbonates are mixed with any soluble salt of lime, such as the nitrate of lime, decomposition occurs and nitrate of soda is formed while carbonate and sulphate of lime are produced. Carbonate of lime is insoluble in pure water and has no power of injuring plants, while nitrate of soda and sulphate of lime are beneficial in supplying them with nitrogen, the former by direct decomposition of its acid and the latter by absorbing ammonia from the air. Nitrate of lime is formed whenever organic matter decomposes in contact with carbonate of lime." Some years later Brown advocated the use of farm-yard manure and green manuring with such plants as Calendula gigantea on the ground of their supplying the nitrogen which, in combination with the lime (naturally present in all Usar soils), would tend to reduce the carbonate of soda to a harmless condition. Center wrote a long and highly instructive report on the chemistry of the Usar soils, and confirmed in the most striking way Brown's recommendations for lime nitrate. He also gave an account of the operations in the Utah Basin and other parts of America, where heavy nitrating manures were employed as a remedial measure for alkalai soils. Later on the sulphate of lime (Gypsum, see pp. 716-7) gained a well-deserved reputation as a chemical substance that might be employed with great advantage in the neutralisation of the sodium carbonate in Usar soils whenever that salt predominates. Where râh consists chiefly of sulphate of soda, gypsum would very possibly do harm rather than good.

The next most important step, therefore, in the study of the chemical treatment of Usar soils may be said to be Leather's various papers that have appeared in The Agricultural Ledger. These give extensive analyses of soils, waters, etc., from the entire alkali area of India. They contain the results of practical experiments to test the amount of soluble alkali salts that may exist in soils before these become poisonous to vegetation. They indicate the plants that first show signs of succumbing to the influence of these salts, and the amount of each salt that proves fatal. By special pot cultures of various plants, Leather proved that sodium carbonate is (as has always been upheld) infinitely more injurious to plant life than are any of the other soda salts. But perhaps the most instructive part of his researches was the demonstration of the physical property (alluded to by Romanis, Wallace and others) possessed by carbonate of soda, which greatly augments its injurious chemical influence on plants. While filtering soils in order to obtain their soluble salts, Leather observed that certain soils could practically not be filtered. A little muddy water percolated through at first, but very soon the surface of the filter-cloth became coated with a perfectly impenetrable layer, and further filtration was then impossible. The soils that manifested this peculiarity were those most highly charged with carbonate of soda. To remedy this defect he experimented with gypsum and soon ascertained that its well-known merit as a chemical manure in the reclamation of Usar soils rested as much on the destruction of the impervious deposit as in the reduction of the "white" to the "black alkali." It would thus appear that should climatic and soil conditions exist sufficient to give origin to a râh efflorescence containing carbonate of soda, there must sooner or later be produced (at a certain position or depth) an impenetrable layer through which surface percolation of water would be impossible. This waterproof layer may not be sufficiently developed to be visible to the naked eye as a "hard pan," but if carried near to the surface it will give origin to a crust of salt. A change in the physical condition of the soil is accordingly quite as urgent a necessity as in its actual chemical composition. It may thus be inferred that subsoil drainage, below an impervious layer, would be next useless unless the soil be chemically treated with some of the soluble lime salts, or be penetrated for tree cultivation by deep pits filled in with fresh soil. It would indeed seem probable that the surface vegetation that has been reported as accompanying successful tree cultivation, may be due very largely to the pits dug for trees having acted as openings through the impenetrable layer by which the soluble salts of the surface have been washed into the main drainage.

By way of concluding these observations regarding gypsum, it may be suggested that it is not necessary to assume that the exact amount of that salt which would be required chemically to neutralise the ascertained weight of carbonate present need be given as a manure before beneficial results may be

looked for. Gypsum is useless without water and unnecessary where the carbonate is absent. But its action is largely physical in allowing soil percolation. Unless, therefore, a free subsoil natural drainage exists it must be provided before any heavy expenditure is incurred for gypsum as a manure. At the same time land treated with gypsum should be planted with saltworts or other plants that have been found hitherto incapable of cultivation. If these can not be raised on the soil, it may be inferred that provision has been thereby made for the injurious salts being washed out of the soil, and that, too, long before it has been necessary to add, from a financial point of view, a prohibitive amount of gypsum.

American Results.—This leads, therefore, very naturally to a brief reference to the admirable investigations and practical results that have been attained by Hilgard and Loughbridge in the reclamation of alkali wastes in California (Agri. Ledg., 1896, No. 1). These officers performed an extensive series of experiments and analyses, with the result that they arrived emphatically at the same conclusions as our Indian experts had done many years previously, namely, regarding the history of the formation of the alkali salts, their movements in the soil, and lastly their treatment with drainage, chemical manures, and selected or special crops. The difference between American and Indian experience in this matter may therefore be said to be that in the former country the scientific experts were at the same time the administrative staff who had to deal with the alkali wastes. Their observations were not treated as scientific theories, but were at once put to practical test, with this result, that alkali wastes are in America not only regarded as comparatively easy of reclamation but have actually been largely turned into some of the most profitable of lands.

Helpful Vegetation.—Medlicott urged that to protect the soil from the excessive heat of the summer months and consequent injurious capillary efflorescence, it was most important to alleviate the serious Indian defect, viz. the almost total absence of arborescent vegetation from the agricultural tracts of the country. But there is an aspect of vegetation that seems to have entirely escaped Medlicott's observation, namely, the employment of certain plants as direct agents in reclamation. It is well known that many plants not only can survive on soils that contain a proportion of alkali that would be fatal to others, but that they actually luxuriate under such soil conditions. Of this nature may be mentioned the Saltworts (see under Barilla, pp. 113–4). Long, therefore, before reclamation could be carried to the extent of admitting of ordinary crops or even of arborescent cultivation, the soil might be protected from the sun by saltworts, and have at the same time large amounts of its poisonous salts removed by the temporary cultivation of such plants.

This subject has not, however, been entirely neglected in India. It was believed that were alkali lands protected from cattle for a number of years, or even annually from the close of the rains through the hot months, the plants produced during the rains might be encouraged to survive and even others, including trees, gradually to invade such protected localities, until in a few years' time the growth of a soil garment might ultimately prevent efflorescence. Such experiments have actually been conducted, and with considerable success. The plant found first to invade the parched barren lands was the grass known as khdr uara (Sporobolus arabicus), which from its vernacular name may be inferred to be a salt-loving species. Sporobolus coronandechianus (bhubo) also springs up readily enough, but only during the rains. It, however, affords useful fodder, although it does not protect the land from the summer's heat. After partial reclamation the ḏāb (Eragrostis cynosuroides), the ḏūb (Cynodon dactylon), the bat (Digitale fusca), the ānvara (Andropogon annulatus) and several other species readily appear. Since fodder is of necessity a pressing need in all parched lands, it is valuable to know the Indian grasses that should be first resorted to in reclamation operations, but it is unfortunate that the true saltworts have not hitherto been seriously investigated in India since they would appear more desirable preparatory plants to any of the grasses named. We read of a few desultory experiments having been put forth to acclimatise the Australian Saltbush, but it does not seem to have occurred to any of our Indian agricultural authorities that this country possesses perhaps a richer and more varied assortment of indigenous saltworts than is to be found in any other. In the Panjab and elsewhere a few of these have been (one might almost say) systematically cultivated for the production of barilla, but not one of them, so far as I can discover, has been seriously investigated as a preparatory crop in
Industrial Uses of Soda.—Incidentally this subject has already been dealt with. Throughout India soda soils are washed and more or less pure carbonate obtained. At one time a fairly large trade was done in this way in South India (Saleem, Mysore, etc.) and expectations of a considerable development entertained. Licenses were granted in Bihār, the United Provinces and elsewhere for the manufacture of saijī and rasi (two qualities of carbonate of soda) from saline earths. The object in licensing the industry is to protect the revenue, since from the factories concerned fairly large quantities of common salt are obtained, especially at the factories and refineries for the production of saltpetre. (For method of manufacture, see Glauber’s Salt, p. 56.)

Carbonate of soda of a very pure kind is regularly prepared at the Lonar Lake at Berār. Ball says (Man. Econ. Geol. Ind., 494), “Blocks of mixed salts are obtained by divers in certain parts of the lake, but the waters of the lake, on evaporation, deposit salts among which the principal is carbonate of soda. . . . The local names for these products are dalla, which consists of a close collection of acicular crystals, between two compact surfaces; kappal, a thin kind of dalla, principally of red colour; papadi or papri, a white saline froth.”

Whether obtained from soil efflorescence or from salt lakes by treatment with sulphuric acid, the mixed salts (especially where the greater proportion is already the sulphate) may be reduced to a salt-cake (similar to that obtained in the first stage in the Lé Blanco process of manufacture), and by calcining with lime and coal that may be converted into soda-ash. At Awah, in the United Provinces, an attempt was made, in 1880, to utilise the rēḥ efflorescence in the manufacture of glass and glass-beads. A complete set of tools was imported from Venice, but the following, among other conclusions, appear to have been arrived at regarding these and all such experiments at utilising the alkali deposits in glass-making:

(a) The impurity of the alkali prevents the formation of good quality of colourless glass.

(b) It is, therefore, necessary to organise chemical works to produce pure alkali.

(c) Good beads could be made, but doubtfully at a lower price than they can be imported.

(d) Improvement of glass manufacture in India would depend on the work being done on a large scale with skilled supervision.

Wherever soda efflorescence is at all abundant, the native industry of glass-making (such as it is) is more or less prevalent, especially that of glass bangles. But rēḥ and saijī are put to an infinite variety of other uses by the Natives. They are employed for dissolving crude lac and kameḷa, preparatory to dyeing silk, also for extracting the crimson dye from safflower in cotton dyeing. They are used for bleaching silk, cotton and wool. Sajī is employed, in Farukhābād, in making country paper from hemp. Both salts, in conjunction with shell-lime, enter into the composition of country soap. White rēḥ sprinkled into boiling cane-juice is employed to neutralise the organic acids in the manufacture of sugar, a process very similar to that of the use of lime (p. 712), barium carbonate (p. 57), or strontium carbonate (p. 58) in Europe. Rēḥ is an adulterant of tobacco, and is added to
increase the weight. In Native medicine these salts are supposed to be digestive and hepatic. The effort to utilise in the potter’s art the peculiar clays that are in association with carbonate of soda has not as yet received the consideration that it deserves, although the ceramic art of India has been the subject of special study. As a historic fact, that has escaped the attention of most writers on this subject, it may be said that some 60 years ago Sir William O’Shaughnessy submitted to the Government of India the results of an inquiry which included extensive trials of Bengal clays, such as Kolgong khari, Saban mātī, Rotas clays, Moulmein clays, Singapore clays, etc., as also numerous experiments in glazing the pottery turned out. [Cf. Beng. Dispen., app., 700-17.]

Black Salt. 6. **Black Salt** (kāla-nun, kāla-nimāk) is an article of some importance in the local markets of India. It is prepared in Upper India, chiefly at Bhiwānī in Hisār.

Medicine.

Common salt is heated with the chebulic and emblic myrobalans together with sajī, until a sort of fusion takes place. The article so manufactured is used as a medicine. Dr. Warth favours me with a note on this subject from which he would appear to regard sodium sulphate as an indispensable ingredient. He writes: “I have produced perfect specimens by fusing a mixture of pure common salt with sodium sulphate, a little sodium carbonate and organic matter represented by sugar.” According as the proportion of anhydrous sodium sulphate varied from 1 to 3 per cent., a more or less strongly medicinal salt was produced varying from pink to a decided vermilion colour, whilst as much as 15 per cent. of the sulphate yielded a very dark purple-coloured salt. All these had the characteristic sulphuretted-hydrogen smell, and gave the same chemical reactions as the Native-made product. The jungle fruits which they add can have no special influence on the salt because they are completely carbonised and serve only as reducing agents for the sulphate to sulphide, the characteristic material of the prepared medicinal (or black) salt.”

7. **Phuli.**—This is believed to be a form of carbonate of soda.

It is imported into Leh from Changthan, Rupshu and Nubra in Ladākh. It is said to be extensively used for mixing with tea to bring out its strength. It is exported to Kashmir and Kūllu and into Lower India. The Bhotiyas are said to use it for washing clothes and for dyeing wool. The average imports appear to be from 50 to 120 tons, and the average cost about Rs. 6-4-0 per maund.

8. **Barilla or Sajji-khar** (see Barilla and The Indian Saltworts, pp. 112-4). 9. **Borax** or Sodium bi-l borate (see Borax, p. 171).

10. **Caustic Soda** (= kshārd in Sanskrit).—So much space having been devoted to carbonate of soda and a further article to sodium bborate, the present salt must be disposed of in the briefest possible manner. At the present day it may be said that India’s supply comes entirely from foreign countries. One of the Indian paper mills is believed, however, to have attempted the preparation of its own supplies from the rēh salts found in the neighbourhood, but it is not known whether its endeavours in that direction were successful.

The greatest possible interest has been aroused in Europe and America through the discovery of a method of direct decomposition of common salt into caustic soda and chlorine gas by means of electricity. With regard to Electro-Chemistry the reader might consult The Mineral Industry (New York, 1900, 763-72).

The Indian press have hailed the discovery of the direct decomposition of salt as bringing a cheap supply of alkali to the doors of our Indian soap-works, paper-works, etc., owing to the possession of a limitless supply of sodium chloride. The great recommendation to India of this new method lies in the fact that sulphuric acid is not required. Without sulphuric acid Le Blanc’s manufacture of soda-ash could not be brought to bear on our supplies of common salt or of rēh efflorescence—hence in all probability the backwardness of India in chemical enterprise.

11. **Sodium Chloride** (see Salt, pp. 963-71).

12. **Sodium Sulphate, or Glauber’s Salt.**—This is generally known in India under the name khār or khārīnun, and as already ex-
ALKALINE EARTHS—Having now discussed the true alkalis and their salts with as much detail as the available space will admit, it becomes necessary to record the chief facts known regarding the Alkaline Earths and their salts as met with in India.

13. Barium and Baryta; Ball, Man. Econ. Geol., Ind., 473-4.

The oxide of this metal (baryta) is an extremely caustic, poisonous and strongly alkaline substance that forms a hydrate with water.

14. Barium Carbonate.—This is imported into India to a very limited extent. It is highly poisonous. In Europe it is employed as an ingredient in certain forms of pottery and glassware, and is the basis of certain delicate colours. In France it is used in the deodoration of beet-root sugar in place of lime. [Cf. Min. Indust., 1900, 53-4.]

15. Barium Nitrate.—This is obtained by decomposing the carbonate by means of nitric acid. It is the chief salt employed in pyrotechny for the production of green fires. It is also the tintorial principle in BARYTA GREEN—a pigment of some value. Recently barium nitrate has been substituted for saltpetre in the preparation of certain explosives.

16. Barium Sulphate.—This is the most important of the barium salts and is known as BARITTES (BARYTES) OR HEAVY-STAR. It is found in mineral lodes and usually constitutes a distinct portion of the gangue thence present. In the Kurnool District, Madras, it occurs along with galena, within the veins of quartz. Large quantities also occur with quartz, forming a network of veins, as for example near Alangayam, Salem district (Holland, Rec. Geol. Surv. Ind., 1897, xxx, pt. iv.). If ever worked, large supplies could be obtained from that locality. So, in the same way, barytes exists in the Central Provinces in association with copper such as at Jabalpur and in the Rewa State. In Rajputana barytes has been reported by Dr. Irvine as occurring at the lead mines of Taragarh in Ajmir. In the Panjab it has also been found in association with galena at Subathu in the Simla district. While it would thus appear that the Indian sources of this alkaline earth have not been worked, barium sulphate is nevertheless available in every bazar and seems to be very largely sold as “white lead,” or in adultera-
ALLIUM SATIVUM

THE ONION AND GARLIC

17. Calcium and its Salts (see Lime, pp. 709–19).

18. Strontium and Strontia.—The oxide strontia does not exist in nature, but it may be produced by burning either the carbonate or the sulphate.

CELESTITE, the sulphate of strontium, has been reported as met with in two localities in India, viz. in the Kirthar limestones of Sind and in the red clays of Sirdag in the Salt Range. In the sugar refineries of the Continent of Europe the native carbonate (Strontianite) was formerly used in place of lime (Journ. Soc. Chem. Indus., Nov. 1901, 1992). But the metal is chiefly known in India in the form of the imported nitrate which is largely employed in the preparation of red-coloured flames in fireworks.

ALKALOIDS (see Aconitum, Cinchona, Papaver, etc.).

D.E.P., i., 168–75.

ALLIUM, Linn.; Fl. Br. Ind., vi., 337–45; LILLIACEÆ. A genus of bulbous herbs which embraces about 250 species, all indigenous to the temperate regions. In addition to the onion and the garlic (which are the most important species), the shallot and the leek (A. ascalonicum, Linn., and A. Ampeloprasum, Linn.) are also cultivated in India, the latter being the parú of Bengal and the kiráth or kirás of Arabia. In Western India, according to Woodrow, leeks succeed best at altitudes of 2,000 feet.

Onion.

A. Cepa, Linn.; Duthie, Field and Garden Crops, iii., 5, pl. lxv.; Mollison, Textbook Ind. Agri., iii., 211.

The ONION is extensively cultivated in India, chiefly near large towns, and is known as piyaz, paldándu, kanda, vella-tengyam, vullu-gadalu, etc. There are two forms, a small silvery and a large red or yellow. Patna and Bombay (Jangira) are famous for their onions, and, speaking generally, the onions from the northern provinces are the largest and best. The size and quality would seem to be improved by transplantation, which is also a preventive against disease from fungi and insects. Seeds will not keep in India for more than one season, hence selected bulbs are planted for seed purposes at the beginning of the cold season. After careful preparation the seed-bed should be sown about September and the seedlings transplanted in November or early in December. The crop may be lifted from March to May. In two test cases mentioned by Mollison the yield was about 25,000 lb. to the acre. Onions are extensively eaten in India by Muhammadans, much less frequently by the Hindus; they are occasionally given to milch cows and buffaloes. There would appear to be a considerable export trade in the bulbs from Bombay to Zanzibar, Japan, etc. [Cf. Ain-i-Akbari, 1590, 63; Sen, Rept. Agri. Stat., Dacca, 1899, 25, 38, app. vi.–xii.; Imp. Dept. Agri., West Ind., Pamphl. Nos. 16–21.]

Garlic.

A. sativum, Linn.; Duthie, l.c. 34, pl. lxvi.; Mollison, l.c. 214. The GARLIC, lasan, rasiin, belloli, thum, sir, vullai-pându, etc., is cultivated throughout India, the cloves (or small bulbs) being planted out in October and the crop gathered in the beginning of the hot weather. As showing the extent to which the seasons of production vary, it is reported of Coimbatore district, South India, that planting commences in May–June and harvesting in September, being followed by a tobacco-crop, or if planted in December and gathered in March, it is followed by chokam. According to Mollison, a good crop will yield 8,000 to 10,000 lb. per acre and be worth Rs. 250 to the cultivator. As a Food, garlic is almost universally used in curries by the Natives, who also eat the bulbs almost daily. In Medicine it is regarded as a stimulant, expectorant, tonic, and employed as a remedy in bronchial affections and as an application for deafness. Dymock (Pharmacog. Ind., iii., 489) says that after intense fatigue a clove of garlic slowly chewed and swallowed acts as a very powerful restorative. The freshly expressed juice makes an excellent CEMENT for glass-ware. The imported Muscat-garlic is much used for pickling. [Cf. Taleef Shereef (Playfair, transl.), 1833, 147.]
THE ALOES OF INDIAN COMMERCE

Several species of ALOE and diverse methods of extracting, drying and preserving the juice result in the supply of the different known qualities of this drug. The following species may be specially mentioned as affording the major portions of the aloes of Indian commerce:

and possibly also the bulk of the Moka aloes imported from the Red Sea coast. This is prepared at the town of Jaferabad in Kathiawar by persons supposed to be of African descent. It is sold in the form of flat circular cakes almost black in colour, has a glassy fracture and yields a yellowish powder having a strong aloetic aroma. This, as also the imported Moka quality, constitutes the aloes most in demand in India.

A. Perryi, Baker, Bot. Mag., 6590. This is the Socotrino Aloes, and possibly also the Zanzibar Aloes of commerce, of which a fair amount is imported into Bombay, and after being assorted is re-exported again to Europe. [Cf. Mandelslo, Travels, 1639, 15.]

A. vera, Linn.; the Common or Barbados Aloes, or Curaçao Aloes. Several forms of this species have become completely naturalised in India, and that too from the hot, dry outer valleys of the N.W. Himalaya throughout the central tableland to Cape Comorin.

Both the aloe plant and aloe drug have Sanskrit and vernacular names attributed to them that would seem fairly ancient. The following may be specially quoted: For the Plant—ghí-kunwá, ghíra-kunwá, kunwá, koro-kanda, kundra, kalabanda, loka-sarú, etc. For the Drug—üloa, etiya, elto, yala, ma-
shábar, musumbá, kaloló, etc., etc. Sir William Jones calls it tarúni, saha, cumárd [As. Res., iv., 272].

Most scientific writers are agreed that although the aloe has been completely naturalised in India for a very long time it is not originally a native of the country. Of late, attempts have been made with comparative success to show that some at least of the species might provide an efficient substitute for the imported drug. Indian aloes seem first to have been mentioned by Garcia de Orta (1563, Coll., ii.) as prepared particularly in Cambay and Bengal. He adds that though Pliny and Dioscurides refer to the Indian aloes as the best, they were referring unconsciously to the re-export of the Socotrino product. Paulus Egíneta (Adams, trans., iii., 34) reviews the information possessed by the early Greeks, Romans and Arabsians, and might be consulted. The early Indian travelers such as Linschoten, Tavernier, Hove, etc., afford useful particulars, but greater details may be learned from Ainslie, Royle, Warring, etc. Rumphius (Herb. Amb., 1750, v., 272) mentions the use of aloes on the Coromandel Coast in the preparation of cement. [Cf. Acosta, Tract. de las Drogas, 1578, 191-211; Ligon, Hist. Barbados, 1657, 98; Rheedo, Hort. Mal., xi., t. 3; Kanny Lall Day, Indig. Drugs, Ind., 19; Taleef Shereef (Playfair, trans.), 1833, 138; Tschirch, Schweiz. Wochenschrift für Chem. und Pharm., 1902, No. 23 (attributes the aloes of the Cape to A. ferox); Johannes Klavoness, Studien Natal Uganda-Aloe, 1901; White and Humphrey, Pharmacop., 1901, 51-2; Ponder and Hooper, Mat. Med.; Bens, Southern Arabia, 1900, 381.]

The Indian Trade in aloes is not a very large one. The total imports come usually to something like 600 cwt. valued at a little under Rs. 20,000 (501 cwt., valued at Rs. 7,994 in 1906-7), a quotation that would seem to be about one-third less than that of 20 years ago. The total exports (including re-exports) would appear to average very nearly the same in quantity and value as the imports. The Indian foreign supply, drawn mainly from Africa and Arabia, and the exports of Indian-grown aloes go mainly from Bombay and Madras. In fact, the most striking modern feature seems to be the growth of an export from Madras to the Straits Settlements. The re-exports (foreign aloes exported) are made almost exclusively from Bombay and go mainly to the United Kingdom, the next largest demand being made by the Straits Settlements.
THE GREATER AND LESSER GALANGALS

ALPINIA, Linn.; Fl. Br. Ind., vi., 252; SCITAMINEA. A genus that contains some 40 species inhabiting the tropical and sub-tropical regions of Asia, Australia, and the Pacific Islands.

The two most important species are A. Galanga, Willd., and A. officinarum, Hance, which are considered separately below. A. Alpinga, Roxb. —taró or tartiko—a native of Bengal, Assam, Burma, Ceylon and the Konkan, has an aromatic rhizome which is used by the natives medicinally. It has been recently stated that the leaves and stem yield a fibre which might possibly be useful in paper-making, owing to its exceeding abundance. [Cf. Hooper, Rept. Labor. Ind. Mus., 1904—5, 28.] A. khutmainj, a supposed new species described by the late Dr. Moodeen Sheriff in 1869 [Cf. D.E.P., i., 194], is believed to be the same as A. officinarum, but owing to the continued uncertainty the latter species has been kept separate. A. Nutans, Roxb., the LightGalangal, is a native of the Eastern Archipelago, much cultivated in Indian gardens. The rhizome is used in place of the Greater or Java-Galangal, and is sometimes mixed with it or with ginger.

A. Galanga, Willd.; the Greater or Java-Galangal, the barkuljinj, mthakoljain, pera-rattai, pera-ratta, padagogyi, etc., is found throughout India from the foot of the Himalaya to Ceylon and Burma; distributed to the Malay Islands and widely cultivated.

It is mentioned by Marco Polo (A.D. 1290) as grown in Bengal, and by Varthema (1510) as found in Cambay. Garcia de Orta (1563) and Linschoten (1598) say that there are two sorts—one Chinese called "Lavandon," the other Javan and there called "Lanqnas." The latter, they say, was sown in Indian gardens. The rhizome of both species are mentioned and figured by Clusius (Hist. Exot. Pl., 1605, 211). The rhizome and the fruit (Galangal carthamin) are sold in the bazars, and the former is said to be used in the United Provinces in calico-printing. It seems probable that the Greater Galangal is only used medicinally as a substitute for the Lesser or Chinese Galangal. [Cf. Acosta, Tract. de las Drogas, 1578, 58; Kew Bull., 1891—5; 1892, 16—20; 1896, 233; Pharmacoeut. Journ., Jan. 31, 1891.]

A. officinarum, Hance; the Lesser Galangal, Alpinia chinensis of chemists, is commonly sold in the bazars as kulijnain or kolijain. Also called chot-panki-juv or chot-juljin, chitta-rattai, khusro-daru, etc.

It is a native of China from whence the rhizome is exported largely to India, and somewhat less than in former days to England. The principal demand for it is in Russia, though it is still an ingredient in certain old-fashioned English Medicines. In India it is considered a nervous tonic and an aphrodisiac.

It is not possible to distinguish between the Greater and Lesser Galangal in the Indian trade returns, but the collective imports have increased from 2,794 cwt., valued at Rs. 21,525 in 1899—1900, to 5,202 cwt., valued at Rs. 39,731 in 1902—3, though they have since declined to 3,818 cwt. in 1906—7, valued at Rs. 21,375. The collective exports also have fallen from 1,327 cwt., valued at Rs.12,255, in 1899—1900 to 393 cwt., at Rs. 3,476, in 1902—3. Since then, however, the exports have shown an increase—viz. to 1,245 cwt., valued at Rs. 12,249 in 1905—6. In 1906—7, however, they fell to 614 cwt. and Rs. 6,338. By far the largest increase is in the trade from China (Hongkong)—viz. from 692 cwt. in 1899-1900 to 3,290 cwt. in 1904—5, and 2,104 cwt. in 1906—7.

ALSTONIA SCHOLARIS, K. Br.; Fl. Br. Ind., iii., 642; Gamble, Man. Ind. Timbs., 483; Cooke, Fl. Pres. Bomb., ii., 132; APOTOCYANE. A tall evergreen tree of the moister regions of India, but nowhere very common. It affords the dita-bark of commerce, and is known in the vernacular as chatwan, chatium, lationj, satidna, pala, pala-garuda, rukatana, etc.

The bark is used in Medicine as an astringent tonic, anthelmintic, alterative and antiperiodic. It is a remedy in cases of chronic diarrhoea and advanced dysentery, as also of catarrhal fever and stomachic debility. Externally the milky juice is applied to foul ulcers and is also used with oil in earache. Dita-bark, an uncrystallisable substance obtained from the bark, and also a tincture of Alstonia, appear to be useful in cases where quinine produces distressing secondary symptoms. The Report of the Indian Indigenous Drugs Committee (i., 419—38) seems to show that the drug is useful in diarrhoea and dysentery, but
ALUM AND ALUMINIUM

that its effect as a febrifuge is not lasting (Pharmacog. Ind., ii., 386). The Timber, which is not durable but easily worked, is used for boxes, furniture, scabbards, coffins, etc., for blackboards (dusted with sand) in Burma, whence the name schorlaris, and, according to a correspondent of The Agricultural Bulletin of the Straits and Federated Malay States (1903, ii., 114), the young wood is employed in Borneo as a substitute for cork in bottle-stoppers (see Gutta-percha, p. 627).

ALTINGIA EXCELSA, Novonuia: Fl. Br. Ind., ii., 429; Gamble, Man. Ind. Timbs., 332; Brandis, Ind. Trees, 302; HAMAMELIDACEAE. Burmese storax, rasamala, sildras, jatuli, namlayok, etc. A lofty deciduous aromatic tree of Assam and Burma, Yunnan, Java, etc.

This, like the closely allied Liquidambar orientalis, Mill., of Asia Minor (the Liquid Storax), yields a fragrant balsam, known as nan-ta-yok in Burma, which is used in that country as a perfume, incense and medicine. The true Storax (Styrax Benzoin) is imported into Bombay, and is used all over India as a Medicine only by the Muhammadans and Hindus. The Burmese article to all intents and purposes is identical with the rasamala of Java, and is little if at all inferior to the resin of Asia Minor. Hooper (Agr. Ledy. 1904, No. 9) reviews all available information on this subject, and concludes by saying that his chemical investigations confirm those of Prof. A. Tschirch and Dr. L. van Hulloo viz. that while the Burmese storax (like the rasamala) differs in some respects from the true article, it might be pushed in trade as a good substitute. [Cf. Pharmacog. Ind. i., 593–8; Archiv. der Pharm., Sept. 1901, 239, 541–7; Journ. Chem. Soc. Indist., xx., 1122; Hooper, Rept. Labor. Ind. Mus., 1900–1, 18; 1904–5, 24–5.]

ALUM AND ALUMINIUM-ORE; Bauxite, Latereite, etc.; D.E.P., i., 201-4.
Holland, Rev. Min. Prod. Ind., in Rec. Geol. Surv. Ind., 1905, xxxii., 94; Oldham, Man. Econ. Geol. Ind., 303, 352; Ball, Man. Econ. Geol. Ind., 1904–5; Journ. Soc. Arts, 1903–4, lii., 145; Brough, Cantor Lect. Alum, phikari, phakiri, spakikari, shib, zák, patakri, kyankchin, etc., is prepared from alum-shale in several localities of Bihar, Kach and the Panjáb. It is also found, but not worked, in Upper Burma.

Alum appears at one time to have been very extensively imported into India from China, and the price on the Calcutta market in 1809–11 is quoted as 3½–6 sicea rupees per maund (Milburn, Or. Comm., 1813, ii., 498), but it is curious that there is no hint of any such trade in the E. India Co.'s records, at the beginning of the 17th century, although we learn that it was then an article of extensive trade with Japan, "for they cannot dye with sapanwood without it" (Foster, E.I.C. Letters, v., 7). The Indian production is very uncertain, probably not amounting in all to more than 1,000 tons yearly. Kalabagh on the banks of the Indus and Kotkil at the mouth of the Chichali pass, produce about 400 tons annually between them (Min. Rev., 1894–7, etc.). Mr. Holland says that the yield in 1898 was 750 tons, valued at £3,150, but in 1901 it fell to 98 and in 1902 was 112½ tons. No returns for 1903 were available. But the Indian alum is not so white as the imported mineral, being discoloured by impurities. The alum imported into India during the six years 1898–1903 averaged 69,296 cwt., valued at 3 lakhs of rupees. The actual figures for 1906–7 were 72,344 cwt., Rs. 3,19,407. The principal use is as a mordant in Dyeing, but it is also employed in Medicine, photography, etc., and in the purification of vinegar (see p. 1110).

Recently it has been discovered that many of the rusty-coloured laterite deposits which cover large areas in the Peninsula and Burma are identical with the substance known as bauxite, now the chief source of Alumínium. Like the original bauxite of Les Baux, these deposits were originally worked without
success as a source of iron. "It is difficult at present to fully estimate the value of this discovery, as a deposit of laterite, which ordinarily would be regarded as small and of little consequence, contains enough alumina in some of the instances examined to completely swamp the market of bauxite, of which the world's total production is at present little more than 110,000 tons a year. Without any disturbance of present prices, the aluminous laterites would hardly pay, at the ordinary rate for first-class bauxites of 21 to 22 shillings a ton, to mine for export to Europe and America, and they must consequently be utilised for the extraction of alumina on the spot, either for export as such, or for the manufacture of aluminium in the country. To prepare the alumina from the bauxite (or laterite) would, according to the most recent processes, require the use of caustic soda, which is not at present made in the country. But one of the latest successful processes for the manufacture of caustic soda involves the separation of chlorine (from which bleaching powder is prepared) by the electrolytic decomposition of dilute brine, and as both caustic soda and bleaching powder are now largely imported for use in paper-making, there would be a market for both, apart from the requirements of alumina manufacture."  

Aluminium Manufactures.—It is impossible to furnish actual statistical returns of the extent to which this metal has been introduced as an Indian industrial material. Mr. Chatterton, Principal of the Madras School of Arts, pioneered the new industry so very successfully that others were induced to engage in this trade and finally the school withdrew in favour of private enterprise, viz. The Indian Aluminium Co. at Madras, which purchased the Govt. Aluminium Dept. in the school. The Company employed 150 persons in 1901 and 356 in 1904. There are three other factories at Madras, but apparently of small importance. The impetus due to Chatterton's success would seem, however, to have given South India a hold on the aluminium trade that she is not likely to forgo. The imports of aluminium-ware must also be very considerable judging from the extent aluminium cooking-pots, water-bottles and other articles of that nature are now met with throughout India. (See Corundum, p. 428.)

There may be said to be two or perhaps three distinct groups of amaranths that are of economic value to the people of India. These are the species cultivated in gardens and mainly if not exclusively as Pot-herbs: second the wild species that are eaten as pot-herbs or Medicines: and third the forms cultivated in fields and exclusively so as edible Grains. The last mentioned are by far the most valuable and hence may be taken up in greater detail than the others. But in passing it may be observed that the Indian species of this genus seem to be sadly wanting careful study and revision. The limitations of scientific and vernacular names here adopted are given tentatively. Of the garden pot-herbs there are many varieties or recognisable races under each botanical species. These may be indicated as follows:—

Section A. Pot-herbs.

1. A. Blitum, Linn., var. oleraceus (sp. Linn.), a plant with small obtuse leaves cultivated mainly in sub-montane tracts. The leaves serve as a pot-herb and the seed as a grain (Rec. Bot. Surv. Ind., i., 169). This may be only a form of the following:—

2. A. gaughticus, Linn.; Agri. Ledg., 1904, No. 6, 63; Duthie and Fuller, Field and Garden Crops, iii., 17–8, pl. lxvii.; lalsag, chauleisag, etc. The vernacular names apply equally to the foregoing species. Roxburgh differentiated A. gaughticus proper from oleraceus, polygonus and other forms mentioned below as varieties, by the fact that it gave only one crop and was pulled and sent to market with the roots. Some forms, such as A. bicolor are grown as ornamental plants. Of the many varieties tuscaculos is used in curries, itidum as a pot-herb, and oleraceus (sp. Roxb.) as a substitute for asparagus. Then there may be mentioned polygonus (sp. Roxb., non Linn.) [cf. Long in Journ.
AMARANTUS

PANICULATUS

Grain

A. caudatus, Linn.; Fl. Br. Ind., iv., 718; Duthie, Field and Garden Crops, iii., 24, pl. lxviii.; A. cruentus, Willd., in Roxb., Fl. Ind., iii., 610. Love-lies-bleeding; the kedari chua, ramdana, etc.

This is fairly plentifully cultivated throughout the plains of India as a garden ornamental plant (and to some extent as a pot-herb also) much after the same fashion as its near allies, the Prince's Feather (A. hypochon-driacus); the Weeping-willow-leaved Amaranth (A. sativifolius); and the Cockscorn (Celosia cristata)—all great favourites with the Native gardeners. But A. caudatus in India takes a further and more direct economic position since it is cultivated by the hill tribes as a regular field crop, on account of its Grain, the ramdana. The seed is sown in May and June and the grain is harvested in October. In the plains of Northern, Western and Central India it is also occasionally seen as a cold-season crop being grown on the borders of fields. It is chiefly distinguished from the next species by the obtuse tips of the leaves and the long pendulous tails or spikes of the inflorescence.

A. paniculatus, Linn.; Fl. Br. Ind., iv., 718; Duthie, Field and Garden Crops, iii., 23, pl. lxviii.; A. frumentaceus, Ham., in Roxb., Fl. Ind., iii., 609; A. Anardana, Ham., in Wall., Cat.; and A. farinacea, Roxb., Herb. This appears to be the anardana of the early writers but is best known as chia, chuko, ganhar, māra, bāthu, etc.

Cultivated on the Himalaya from Kashmir to Sikkim between the altitudes of 3,000 and 10,000 feet; also on the hills of Central and South India and Burma, and on the plains of Northern, Western and Central India, as a cold-season crop. It is one of the most important sources of Food with the hill tribes of India, and there are both golden-yellow and bright purple conditions. The former is more frequent and seems therefore to be preferred; most fields, however, contain a few red plants among the yellow. It is an exceedingly ornamental crop; the hillsides, on account of the fields of this plant, become in autumn literally golden-yellow and purple. It is sown in May and June and reaped in October—November, but in the plains it is not ripe until February to March. (Madden, Edinb. Bot. Soc. Trans., 1858, v., 118.)

It is not possible to furnish information as to the total production of this grain. It is grown as a rule for local consumption and is hardly if ever exported. The grain has been analysed by Church (Food-Grains of Ind., 107–9) and the average of three samples gave the nutrient ratio at 1: 5:3 and the nutrient value 90. It has been estimated that one plant will produce 100,000 grains. Speaking of another sample, which Church attributed to A. gangeticus, but which may possibly have
been one of the many forms of the present species, he remarks: "The analysis shows that we have in these seeds a food in which the proportions, not merely of albuminoids to total starch plus the starch-equivalent of the oil, but also of the oil itself, are very nearly those of an ideal or standard ratio." Visitors to the hills of India are inclined to smile at people who live very largely upon these minute grains, but they might with advantage to themselves use this extremely wholesome article of diet.

This substance to a small extent is still procured from the ancient mines of Upper Burma (in the Hukong valley), but a fair amount of Baltic amber is regularly imported into India and Burma. It is used in native medicine, being often confused with ambergris, the word amber having been derived thereof. In Europe it is boiled in oil (rape or linseed) until it becomes transparent and ductile, when it is moulded into beads, broaches, mouthpieces for pipes, etc. Certain qualities are extensively made up as varnishes. In Upper Burma Dr. Anderson tells us (Mandalay to Mowmien, 1876, 202) that there were then only a few workers, and that the amber most prized is perfectly clear and of the colour of dark sherry. Amber is much in demand in Burma by the wealthier ladies, who wear cigar ear-holders of this material. Accurate returns for the production in Upper Burma are not available, but an estimate made by the Deputy Commissioner of Myitkyina gives the average annual output at about 51 cwt., valued at about Rs. 5,000. The Burmese material differs chemically and physically from the Prussian amber, the chief difference being the absence of succinic acid; it is distinguished by the special name "Burmite." It is harder and tougher than many other amber-like resins, and therefore more fit for carving and turning. [Cf. Barboza, *Coasts E. Africa and Malabar* (ed. Hakl. Soc.), 165; *Paulus Egineta* (Adams, transl.), iii., 129; Marco Polo (ed. Yule), ii., 341; Milburn, *Or. Comm.*, i., 61; Crawford, *Journ. to Ava*, 1834, ii., 206, etc.]

**AMBERGRIS;** a concretion formed in the intestine of the sperm-whale (*Physeter macrocephalus*). It is a substance often found floating in the sea on the coasts of India, Africa, and Brazil, and the whales are also hunted and killed to procure it. Is met with in the Indian bazars in the form of special preparations known as *abrir-amber, amber, or araba*.

It is a very light substance, highly inflammable, has a peculiar aromatic odour and almost completely volatile by heat. It is used as a medicine, the supply coming mainly from the Nicobar and other islands in the Indian Ocean. Though not of great value in modern commerce this substance at one time attracted much attention. It was unknown to the Greeks and Romans, but according to *Paulus Egineta* (Adams, Comment., iii., 426–6) was made known to pharmacy by the Arabs. Marco Polo (Travels (ed. Yule), ii., 341–2) and Clusius on Garcia de Orta (in *Hist. Exot. Pl.*, 1605, 147–9), also Ball on Garcia (Cott., iii., in *Proc. Roy. Ir. Acad.*, i. (3rd ser.), 390), Barbosa, etc., all allude to this substance, so that it has been associated with India for several centuries. Francis Pyard (Voy. E. Ind., etc., 1601 (ed. Hakl. Soc.), i., 229) states that in the Maldives the ambergris (called *gomen*, and when prepared *meuware*) thrown up on the coast formed part of the King's revenue. Jahangir (Memoirs (Price, transl.), 2–3) describes the way in which it was employed to perfume the throne. In Europe some time ago it was used as a flavouring material with food. By Milton it is alluded to as *grisamber* (Par. Reg., ii., 337). [Cf. Blanford, *Nat. Br. Ind.* (Mammalia), 571; Ainslie, *Mat. Ind.*, i., 15–7; *Trans. Med. and Phys. Soc. Bombay*, n.s., i., 149; xii., 172; Madras, *Man. Admin.*, i., 30; Baden Powell, *Pb. Prod.*, i., 190; Hunter, *Imp. Gaz. Nicobar*, x., 297; Birdwood and Foster, *E.I.C. First Letter Book*, 58, 81, 119, 128, 245–6, 258, 299; Foster, *English Factories*, 1618–21 (ed. 1900), 55; *Burma and Its People* (ed. Theobald), 1882, i., 445; *Journ. Chem. Indus.*, 1890, ix., 429; etc., etc.]
THE ELEPHANT’S FOOT—OL

AMOMUM SUBULATUM, Roxb.; Fl. Br. Ind., vi., 240; Madden, Edinb. Bot. Soc. Trans., 1858, v., 120; King, Journ. Linn. Soc., 1880, xvii., 3; Duthie and Fuller, Field and Garden Crops, iii., 35; Pharmacog. Ind., iii., 436; Scitamineæ. The Bengal or Nepal or winged Cardamom, sometimes also called Greater Cardamom, bari-ilachi, eicho, moté-veldóde, jātī-yelak-kāy, etc. Is most readily found in Calcutta but may be had at Bombay, and perhaps in the bazārs of most large towns. A herbaceous plant, native of Nepal.

The seeds yield a Medicine in the shape of an agreeable stimulating oil with an aromatic camphoraceous taste. It is considered carminative and stomachic, but this so-called Greater Cardamom is medicinally only a cheap substitute for the common or Malabar Cardamom (Elettaria Cardamomum, of which there is both a large and a small kind, see pp. 511–2). The seeds are also much used in the preparation of Sweetmeats owing to their cheapness (Rs. 12 per maund of 37½ lb., Pharmacog. Ind., l.c.). The present Cardamom is also used in the preparation of bhang-massāla (see Cannabis sativa, p. 258, and Ind. Hemp Drugs Rept., 1894, iv., 50, 152, etc.). The seeds of A. xanthioides, Wall. (tāycychi-dānē), are imported from Siam and Singapore and sold in the Indian bazārs. The smell and taste are said to be stronger than those of Elettaria Cardamomum but not so pleasant. [Cf. Sonnerat, Voy. aux Ind. Or. Planch., pl. 137. For A. aromaticum, Roxb., cf. Kew Rept., 1877, 27.]

AMORPHOPHALLUS CAMPANULATUS, Blume; Fl. Br. Ind., vi., 513; Pharmacog. Ind., iii., 546; Mollison, Textbook Ind. Agri., iii., 189–91; Aroideæ. Elephant’s Foot, zānim-kand, ol, surana, jangli-surān, karunāt-kīzhangu, kanda-godda, va, etc. A tuberous rooted herb found on the plains of India from the Panjāb to Bengal, the Deccan and Ceylon, cultivated in rich moist soils.

Sympanthus gymnandrus, Schott., an allied plant met with in the Deccan, is regarded by the Hindus as a kind of wild surana, and Sunromatum gutta-tum, Schott., a species of the plains of Upper India and the Konkan, ascending the Himalaya to 6,000 feet in altitude, has similar medicinal characteristics, but these are too unimportant to justify independent positions in this work. In Medicine the horns and also the seeds of Amorphophallus are used as external irritants to relieve rheumatic swellings. Confections of the tubers (corns) with treacle, aromatics and Plumbago-root are given in cases of piles and dyspepsia. One of the Sanskrit names of the plant is areogna—‘‘destroyer of piles.’’ The wild tubers peeled, cut into segments and dried by being strung, constitute the madan-mast of the shops. The cultivated cones are cooked and form a common article of Food with the poor. They are boiled like potatoes, cooked in curries and pickled or preserved.

Mollison says the crop is important chiefly in the Gujarāt and Baroda territory. He gives the accumulated cost of cultivation in the fourth year (Surat district) as Rs. 484 per acre and observes that the cultivation can accordingly be undertaken only by well-to-do persons. In Bengal the average crop under favourable circumstances is about 200–400 maunds per acre and the price about Rs. 2½ per maund, and Duthie and Fuller (Field and Garden Crops, iii., 6, pl. 69) say the bazār price at Saharanpur is 2 annas per seer (Rs. 5 per maund). The tubers are usually planted out in May to June, and in 12 months they are fit to be dug up. If properly cultivated each tuber will weigh from 2 to 10 lb., or as much as 40 lb. [Cf. Ann. Rept. Govt. Exper. Farm, Poona, Bomb., 1896, 15.]

ANACARDIUM OCCIDENTALE, Linn.; Fl. Br. Ind., ii., 20; Gamble, Man. Ind. Timbs., 214; Pharmacog. Ind., i., 389 and 545; Cooke, Fl. Pres. Bomb., i., 274; Agril. Ledg., 1899, No. 12, 146; Anacardia-ceæ. The Cashew-nut, kātū, hījī, bādam, mundiri, kotī, jīdi-mānīdi viṭṭu, jīdi-vāte, etc. A tree originally introduced from South America, but now established in the coast forests of India, especially in sandy places.

ANANAS SATIVA

Pine-apple

where it is often gregarious. In South India it is important in coast-dune reclamation.

The bark yields a Gum which is obnoxious to insects. The juice which issues from incisions in the bark is used as an indelible marking-ink. The bark and the pericarp yield an Oil (called dák), which is occasionally employed for fishing-nets. Two Oils are obtainable from this plant: (1) a light-yellow from the pressed kernels, of which the finest quality is equal to almond oil; and (2) "Cardole," obtained from the shell of the nut—an acrid and powerful fluid efficacious for preserving carved wood, books, etc., against white ants. It is used as a rubefacient and vesicant Medicine. The spirit distilled from the juice of the fruit and sold when redistilled at about Rs. 1₃ per gallon, is a useful stimulant and the fruit itself has antiscorbutic properties. The seeds, known as Cashew-nuts, are usually eaten roasted and are made into confectionery with sugar. The fruit-pedicels are also eaten. The Timber (weight 30 to 38 lb. per cubic foot) is used for packing-cases and for boat-building and charcoal. Cashew-nuts are imported into Bombay from Goa in very considerable quantities. The kernels are valued at about Rs. 1₃ per cwt. [Cf. Garcia de Orta, 1563, Coll., v.; Acosta, Tract. de las Drogas, 1578, 232; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), 1598, ii., 127; Acosta, 1598, in Clusius, Exot. Pl., 1605, 272; Garcia de Orta in Clusius, Exot. Pl., 1605, 198; Boym, Fl. Sin., 1656, C.; Milburn, Or. Comm., 1813, i., 273; etc., etc.]

ANANAS SATIVA, Schult. ; Bromeliaceae.

Shortly after the discovery of America the Pine-apple appears to have been dispersed rapidly over the world and acclimatised in most tropical countries. The Spaniards called it Pínas because of its resemblance to the pine-cone, but the Portuguese adapted to their own tongue its Brazilian name Nanas and called it Ananas, a word which in some form or other has accompanied the plant throughout the world. In most of the languages of India it bears names clearly derived from the Brazilian, such as anánas, anádash, anáras, anáshappazham, na-ndt, anásá, etc. Or it is called Foreign Screwpine, European Jack Fruit, etc.—all modern names. There are no names for it in any of the classic languages of Europe, Asia, Arabia or Egypt.

History.—Oviedo (Hist. de las Ind., 1548 (ed. 1853), iii., 290-4) described the plant as grown in the West Indies and on the American mainland, and Christopher Acosta (in Clusius, Hist. Exot. Pl., 1605, 284) speaks of it as plentiful in India. He mentions a wild form in the Deccan called gueura, which suggests a confusion with Pandanus odoratissimus, and it is curious that Abul Fazl (Ain-i-Akbari (Blochmann, transl.), 83) should contrast the leaves of the kevrah (Pandanus) with the maize—a plant then only recently introduced into India. Maregraf (in Piso, Ind. Utri re Nat. et Med., 1658) mentions the pine-apple in Brazil, and Hernandez (1651) in Haiti and Mexico. It is figured and described by most botanists of the 16th to 18th centuries, e.g. J. Bauhin (1651), Boym (Fl. Sin., 1656), Ligon (Hist. Barbados, 1657), Bontius (in Piso, i.e. 1658), Rheede (Hort. Mal., 1692, xi. tt. 1-2), Merian (Insect. Surinam, 1705, tt. 1-2), Rumphius (Herb. Amb., 1750, v., 228, etc., etc. Boym speaks of it as brought from India to China. Rheede (confirming Acosta) declares it to have been introduced by the Portuguese, but less than a century later it had become so common as to be considered indigenous by Rumphius. Marco Polo naturally says nothing of it, and the reference usually given to Garcia de Orta is properly a note by Clusius contrasting Garcia’s description of the Mango with Oviedo’s description of the pine-apple. It is mentioned prominently by Linschoten, Pyrard, Bernier, Herbert and other travellers, and Jahangir (Memoirs (Price, transl.), 13-4) alludes to its introduction, but the Emperor Baber (1519) does not include it in his list of the fruits of Hindustan. Finally in 1800, Buchanan-Hamilton wrote that it was regarded as the fourth most important fruit in Dinajpur. [Cf. Herbert, Travels, 1677, 334; Turner, Acc. Emb. Tibet, 1800, 13-5; Talleef Shereef (Playfair, transl.), 1833, 17; As. Journ., 1819, vii., 264; Watson, Journ. As. Soc., Beng., 1834, iii., 27; Bennett, Wanderings N.-S. Wales, 1834, ii., 208-9; Logan, Pina Cloth, Journ. Ind. Archi., 1848, 528; De Candolle, Orig. Cult. Plants, 1884, 311-2; Blechydend, 66]
CULTIVATION FOR FRUIT

Cultivation for Fruit.—The English hot-house pine-apples are often spoken of as much superior in flavour to those grown in tropical countries. The fruit appears to have been first cultivated in Europe at Leyden in 1650, and the first pine-apple grown in England was raised in the Duchess of Cleveland’s hot-house at Downey Court and presented by her gardener (Mr. John Rose) to King Charles the Second some time before 1672—the date at which Rose became the Royal gardener. [Cf. Murray, Hist. Roy. Hort. Soc., 1863, 4 and pl.] With the modern facilities of rapid transport to Europe and America, large supplies of the fruit have recently reached these continents from the West Indies, from Madeira and from the Canary Islands. This has led to a decline in hot-house cultivation, to an immensely increased supply and consequent great reduction in price, and has given birth to a highly lucrative new planting industry in all tropical countries situate within practical access of the European and American markets.

Much attention has recently been given to the study of the varieties and races of pine-apple, as also to the methods of cultivation and markets of supply and demand. In India, while the plant is extremely abundant as a fruit grown in gardens and in some localities has even become completely acclimatised, little or no effort has been put forth either to improve the quality or to develop, on a commercial basis, the industry of pine-apple growing, which it would appear might be originated with advantage to India and profit to those concerned.

Climates and Localities.—The pine-apple was first introduced on the West coast of India, but rapidly crossed the country and attained its greatest perfection in the Eastern Peninsula. From Calcutta through Eastern and Northern Bengal to Assam and Burma may be said to be its best Indian habitat, though it also occurs here and there throughout India, and is very abundant on the Western Ghats, especially on their southern extremity. Speaking of Bengal, Thevenot (Travels, Levant, Indostan, etc., 1687, pt. iii., 68) mentions the pine-apple growing as large as a melon. In Assam (more particularly the Khasia hills) it might also be said to exist as a wild plant and yields a profusion of most delicious fruit. In Tenasserim it has become so completely acclimatised and is so abundant that, as observed by Dr. Helfer many years ago, a boat-load of fruit might be purchased in June or July for one rupee. It is thus not by any means exclusively on the littoral tracts, nor within the inundated areas of India, that the pine-apple has attained its greatest perfection, but rather considerably inland and on the dry, sandy loams of the lower hills and terai, though in tracts of country subject to a high annual rainfall. A warm, moist atmosphere and a well-drained sandy loam would appear, therefore, to be the essentials for success with pine-apple.

Varieties.—Indian writers allude to only one or two recognisable varieties. Firminiger, for example, speaks of the Sylhet or komalh pine—a small fruit with very few but exceptionally large eyes; and the Dacca—a remarkably smooth pine with white eyes. He then discusses imported
THE PINE-APPLE

pines, such as the Ceylon, Penang and several English hot-house forms, occasionally met with in the fruit gardens of Europeans. Practically, therefore, little or nothing has been published as to the cultivated races of the plant met with in India.

Soils, Manures, etc.—Nicholls says the best soil is a sandy loam with good drainage, and next come the free sands and gravels. Clay of all kinds and badly drained lands are unsuited. A good proportion of lime is advantageous, but animal manure, unless perfectly rotted, should not be put near the plants as it is inimical to their growth. Speede, one of the earliest of Indian practical writers, on the other hand, affirms that no soil can be too rich and no manure too strong for pine-apples. Woodrow recommends dried salt-fish as a manure, and urges that during the first opportunity of dry weather in the monsoons the manure should be dug into the soil. But as opposed to such views, and in support of the West Indian experience, Firminger tells us that he found the plants to rot and perish from an oversupply of manure. Further that a soil thoroughly lightened with leaf-mould, well-decayed cow-dung and sand, may be mentioned as that on which pine-apples will thrive to perfection. He then urges that shade of any kind is to be avoided, as it will increase the size of the fruit but greatly injure its flavour. Repeated watering, as the fruit forms, is essential. Firminger further urges, as of great importance, that the plants should be removed after comparatively short intervals to new soils. On this subject Nicholls remarks that after three or four years the plants show signs of exhaustion, and they must in that case be up-rooted and the land prepared for fresh stock.

Propagation and Seasons.—When the fruit has formed, numerous suckers will be found around the parent stem. These are preferably selected for propagation, though of course plants may be raised from the crown of leaves taken from the fruit, and even from the black seeds often found within the fruit itself. In the West Indies it is stated that in lining an estate the distances apart at which the suckers are to be planted should not be less than 3 feet, which would give nearly 5,000 plants to the acre. Nicholls adds, however, that "a better plan would be to line out the land in rows 6 feet apart, and to plant the suckers at a distance of 3 feet in the rows—this would allow nearly 2,500 plants to the acre; and after the first crop a few of the suckers, say four to each plant, could be left, and then this would give nearly 10,000 fruits for the second crop." It is most important to have fairly large spaces between the rows, since the plants being spiny the necessary room for working the land has to be provided. Moreover, after uprooting and preparing the land for re-lining it is possible to set the new plants on the interspaces not occupied by the former crop, and thus to continue cultivation on the same land very nearly indefinitely.

The fruit comes into season in the West Indies in from eight to nine months from the time of planting. Firminger says that for the Lower Provinces of India the proper season for planting out pine-apple is in August. The plant flowers in February and March and ripens its fruits in July to August, after which, in September and October, it makes its perfect growth. It sometimes happens, however, that it breaks into flower during the latter months and produces fruit in the cold season—most undesirable condition, since without heat the fruit cannot ripen and is accordingly acid and uneatable. On the other hand, Woodrow, writing
of the Bombay Presidency, says that strong suckers may be planted between January and March and watered until roots are formed.

**Packing.**—The fruit should be cut off with a sharp knife through the middle of the stalk and a little before it is fully ripe. In dispatching to a distance each fruit should be wrapped in straw or paper, and deposited if possible in a separate compartment made for itself, or at most a compartment for two or three fruits. When either bruised or over-ripe, fermentation takes place and the entire consignment may be ruined through the presence of one fermenting fruit.

**Production of Fibre.**—The leaves afford a superior fibre, which in the Philippines is woven into a beautiful fabric called *pina* (or *pigna* = Spanish for a cone) or *batiste d'ananas*, a fabric resembling the finest muslin. In the Rangpur district, Northern Bengal, the fibre is in considerable demand for the string said to be used by the shoemakers. It is also employed for necklaces in the Southern Maratha country (Goa). Jenkins drew attention to the Khasia pine-apple fibre in 1836 (*Trans. Agr.-Hort. Soc.,* 1867, iii., 137), and Wallich purchased, on the Khasia hills in that year, a bag made of the fibre. Royle speaks of supplies of the fibre obtained from Madras. It will thus be seen that the fibre is by no means unknown in India, though little or no progress has been attained in the establishment of a commercial supply. In 1887 Mr. Weynton read a paper before the East Indian Association on the commercial prospects of Assam, in which he made special reference to Sylhet as a country in which pine-apple fruit, fibre and alcohol might be produced. Recently Sir J. Buckingham, then of Anguri, Assam, furnished the Reporter on Economic Products with a sample of the fibre. This was forwarded to the Imperial Institute, London, for opinion and valuation. The late Sir F. A. Abel furnished in reply a most encouraging report, which will be found in *The Agricultural Ledger* (1898, No. 11). The fibre was found to be fully up to the quality of any hitherto seen in London, and it was thought would probably fetch £20 to £25 per ton.

For particulars regarding the method of separation of fibre, the machinery employed and the yield obtained in America and other countries, the reader must consult the publications enumerated. Though much advantage might be expected to accrue to India from the organisation of a pine-apple fruit and fibre industry, the fact that so little interest is taken in the subject precludes more detailed treatment in this work.

**Minor Uses.**—In conclusion it may be added that the minor uses of the pine-apple, such as its reputed medicinal properties, the prospects of an industry in the manufacture of alcoholic or other beverages from the juice, also vinegar (see p. 1109), as well as the industrial utilisation of the plant, have been purposely excluded from consideration.

**ANDROGRAPHIS PANICULATA, Nees; Fl. Br. Ind., iv., 501; Pharmacog. Ind., iii., 46; Acanthaceae.** The Creat, kiryát, kalmeg, olen-kitaita, shirat-kuchhi, nela-veemu, nila-veppa, nela-bevinagida, kiryato, etc. An annual bitter shrub common throughout the plains of India, from Lucknow to Assam and Ceylon, also cultivated in gardens.

This forms the principal ingredient of a household medicine called *alui*, which is extensively used in Bengal. The expressed juice of the leaves with certain spices, such as cardamoms, etc., dried in the sun, is made into little globules and given to infants to relieve griping, etc. The roots and leaves are febrifuge, stomachic, tonic, alterative and anthelmintic. The drug has been

SYNONMY OF THE GRASS-OILS

D.E.P., i., 241-52.

ADROPAGON, Linn.; Fl. Br. Ind., vii., 164-210. A genus of Grasses (Gramineae) by botanical writers usually referred to several sub-genera. Sir J. D. Hooker (Fl. Br. Ind.) has, for example, accepted eleven, but Dr. Alfred Barton Rendle, in the Catalogue of Welwitsch's African Plants, gives only six (which practically correspond to as many in the Flora of British India), while he restores 

Cymbopogon, Heteropogon, Sorghum and Vetiveria to independent positions.

In point of botanical structure there is perhaps little justification for the separation of these four genera, but as a matter of expediency (more especially from the standpoint of economic botany) it is most desirable that Andropogon should be broken up into a few independent groups or genera. This view was taken when the original edition of the Dictionary was penned, and it is believed the majority of botanists, including Hooker himself, would not seriously oppose the four genera named being treated as distinct from Andropogon. He has in fact (Handbook Fl. Ceylon, pt. v., 228) admitted that some such view will have to "be eventually adopted." I have, accordingly, resolved to assert the available economic information regarding these plants as follows:—

8. Andropogon Nardus, Linn.; see Cymbopogon Nardus, Rendle (p. 455). [Cf. Stapf, Lc. 354-5.]

9. Andropogon odoratus, Lsb., in Journ. Bomb. Nat. Hist. Soc., 1889, iv., 123 and t.; 1891, vi., 168, 203; also Bomb. Grasses, 1896, 70; Fl. Br. Ind., viii., 177; Stapf, Lc. 363. This sweetly scented grass, Mrs. Lisboa says, bears the following vernacular names—vaidia-gavat, usad han, bhos, tambrut. It is common at Lanowli, Poona, etc., and at the end of the rains gives a purple colour to the countryside. The authors of the Pharmacographia Indica (iii., 370-1) observe: "We have distilled the grass and obtained from it an essential oil, having at first an odour recalling that of cassia and rosemary, but afterwards a strong persistent odour of oil of cassis. Messrs. Schimmel & Co. noticed the odour of pine-needle oil in this sample, and found the sp. gr. to be 0'945..." "The yield of oil from the grass was equal to that obtained from A. Schoenanthus; it had a deep sherry colour, a sp. gr. of 0'931 compared to an equal volume of water at 84° F." [Cf. Gildemeister and Hoffmann, Volatile Oils, 290.]

ANILINE AND ALIZARINE (see Coal Tar, p. 344).

D.E.P., i., 256-8.

ANOGIESSUS LATIFOLIA, Wall.; Fl. Br. Ind., ii., 450; Gamble, Man. Ind. Timb., 346; Combretacee. The dhaur, dhauri, dhavada, hesel, bákti, arma, vellay naga, chiriman, etc. A large deciduous
THE CUSTARD-APPLE

Dhauram Gum is used in calico-printing and has been suggested as likely to be useful to dyers in England (Journ. Chem. Soc. Industr., Dec., 31, 1887, 79). It is largely exported, and constitutes the bulk of the Gum Ghati sold in Bombay (see Acacia, pp. 15, 17). [Cf. Hooper, Edible Gums, Rept. Labor. Ind. Mus., 1894-5, 23.]
The leaves yield a black dye and a tan. Hummel (Select. Rec. Govt. Ind., 1888-9, 93) valued the leaves for tanning purposes at 4s. 2½d. per cwt. (about one-third of the relative value of dindir). A tanning extract has been prepared from the bark by Hooper, containing 43.8% of a tannin. The tannin is strong and tough, but splits in seasoning and will not stand damp. It is used for axe-handles, axles, etc., also in furniture-making and ship-building, and has been recommended for railway sleepers. It gives a good fuel and charcoal. The white-wax insect (Ceroplastes ceriferus) has been reported as found on this tree. Other two species of economic interest are—A. acuminata. Well, shakuda, panchi, etc., met with in Bengal, South India and Burma, which yields a poor timber; A. pendula, Wall, dhaou, dhaouka, etc., a small gregarious tree of the dry forests of Rajputana and Bandelkhand, which coppices well and yields a timber much like that of A. latifolia.

ANONA SQUAMOSA, Linn., and A. RETICULATA, Linn.; Fl. Br. Ind., i., 78; Pharmacog. Ind., i., 44; ANONACEÆ.
The former is the Custard-apple of Anglo-Indians, Sweet-sop or Sugar-apple (West Indies and America), sharijou, sitaphal, ata, loma, sitdi-palam, situi-punda, anza, duranjii, etc. A small tree native of tropical America but much cultivated in India. In Central and Western India it occurs wild and so abundantly as almost to constitute forests. The latter is the Bullock’s Heart, or ramphal, ranamba, which yields an inferior fruit sometimes eaten.
The bark affords an inferior fibre and the fruit, bark, leaves and roots are used in medicine, the latter being considered a drastic purgative. The crushed leaves are applied to the nostrils of women in hysterical or fainting fits. Dymock informs us that the seeds yield an oil and three resins; the latter appear to be the acid principles and are useful as insecticides. The same quality is ascribed to the leaves and immature fruits. The fruits are eaten by both natives and Europeans, and in the West Indies a kind of cider is made from them. The fruits of the wild plant have proved useful in famine. The cultivation is said to be simple. The seeds, obtained fresh from the fruit, are sown in pots about the middle of February. The seedlings are transplanted into holes 3 feet deep by 3 feet diameter, which have been filled with cow-manure, old mortar and garden soil in equal parts. The trees should be pruned and re-manured every March or April and well watered until the rains set in (J. H. Dives, Ind. Gard., Feb. 23, 1899). The Custard-apple is in season in Bengal during the greater part of the rainy and cold months (Firminger), and constitutes one of the chief fruits of that season. Another species, the Chirimoya of Peru (A. cherimolla, Miller), is cultivated in parts of Burma for the fruit, and it appears to do well [Cf. Land Rec. Admin. Rept., Rangoon, 1904, 18.]

ANTIARIS TOXICARIA, Lesch.; Fl. Br. Ind., v., 537; Gamble, Man. Ind. Timbs., 651; Urticaceæ. The Upas Tree, jasind, karvet, alli, jazigir, aranjii, hnyaseik, etc. A gigantic tree of the evergreen forests in Burma, the Western Ghats and Ceylon.

Very full accounts of the legendary attributes of this tree and of the investigations into the subject may be found in the above-named works, and also in the Pharmacographia Indica (iii., 348-55), Yule and Burnell (Anglo-Ind. Gloss., Hobson-Jobson, 952-9), and the Kew Bulletins for February, October and November, 1891. The tree exudes a white resin used for poisoning arrows. [Cf. Lewin, Die Pflanzen, 1894, pt. iii., 301, etc.] The inner bark gives a fibre which makes strong cordage. The Natives strip the bark into large pieces, soak them in water and beat them to obtain the white fibre. In Western India the tree is known as the “Sacking-tree,” because the tough bark is stripped off whole from branches or young trees to form rice-sacks, a section of the stem being left to serve as a bottom to each sack. The seeds are said to be used in

THE CALAMBAČ OR EAGLE-WOOD

Antimony-sulphide (stibnite) occurs at Shigri in Lahoul, also in the Jhelum district of the Panjáb, and in Tenasserim of Burma. Large quantities of the ore, containing gold, have also been discovered in the Amherst district of Burma. Natives do not seem to utilise this metal as an alloy. Its chief use is in the manufacture of type-metal. It is employed by the ladies as a cosmetic, but much of the antimony sold for that purpose is really \textit{galona} imported from Kabul and Bokhára, which is often confused with antimony.

\textbf{APIM GRAVEOLENS,} \textit{Linn. ; Fl. Br. Ind.}, ii., 679; \textbf{UMBELLIFERÆ.} Celery, \textit{ajnád, chanú, ajwán-kaputa, karaf}, etc.; commonly called \textit{salerí} in Indian bázár.

A glabrous herb native of England and other parts of Europe, and widely distributed—\textit{e.g.} to North Africa and the shores of New Zealand. It is cultivated in different parts of India during the cold weather, chiefly in gardens near towns for the use of the European population. It is also cultivated in Bengal for its seed and in the Panjáb for its root. In \textit{Medicine} the officinal root is considered alterative and diuretic, and the seeds are given as stimulant and cordial. Cooked celery is said to be useful in rheumatism. The seed is eaten as a \textit{Spice} by the Natives, and the blanched stems and leaf-stalks by Europeans. In the wild state it is, to a certain degree, poisonous. [\textit{Cf.} Forster, \textit{Pl. Esc.}, 1786, 67; \textit{Paulus Ægineta} (Adams, Comment.), iii., 106; \textit{Pharmacog. Ind.}, ii., 122–4; \textit{Queensland Agri. Journ.}, 1903, xiii., 257; U.S. Dept. Agri., \textit{Farmer's Bull.}, 1902, No. 148.]

\textbf{AQUILARIA AGALLOCHA,} Roxb.; \textit{Fl. Br. Ind.}, v., 199–200; Gamble, \textit{Man. Ind. Timbs.}, 579; \textit{Pharmacog. Ind.}, iii., 217; Brandis, \textit{Ind. Trees}, 546; \textit{ThymeLæaceæ.} Calambarc, Aloe- or Eagle-wood, the Aloes or Lignum Aloe of the Scriptures, \textit{agar, ugar, ugal, úd, sasi, akýáu, kóyu, garu}, etc. The Sanskrit \textit{agaru} (a privative, and \textit{garu} heavy—a name given to it from the circumstance that it does not float on water) is the root from which most of its vernacular names have been derived. \textit{Laghu} or \textit{lauha}, another Sanskrit and Pali synonym, is supposed by some to be the origin of the expression Aloe-wood—and might therefore be accepted as denoting a light form that would float on water.

It is a large evergreen tree of the Bhutan Himalaya, Assam, Khasia hills, Eastern Bengal and Martaban hills (Burma). It attains a height of 60 or 70 or 100 feet and a girth of 5 to 8 feet. It is fit to be cut down for \textit{agar} collecting at 20 years, but some authors consider it not mature until 50 or 60 years. Another species, \textit{A. mutlicellis}, \textit{Lamk.}, is supposed to be the Eagle-wood of Malacca and of Tenasserim.

Habitat.

\textbf{Perfumery.}

A review of the recent information collected by the Reporter on Economic Products (written by Hooper) will be found in \textit{The Agricultural Ledger} (1904, No. 1). The wood in its ordinary state is not of much value, being pale in colour, light and inodorous. But under certain conditions a change takes place in both trunk and branches, the wood becoming gorged with a dark resinous, aromatic juice, which gives it a greater specific gravity. The portions thus impregnated are collected and constitute the drug called \textit{agar}, which is esteemed in proportion as it abounds in resinous matter. In no other part of the tree is this fragrant resin deposited. There is no external mark by which to recognise good from bad trees; they have to be cut down to discover the resin, which is only rich in one out of twelve. The average yield of a mature tree is 6 to 8 lb., and an exceptionally good tree may afford as much as Rs. 300 worth of \textit{agar}. It is
difficult to decide what is the predisposing cause of the secretion of this oleo-resin, but the majority of forest officers are of opinion that it is usually, if not always, found where some former injury has been received. The old tradition mentioned in the Ain-i-Akbari (Blochmann, transl., 80), that the branches were lopped off and buried in the ground in order to cause the formation of the resin, has been completely exploded by modern research.

The Drug occurs in pieces of extremely irregular shape and size. The largest rarely exceeds a pound in weight, while some of excellent quality is met with as small chips or splinters. The lighter portion of wood called doom is the cheapest and is sold for Rs. 1 to Rs. 3 a seer, the black or brownish-black is the true agar of commerce and is called shurkee; it is worth from Rs. 10 to Rs. 20 a seer. The Ain-i-Akbari (i.e. 81) gives full directions for the distillate called chuwak, used in perfumery.

From ancient times agar has been used all over the East on account of its perfume and its supposed medicinal qualities. It is alluded to repeatedly in The Bowser Manuscript as aguru (Hoernle, transl., 21, 23, 104), which may be described as a medical treatise which dates from the 5th century. It is to-day employed largely in China, and utilised as incense and in the manufacture of joss-sticks. It is met with in most Eastern bazars, including those in Syria, where Hanbury found it for sale. In Sylhet a certain quantity is collected each year for the sake of extracting from it a sort of essential oil (agar-attar), which is considered as costly as attar of roses. In Bombay agar-batia or agar-lights are made of various sweet-smelling substances of which aloes-wood is the chief ingredient. These sticks are burned as incense or are used to perfume apartments. Marco Polo, Garcia de Orta, Varchema, Barbosa, Linschoten, Herbert and many other of the early European visitors to India allude to Eagle- or Calambac-wood, although in some cases it may be questionable whether it is the present plant. They one and all attribute, however, the finest quality to Cambodia, or to some part of the Malay Peninsula or Archipelago. Prebble, speaking of the present traffic, says the best quality, imported into Bombay, comes from Bankok. He mentions two well-known trade qualities the gajali (A. Agallocha) and the mawardi (A. malaccensis). Do these correspond to the gharki and mandal of the early writers? To A. malaccensis has very possibly to be referred the jangli agar and the Singapore agar of the Bombay market. But the Sylhet agar holds an honourable position. Various qualities are mentioned by most of the early writers such as Abul Fazl (in the Ain-i-Akbar, i.e.). Roxburgh wrote a long and highly instructive article on A. Agallocha, which was followed by an article by Henry Thomas Cebrook. These two papers give practically all that is known of the Indian Agar-wood (Trans. Linn. Soc., 1855, xxi., 199-206, pl. 21). Rumphius some time previously described two kinds of true and two kinds of false aloes-wood. The first of the true forms he says was the kilam of the Chinese and calambas of the Malays, and was obtained from Cambodia; the second true form was the garo or garu (a word that may be accepted as the Malayan variant of agaru)—both are possibly varieties of A. malaccensis. According to the authors of the Pharmacographia Indica the best medicinal quality is the gharki ud from Sylhet. [Cf. Paulus Egineta (Adams, transl.), ii., 18; Pyrard, Voy. E. Ind., 1601 (ed. Hakl. Soc.), i., 335; ii., 360; Clusius, Hist. Exot. Pl., 1605, 172; Barbosa, Coasts E. Africa and Malabar (ed. Hakl. Soc.), 204; Herbert, Travels, 1677, 333; Milburn, Or. Comm., 1813, ii., 312-3; Birdwood and Foster, E.I.C. First Letter Book, 337, 340, 406, 410, 427-8; Buchanan-Hamilton, Comment. on Herb. Amb., in Mem. Wern. Soc., 1832, vi., 276; Taylor, Topog. Stat. Dacca, 250; Hooker, Him. Journ. (ed. 1854), ii., 328; Moeller, in Pharm. Post., 1896, 1897; Holmes, Mus. Rept., Pharm. Soc. Gt. Brit., 1895-1902, 39-45]. The last-mentioned work is an exceedingly instructive review of Moeller's results, and republishes his illustrations of microscopic sections of the various forms of the wood, etc., etc.

Mr. E. A. Gait, who was director of Land Records and Agriculture, Assam, in 1894, drew attention to the fact that the bark of Aquilaria Agallocha affords a Natural Paper that appears to have been used for ages by the aboriginal tribes of Assam, like the birch bark of the Aryans. The information then collected will be found in a paper on the Abstract of Contents of one of the Assam Puthis (Journ. As. Sac., Beng., 1894, lxiii, pt. 1, No. 9), from which the following may be given: "Although the bark was widely used as a writing-material throughout Assam, prior to the introduction of paper, its employment as such seems to have escaped notice. Brahmins and Goshais in the habit of performing religious ceremonies in the houses of their disciples or in the presence
of the gods in the temple, consider it impure to have their mantras written on mill-made paper and, therefore, retain the custom of writing their sacred books on the prepared bark of the sachi tree." Loureiro says that the common paper of the Cochín-Chinese is made of the bark of A. mutacecaasia. Besides forming the leaves of books the bark is sometimes used as covers for binding books. The Nagas and other hill tribes prepare strips of the bark by which they hang their baskets on the forehead. The Flax is employed for making ropes, but it is not very lasting.

Taggar Wood, according to Holmes, is a dark-brown timber exported from Madagasca to Zanzibar, and thence to Bombay, but Colebrook so long ago as 1851 spoke of it as a wood sold in Bengal to the unwarv for agar. Dick, in a letter to Roxburgh, gave tuggar as the Bengali name for a wood found in the hills near Sylhet, a geographical reference that might suggest Eucanevilia Agulnca, a plant known by various Indian names such as thilla, tilai, and tayaw kayaw in Burma, and tata kiriya in Ceylon. So far as Roxburgh was aware, however, it did not afford any form of agar-wood. Mason speaks of it as Blinding Aloe, and by others it is called the Tiger's Milk Tree.

ARACHIS HYPOGÆA, Linn.; Fl. Br. Ind., ii., 161; Cooke, Fl. Pres. Bomb., i., 408; De Candolle, Orig. Cult. Plants (Engl. ed.), 411; Mollison, Textbook Ind. Agri., iii., 102; Agri. Ledg., 1893, No. 15; 1899, No. 12, 147; 1900, No. 1; Burkhill, Kew Bull., 1901, 175–200; Leguminosæ. The Ground-nut, Earth-nut, Pea-nut, Monkey-nut, Pindar, Katjang, Pistache de terre, Manila-nut, Chinese-nut, and in the vernaculars of India (which for the most part are translations of one or other of the names mentioned), mung-phali, bhui-mung, bhui-singh, bhui-chana, villiyoty-(biláti) mung, chini-badam, Manila-kotai, veru sangalu, myeleh, mibe, etc. There are thus no Indian names that would imply an ancient knowledge of the plant.

This is undoubtedly, therefore, another of the very long list of plants introduced into India in comparatively recent times. There would seem little room for doubt that though nowadays extensively cultivated in all tropical countries it is originally a native of Brazil. But there would appear to have been successive and possibly independent efforts to introduce it into India. It may have come from China to Bengal (hence the name Chini-badam); from Manila to South India (Manila-kotai), and from Africa and very possibly direct from Brazil as well, to Western India.

History.—It does not seem necessary to quote all the passages that support these conclusions. Perhaps one of the earliest direct references to this plant, as grown in India, occurs in Buchanan-Hamilton’s Travels through Mysore, etc., published originally in 1800. In the Report of South Arcot (1850–1) mention is made of 4,000 acres being under the crop. The nut made its appearance in Europe as a commercial product about the year 1840. The Indian modern trade may be said to date from a Resolution of the Government of India published in November 1877, and a subsequent Resolution of August 1879. In consequence of the replies to the latter, J. E. O’Conor wrote a report on The Cultivation of Ground-nut in India (Journ. Agri.-Hort. Soc. Ind., 1879, n.s., vi., 87–98). After detailing the facts ascertained regarding the extent of cultivation and other useful and interesting particulars, he drew attention tersely to the present position and future prospects of the Indian foreign trade in the nut. The exports were in 1878–9, 25,472 cwt., "or little more than 1 per cent. of the imports into France. The question now is, whether India should be content to leave France to draw all her supplies of this valuable food-stuff and commercial product from Africa or whether she should not enter actively into competition for at any rate a substantial portion of the trade " (i.e. 97).

Space cannot be afforded in this work to deal very fully with the subject of the ground-nut. It may, however, be useful to enumerate, in sequence of date, some of the more important publications in addition to those mentioned in the Dictionary. (Cf. Dymock, Mat. Med. Western Ind., 1884, 674; Church, Food-Grains of India, 1886, 127; Pharmacog. Ind., 1890, 74.)
A CHANGE IN AREA OF PRODUCTION

CULTIVATION.—Although grown here and there all over India as a garden and even an occasional field crop, it is only in Madras and Bombay that the pea-nut is produced on a commercial scale. The remarks that follow will, therefore, be restricted very largely to an abstract of the available particulars regarding these two Presidencies.

Area.—In most provinces the area under the crop is not returned separately from other pulses or other oil-seeds, so that a complete statement cannot be furnished. O’Conor tells us that in 1879 there were in all India 112,000 acres under the crop, of which 70,350 acres were in Bombay and 34,630 acres in Madras. Ten years later (1889-90) Madras alone was returned as having had 279,355 acres, of which 189,876 were in South Arcot, the chief seat of South Indian production. From that date the popularity of the crop steadily declined up to 1897-8, from which date it improved. Omitting the last three figures, the areas in Madras were as follows:—258 in 1890-1; 201 in 1891-2; 226 in 1892-3; 247 in 1893-4; 226 in 1894-5; 243 in 1895-6; 157 in 1896-7; 94 in 1897-8; 116 in 1898-9; 102 in 1899-1900; 229 in 1900-1; 337 in 1901-2; 421 in 1902-3; 384 in 1903-4; 366 in 1904-5; 393 in 1905-6, and the estimate for 1906-7 shows the Madras area as 507,600 acres, while that of Bombay is only 93,800 acres. The explanation of this decline and subsequent expansion will be found below—viz. the improvement rapidly accomplished by the introduction of a new stock. The experience of Bombay (including its Native States, mainly Kolhapur) has been somewhat similar, except that production has not recovered. The acreage under the crop in 1891-2 stood at 145,468, and in the succeeding years, expressed in hundreds, was as follows:—142 in 1892-3; 184 in 1893-4; 159 in 1894-5; 164 in 1895-6; 148 in 1896-7; 120 in 1897-8; 101 in 1898-9; 71 in 1899-1900; 64 in 1900-1; 96 in 1901-2; 69 in 1902-3; 89 in 1903-4; 93 in 1904-5; and 95 in 1905-6. Bombay cultivation may be said to be confined to the Deccan and the Karnātak with Sholapur and Satara as the most important districts.

Varieties and Races, also Deterioration of Stock.—From the early imported stock there had gradually developed certain races of the plant that within the past few years came to be spoken of collectively as the “Indigenous Variety.” Some of the so-called indigenous races are grown purely and simply on garden soil and eaten as nuts, others are specially adapted for field cultivation and vary greatly in the amount of oil they contain. Although doubtless inferior, India thus possesses a series of races that correspond to the large edible forms produced in perfection in America, and to the special smaller oil-yielding nuts of Africa. In the Madras Bulletin (No. 37) mention is made

|-------------------------------|-------------|-------------|----------------------|-----------------|-----------|------------------------|
of a communication from the Madras Chamber of Commerce attributing the
decline in the production of the nut to a deterioration in the quality of the
Indian stock. In reference to that opinion, Sir William Thiselton-Dyer,
then Director of the Royal Gardens, Kew, addressed the Under-Secretary
of State for India on February 23, 1899. The following passages may here
be given from that letter: "I may say at once that deterioration of
seed is a facile theory which is continually advanced when the produce
of a crop is disappointing. It is one in which I have very little belief.
The real explanation of the falling off is to be found usually in the ex-
haustion of some constituent of the soil. Madras ground-nuts have long
been known to be poorest in quality of any to be found in commerce.
The percentage of oil in shelled kernels is given in the United States Con-
sular Report (April 1, 1894, 683–9) as follows:—Senegal, 51; East African,
49; American, 42; Madras, 43. From these figures it does not appear
that any advantage would arise from introducing American seed. As to
Japan ground-nuts I have no information. The oil from the American
seed again appears to command an inferior price to that of Africa."

"The problem is one which should be taken up on an experimental
farm. It is not improbable that want of potash is the cause of this dimin-
ished yield, if the diminution be a fact. Manuring with wood-ashes would
be a simple means of testing this." "Formerly the cake or residue after
the expression of the oil was only used for cattle food. It is now converted
into various palatable forms of human food, the use of which has been
tried with success in the German army."

The reference to American and Japanese seed was doubtless in
consequence of the proposal to import such seed having been made
in the Madras Government Proceedings. The above letter caused a
searching and highly beneficial inquiry to be instituted in both Madras
and Bombay. Opinions were called for from the District Officers of
Madras Presidency, but the replies may be said to have manifested a re-
markable agreement in favour of the theory of a deterioration of the Indian
stock having actually taken place. Mollison, on the other hand, wrote:
"I do not think that any positive deterioration in the seed of the Bombay
crop can be proved. There is, however, perhaps good reason to join issue
with the Madras Agricultural Department and test on Government Farms
whether imported seed of the better varieties give better results than the
indigenous seed. I should, however, do this in the first instance on a
small scale." It has been shown by the areas of production, that quite
as serious a decline, however, took place in Bombay as in Madras. It is
probable, therefore, that the shrinkage in both Presidencies may have
been due to the same causes, whatever these may have been.

Acting on the opinion of its local officers, the Madras Government
imported various reputed races of seed, and private individuals seem to
have done the same. The result was that the indigenous varieties were
rapidly displaced, and it is believed at the present moment they hardly
anywhere exist in the Madras area of field cultivation. Barber in his
report (published 1890) says: "Two or three years ago something like a
revolutions had occurred in the introduction of a new variety called the
Mauritius ground-nut. The suddenness and completeness of this change
is worth considering." Barber accordingly gives particulars of the
crops found by him on certain fields. He only came across four little
pieces of land containing the indigenous plant, and these he did not think
INTRODUCTION OF NEW STOCK

collectively could equal an acre in extent. He then continues: "The
roots of this neighbourhood have, therefore, changed their seed, and I
believe that they have obtained a good variety and have thus greatly
improved their position." In another passage Barber again returns to
the subject: "There has recently," he says, "been a change of seed—
a fact which is of undoubted importance in the checking of disease, if of
no further advantage."

Benson (Bull. No. 41) gives the results of the Madras Govern-
ment experiments, as also of the French Government experiments at
Pondicherry. These showed splendid results in Madras with the Haut
Saloum variety from East Africa, and in Pondicherry with the Senegal.
The returns of the Saidapet Farm were as follows:—Country, 271 lb.;
Mauritius, 425 lb.; Japan, 427 lb.; Ruffisqul, 598 lb.; Sine, 884 lb.;
Gambia, 1,021 lb.; Haut Saloum, 1,379 lb.; American large, 303 lb.;
and small, 436 lb. per acre. The figures of the Pondicherry experiment
from equal plots were as follows:—yeld, 21 lb. from Bombay seed;
41 lb. from local seed; and 652 lb. from Senegal seed. Benson then
concludes by explaining that the so-called Mauritius, now largely being
grown in the Presidency, came in reality from Mozambique, though
brought to India by a passenger from Mauritius. "That variety," he
adds, "has given results on a par with the Senegal, but the seed contains
a resino-gommeuse substance which, as it remains in suspension in the
oil, delays the settling and gives a very pronounced taste of the ground-
nut to the oil." Mollison (Textbook, i.c. 104) says: "A good crop on
suitable land liberally managed will, on an average, yield from 3,200 to
to 3,500 lb. of unhusked nuts per acre. These figures apply only to good
land. The proportion by weight of unhusked nuts to those with husk
removed is as 4 to 3." "They are usually sold unhusked, and are worth
from 30 to 45 lb. per rupee according to locality and season."

In response to the reputation of an inferior yield of oil from the Indian
nut, Leather made an extensive series of analyses, the result being the dis-
covetory that the yield in the indigenous seed averages from 40 to 44 per cent.
and that of the so-called Mauritius from 44 to 49 per cent. It would thus
appear that India has not only secured a more prolific plant but one richer
in oil by the importation of the Mozambique seed. As already indicated, an
improvement in production has taken place, which must, to some extent,
be the direct expression of the renewed popular favour of the crop. Of
Indian agriculture, however, it would not be far from correct to affirm
that the selfish systems pursued very often result in an unconscious
retrograde selection, so that it may be believed degeneration of imported
stock is an exceedingly frequent result. But it goes without saying that
the continuous cultivation of the same plant with little manure and an
imperfect rotation must produce a poverty of soil and a corresponding
decline in the value of produce. Fresh supplies of seed or seed brought
from a distance to the country or locality of cultivation, is in all branches
of agriculture an admitted advantage. It remains to be seen how long
the new seed will retain its superiority on the Indian soil and under Indian
methods of cultivation. By way of concluding this paragraph, therefore, it
may be added that there is little or nothing to prove that a decline in the
oil-yielding property of the Indian stock had actually taken place. It
was grown originally as an edible nut, and it is probable that no effort was
made to improve the stock into an oil-yielding form, so that it was, doubt-
ARACHIS HYPOGAEA
Ground-nut

THE EARTH OR PEA NUT

less, always inferior as an oil plant, just as the American plant is so, compared with the special oil forms of East Africa. Mr. E. Solly reported to the Royal Asiatic Society (Committee of Commerce and Agriculture) in 1838, that he found the Indian ground-nut to contain 45·5 per cent. of oil. O’Conor tells us that in 1878–9 the husked seed yielded from 33 to 50 per cent. of oil. It thus seems highly probable that the present average, ascertained by Leather, may have prevailed ever since India participated in the world’s supply of the nut. But within recent years the Indian plant has been subject to several diseases, and may have become in consequence less profitable to the cultivators than was formerly the case.

Diseases. Diseases and Pests.—In The Agricultural Journal of India (15, pt. ii., 170–1) there will be found a short note by C. A. Barber on this subject. "The pests attacking ground-nut are comparatively few, the principal ones being ‘Surul’ or ‘Mudupuchi’ and ‘Tikku.’ The latter is a fungid disease which is not at present very serious in this part of India and apparently prevails in damp, close weather. ‘Surul’ on the other hand is universally present and does great damage. The word ‘Surul’ means a ‘curling,’ and is dependent on the habit of the insect of burrowing inside the tissues of the leaves, which curl up and get distorted. The chrysalis is formed in a fold of the leaf. The insect is a minute dark moth (Anacampsis vexatoria, Meyr.) of very active habits and is probably nocturnal. On walking over the fields a constant shower of disturbed insects may be seen that quickly seek shelter under the neighbouring leaves. The walls of bungalows in the neighbourhood are sometimes blackened at night by millions of the moths attracted by the bright lights.

"The Surul puichi appears to prefer laying one egg in each leaflet, which speedily turns brown and withers. In a bad attack the whole field assumes a blackened or blasted appearance. As is the case with most pests of this class, showers of rain are most beneficial, while hot sun and dry air lead to rapid increase, whether in dry or irrigated crops.

"From the internal working of the caterpillar it is doubtful whether spraying will be of much use, but, on the other hand, it seems probable that light traps may help in destroying the moths at night.”

Soils.

Sols.—The ground-nut requires a sandy loam, light and porous, with plenty of lime, free subsoil drainage and a liberal supply of water. In Madras, according to C. K. Sabba Rao, the best soil is ash-coloured, absorptive and fairly retentive of moisture. The nut, however, is most generally grown on the more prevalent red sandy loams, but the opinion prevails that the darker the soil the darker the nut and the less desirable for seed purposes. Mr. Handy urges this same fact, namely that a light-coloured soil gives a light-coloured pod and thus improves the selling value as an article of food, though, he adds, “equally sound and well-flavoured nuts may be produced on other soils.” Sabba Rao further observes that salt soils are unsuited, though stony soils rich in sand (if well manured) may yield a highly profitable return, while clayey soils are quite unsuited. In South Arcot, he tells us that the ground-nut had displaced indigo, since it is more profitable; on the soil on which the one crop flourishes the other may be equally successfully grown. Mollison, speaking of Bombay, observes that although raised on black land it delights in a good loam. But he adds that a heavy crop cannot be got without manuring and careful tillage.

Black Land.

Rotation.

Rotation of Crops.—Sabba Rao remarks that the raiyats are unanimously of opinion that ground-nut is an exhausting crop and that it cannot be cultivated uninterruptedly without the liberal use of manure. The rotation, which they observe, is with the second crop off the same field within the year, a rest being given every fourth or fifth year. "In the majority of cases, in South Arcot, the crop is sown amongst a standing crop of kambu (Pennisetum typhoideum), rdgi (Eleusine coracana) or other crop when the latter is being hand-hoed. In places where the crop has been recently introduced and plenty of good manure is available, it is cultivated either year after year on the same land, or only with an intervening crop at intervals of 4 or 5 years, whilst in some villages of the Shiyali taluk it is cultivated without intermission. In the neighbourhood of Panruti... the crop is changed once in 4 or 5 years." Sabba Rao next gives particulars of the various crops with which ground-nut may be rotated and

78
the reasons for and against each, and adds that the most popular rotation is with the cereal varagu (**Panicum miliaceum**). Barber recently re-investigated the question of rotation of ground-nuts with other crops and came to the conclusion "that the charge of continuous cropping was well-founded. The answer usually given to general inquiries on the subject was that a rest of one year was allowed in every 4 or 5." "Of scientific rotation it may safely be asserted, as regards ground-nuts, there is none, although the interval of rest allowed to the land shows that the ryot is aware of its advantage." Barber thus views rotation from a different standpoint to that of the Indian cultivator, and by most persons his views would be upheld.

Mollison, speaking of the rotation pursued in Bombay, says the production of ground-nut is undertaken by well-to-do cultivators, and is an indication of prosperity and easy circumstances. It is often rotated with sugar-cane and chillies, and is occasionally taken where potatoes, onions, and *brinjals* (*Solanum Melongena*) are grown. In the garden land of Surat, where *chiclo* (a sedge) is a troublesome weed, the growth of ground-nut helps to suppress it, and the thorough digging which the soil gets in removing the nut is very beneficial. Among garden crops ground-nut occupies the important position which grain holds among dry cereals.

**Manure.**--Sabba Rao observes that the best manure appears to be the silt deposit of tanks, and so highly is this valued that the cultivators carry silt from great distances and even pay high prices for the privilege of removing it. In South Arcot the fields are so manured once in 4 years with from 50 to 100 cartloads per acre. The silt from the Perumal tank (that most in use in South Arcot) has been found to contain about 22 per cent. of lime and nearly 70 per cent. of sand. Lime is fully recognised as a valuable manure for the crop. [Cf. *saidapet Farm Manual.*] Ashes are also reckoned as very good manure for ground-nut, more especially on poor, sandy soils. So important is this that ashes also are carried great distances, even by rail, to the ground-nut area. Ashes are in fact applied every year, sometimes at the rate of 30 cart-loads an acre. With regard to Thiselton-Dyer's recommendation to test the value of wood-ashes as a manure, it may be remarked that Leather made a special examination of certain soils in South Arcot, commonly under ground-nut. He found them all very deficient in lime. Four contained too little phosphate; five were low in nitrogen, and only one showed a defect in potash. Mollison remarks on the subject of manures for ground-nuts that sheep or goat manure, applied either by folding the flock on the field or otherwise, is considered specially suitable, but, failing this, ordinary farm-yard manure should be applied in considerable quantity. Deep ploughing and thorough pulverisation of the soil before sowing help the crop materially.

**Preparation of Land and Seasons of Sowing and Reaping.**—After the remarks already made on soils, rotation, etc., it is hardly necessary to do more than observe that ordinary methods of tillage usually suffice. About 90 lb. of seed per acre will be sufficient for sowings made up to the middle of August, but later on about 112 lb. are required since the plant does not grow so luxuriantly. The crop is sown thickly since the bulk of the pods are borne within a few inches around the central stem.

The crop is generally hand-hoed twice, about fifteen men per acre being required each time. The bullock hoe is not used owing to the injury done by it to the crop. In normal seasons ground-nuts, sown under irrigation, are watered twice a week during the last two months. While being watered it is customary to weed the plots, and in some cases the plants are lightly trodden under foot with the object of bringing them into better contact with the soil. On unirrigated land the crop is sown any time between the middle of June and the middle of August; on irrigated land from the middle of August to the middle of September. The latest possible sowings are from September 30 to October 15, viz. in Chingleput and North Arcot. There would thus appear to be two areas or conditions—an early and a late. The normal dates of sowing for the former

would appear to be from July 15 to August 15, and for the latter from August 1 to September 15.

The duration of the crop in the soil seems to vary considerably. The crop sown on irrigated land in South Arcot normally on July 10 comes into season about October 10, having occupied the soil for only three months. Again, the crops sown normally on June 15 in the Bhavani and Cauvery valleys are not mature until January 15, and have thus occupied the soil for seven months. Usually the crop occupies the soil a little over five months, and thus for the early districts (such as South Arcot) it comes into market from January 15 to February 15 and for the later districts (Chingleput and North Arcot) from February 1 to March 15. As a rule, however, in the districts of late sowing the crop occupies the soil for a slightly shorter period, and thus comes into market approximately at the same time as the other sowings.

Of Bombay Mollison observes that the ground-nut is usually a kharif (rain) crop, sown as soon as the previously prepared soil has been sufficiently moistened by the first fall of rain in June; but in the Deccan it is also grown as a rabi (winter) irrigated crop. The monsoon crop occupies the soil six to seven months, and in the absence of rain the land must be kept moist artificially. It is usual to give two to four waterings during the last two or three months. The seed is ordinarily sown between monsoon showers, when the land is dry enough to be worked by a plough. The crop should be weeded at least twice. As soon as it shades the ground, no further attention, except watering, is required. The crop is harvested likes potatoes, sometimes with a plough, but more often the field is dug over by hand with a Native pick. A cultivator collects a regular army of workers, and usually pays in kind. In order to expedite the digging the haulms or vines are previously reaped and removed. These form an esteemed fodder.

The returns of sowing and reaping furnished by the authorities regarding the Bombay Presidency show the crop to be slightly earlier in Bombay than in Madras. The earliest sowings take place on June 1 and the latest on July 31. Of the Bombay districts Poona and Sholapur sow, as a rule, about fifteen days later than the other districts. The period of occupancy of soil varies considerably; the maximum duration is eight months in Belgaum, where the crop is normally sown on June 10 and reaped usually about February 10. In Ahmednagar it is reaped a month sooner, having occupied the soil for seven months. The shortest duration is four and a half months in Poona, where the crop, sown on June 15 (normally) is reaped on November 1. In other districts the crop occupies the soil a little over five months, and as Satara and Sholapur are the most important producing districts it may be added that the Bombay crop comes into season in November, and thus on an average six weeks before the chief Madras crop. This is therefore a fact of considerable importance which the foreign buyers of Indian nuts should bear in mind.

**TRADE.—Foreign Trade.**—It has already been fully demonstrated that the area of production in India has been vastly extended and the condition and location of the trade exactly reversed since O’Conor’s report of 1879. The greatest area of production is now in South India, and moreover there has grown up in Madras a considerable traffic in the manufacture and export of the oil. In other words, an increased local consumption would seem to be gradually lessening the amount available for foreign
transactions. It would thus seem that to some extent at least this may account for the outcry regarding a decline in the Madras traffic. It is more than probable, however, that the prevalence of disease in the crop and the exceptionally unfavourable seasons of 1897–8 and 1899 (during which the rains failed at the sowing season and the prices of foodstuffs rose on account of famine) directly decreased the available area of production. This state of affairs was not peculiar to the earth-nut but marked the traffic in all other oil-seeds. Such a condition might easily enough be supposed to accentuate the knowledge, if such existed, of the inferiority of the Indian as compared with certain other well-known commercial oil-yielding stocks, until the opinion might have been formed that a deterioration of the Indian nut had occurred. While such deterioration may have been taking place, it is a matter of history that the increasing imports into Europe of improved cotton-seed oil from the United States and India gradually displaced ground-nut and other oils from some of their markets and thus tended to lower the prices offered for them. Be the explanation what it may, the new seed, presently being eagerly sought after by the Indian cultivators, has already given tokens of being much superior to the old stock, and, as a possible result of this as also a consequence of the return of more prosperous seasons, the area of production has greatly increased.

Exports.—The following figures may here be given in manifestation of the past and present Foreign Exports of Ground-nuts from India:—In 1894–5 the total exports were 2,267,222 cwt., of which Bombay contributed 1,598,387 cwt. Taking the subsequent years and for convenience omitting the last three figures, the corresponding trade returns were for 1895–6, total 1,118 cwt. and Bombay’s share 796 cwt.; for 1896–7 they stood at 486 and 238 cwt.; for 1897–8 at 44 and 19 cwt.; for 1898–9 at 87 and 76 cwt.; for 1899–1900 at 155 and 23 cwt.; for 1900–1 at 232 and 29 cwt.; for 1901–2 at 1,085 and 98 cwt.; 1902–3 at 1,035 and 52 cwt.; 1903–4 at 1,921 and 91 cwt.; 1904–5 at 1,674 and 42 cwt.; 1905–6 at 1,374 and 149 cwt.; and 1906–7 at 1,725 and 130 cwt. It will thus be observed that a serious drop in the trade took place in 1896–7 and became accentuated in 1897–8, since which date a revival has gradually set in, but mainly in the Madras supply, the Bombay exports being now only a small proportion of the former magnitude. In 1906–7, however, the Madras supply decreased to 1,350,096 cwt. from 1,827,843 cwt. (1903–4), while the Bombay supply increased from 42,408 cwt. to 130,356 cwt.

Internal Traffic.—The returns of the traffic by rail and river show that the chief movement is from the Presidency of Madras into its port towns and thus to meet the foreign exports. Of the total amount carried by these routes in 1906–7 (viz. 1,733,123 cwt.) Madras ports alone took 1,476,198 cwt.

Trade in Oil and Cake.—The oil may be obtained by cold expression or by moderate heat. The former process affords the best oil but in smaller quantity than the latter. The cold-pressed oil is almost colourless, has an agreeably faint odour and a taste not unlike that of olive oil. That obtained by the hot process is dark yellow and has a more or less disagreeable taste and smell. Although the oil does not turn rancid so quickly as most Indian oils, on exposure it slowly thickens and then becomes rancid. It is a non-drying oil, the best qualities of which have a sp. gr. of about 0·918 at 15°C. when fresh, and

Native Oil Mills.

Oil Mills.—It is significant that the bulk of the Indian manufacture of this oil should be in the hands of the owners of ordinary Native pestle-and-mortar-pattern rotary mills. At Valavapur there are said to be 700 such mills, at Panruti 200 mills, and at Pondicherry there were formerly 200 mills. Mills of the European pattern were tried both at Pondicherry and Cuddalore, but it was found they could not compete successfully with the Native mills. The cake from the European mills was too dry, powdery and wanting in oil, hence everywhere rejected. This is all the more significant since so very economically are the oil mills worked at Marseilles that ground-nut oil is cheaper in France than in India—a circumstance perhaps to some extent due to the fact that African seed is very much richer than Indian. It is commonly estimated, moreover, that 1 cwt. of dry kernels will yield about 5 gallons of oil. The seed produced on unirrigated is more oily than that raised on irrigated land. Formerly it was customary to read of the seed of Tanjore and Shiyoli being richer in oil than that of any of the other districts of Madras. It remains to be seen if the same will be true of the Mozambique seed now being cultivated or if the new seed will preserve a uniform quality throughout the Presidency.
THE BETEL-NUT PALM

Recently mills have been opened in Calcutta and elsewhere in Bengal for the manufacture of this oil. Already these new mills have had the effect of checking the imports of the oil that formerly came from Pondicherry and Madras, and they have given birth instead to a large import-traffic in the nuts. One of the chief markets for the South Indian ground-nut oil has been the supply required by Burma. From recent correspondence hope is entertained of the Shan States being able to meet the Burma demand. For information regarding the chemistry of the oil and of the oilcake and their values as articles of food, as also the medicinal and industrial uses of these and other products of the ground-nut, the reader is referred to The Agricultural Ledger (1893, No. 15) and to the Kew Bulletin (1901, 194), more especially the particulars given regarding the pea-nut flour and biscuits. It seems probable that as an article of food during military operations, special preparations of the pea-nut may have a great future. For microscopic examination of pea-nut cake consult Hanausek (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 387–91).

Habitat.—So much might be written regarding this nut that it is difficult to make a selection of the particulars likely to prove of greatest value from the commercial and industrial standpoint. It is cultivated exclusively within the moist tropical tracts that fringe the coast of India and practically within a belt of land that does not extend inland for more than 200 miles. It rarely ascends to altitudes of 3,000 feet and gradually disappears, even from the littoral area, as localities are entered where the duration of the dry hot months equals or exceeds the monsoons. Usually it is seen as a garden plant, two or three or a dozen palms at most being found around the huts of the more prosperous and industrious. But occasionally, and in certain localities, especially of Southern and Western India (Malabar) and of Burma, where the soil and climate may be exceptionally favourable, it is grown in special gardens along with cocoa-nut, plantain, orange, mango, etc., and either with or without the pān—piper betle—climbing on the palm-stems. Lastly in Eastern and Northern Bengal and some portions of Assam its cultivation has assumed still greater dimensions. In certain districts of these provinces regular plantations of 5 to 20 or even 100 acres in extent occur (exclusively of betel-nuts) and at such frequent intervals that they might almost be said to constitute a distinct agricultural feature scarcely less important than the combined crops raised on the intervening portions of the country.

History.—This cultivated palm is met with throughout the hot damp regions of Asia and the Malay Islands. It is a masticatory of great antiquity with all Asiatic races, best known as Betel-nut, swaká, puga, kramuka (Sansk.), jufal (Arab.), a corruption of pūpal (Pers.), a word cognate with kukbara (Sansk.). By these and other names was originally meant Piper betle leaf—the pān—though subsequently these and many other names were appropriated to the nut or to the special preparation of leaf, nut, lime and spices ready to be chewed. This was first designated bira (sīra) viṭi in Sanskrit but ultimately became pān, the pāna or pan-sapari of modern writers. The nut is symbolical of festivity; it is accordingly a fit offering for the gods, and is an essential at the betrothal ceremony.

From the most ancient times the presentation of pān has been the polite termination of ceremonial visits, hence the expression bira-dena—the dismissal. The name Betel or Betle is Malayan in origin and simply means "a leaf," and came to English through the Portugueso Bete. The best-known vernacular names for the nut are—supāri, hopāri, gua, gaya, kasaile, mari, tambul, pokāraka, oka, kamugu, adike, kunai, etc.

It would seem that the earliest historic reference by a European to the habit of chewing betel-nut occurs in the writings of Marco Polo (1298 A.D.).

First mentioned by a European.
people," he wrote, "have the habit of keeping in the mouth a certain leaf called tembul." Subsequently Vasco da Gama (in 1498), Varthéma (in 1510), Barbosa (in 1516), Garcia de Orta (in 1563), Acosta (1578, 94), Abul Fazl (in 1590), Linschoten (in 1598), François Pyrard (1601), Roe (in 1615), Jacobus Bontius (1629), Bernier (1656-68), Boyen (1656), Vincenzo Maria (1672), Tavernier (1676), and Catchpoole (1703) (cf. Yule, Diary of William Hedges, ii., 301), all give similar accounts. Adams in his translation of Paulus Aegineta refers to the betel-nut as introduced to Materia Medica by the Arabs. He quotes amongst others the passages referring to it from Avicenna, Haly-Abbas, Ebn Baithar, Elmasudi, Serapion and others. Ebn Baithar says that it is the fruit of a palm, and observes that it is a gentle purgative, makes the breath fragrant, is a cordial and strengthens the gums and teeth. Linschoten remarks that "The Indians go continually in the streets and waises with Bettele or Betre and other mixtures in their hands, chewing, especially when they go to speak with any man, or come before a great lord." Abul Fazl apparently never saw the palm growing, since he likens it to a cypress tree that in the wind always till it touches the ground. This circumstance may be accepted as showing that from very ancient times, as at the present day, the nut has been carried to regions remote from the areas of its production. Numerous publications have appeared within the past century that deal with the betel-nut, as met with in India.

The following selection in amplification of the references in the Dictionary, may be mentioned by way of concluding this very brief historic sketch:—Valencia, Voy. and Travels Ind., 1802-6, i., 101; Buchanan-Hamilton, Journ. through Mysore and Coorg, etc., 1807; also Stat. Acc. Dinaj., 1809, 150; As. Journ., 1819; Roxburgh, Fl. Ind., 1832; Taylor, Topog. Stat. Dacca, 1840; Honigberger, Thirty-five Years in the East, 1852; Elliot, Fl. Andh., 1859; Mason, Burman and Its People, 1860; Baden Powell, Fl. Prod., 1868; Jackson, Notes on the Areca Palm, Pharm. Journ., 1874, 3rd ser., iv., 689; De Candolle, Orig. Cult. Plants, 1884, 427; Pharmacog. Ind., 1893, iii., 522-32; Cameron, For. Trees Mysore and Coorg, 1894; Duouviri Balakrishna Murti, Lecture Cult. Areca-nut in Godavari Dist., Ind. Agr., 1900; Collins, Cult. Betel-nut in Tounghoo Dist., Burma, 1900; Journ. Soc. Chem. Indust., 1901; Joret, Les Pl. dans L'Antig., 1904, ii., 208; Cunningham, Plaques and Pleasures of Life, Beng., 1907, 335-51; etc., etc.

CULTIVATION.—Propagation in Bengal.—In my report on A Plague in the Betel-nut Palms of Bengal (Agri. Ledg., i.c.) much useful information will be found on these subjects. In the districts of Backerganj and Noakhali the Areca palms are planted in groves of mandar (Erythrina indica). These enrich the soil, afford shade from the intense heat and protection from sudden wind storms. Branches of the mandar, some 6 feet in length, are planted in rows, 12 to 15 feet apart each way. The planting is done in February to April, and from 2 to 6 years later these plantations are ready for the seedling palms. The betel-nuts are sown in October or November, the seeds being deposited 4 to 5 inches apart, and the nurseries are either close to the homesteads in shady places, or, if conveniently situated, they are made in the mandar groves themselves. The transplanting is usually done after 2 years, sometimes 3 or 4 years. For high lands the seedlings are transplanted in July, for low lands in February or April. In the first transplanting the betel-nuts are placed equi-distant from the mandar trees and thus 12 to 15 feet apart. But a second regular transplanting takes place when the first have come into bearing. Before this is done the mandar trees are cut down or only a fringe left around the circumference of the grove. The betel-nuts in a fully planted grove are thus about 6 to 7 feet apart each way. A certain amount of irregular planting takes place, however, as vacancies occur, and in selfishly conducted plantations the trees may be found here and there not more than 2 or 3 feet apart. It is probable that there is a certain amount of self-sowing, as it is not usual to find two or three trees growing in a clump so close to each other that they could not be healthy. In most
PROPAGATION IN BENGAL

plantations also a distinct percentage of cocoa-nuts are interplanted among the betel-nuts, so that an old plantation in many cases has lost all its original regularity and becomes a dense jungle of palms with only a winding footpath leading to the owner's house. This generally stands on the bank of a tank and near the middle of the holding.

The seasons of flowering and fruiting may be said to be distributed throughout the year. The flowers that form in January will ripen fruit in October; the flowers formed in March will fruit in December and January. The harvesting period is from October to the beginning or middle of January, but occasionally the new flowers may begin to form in December or January on trees from which last year's fruits have not been collected.

If a few trees are planted near villages, but not in regular groves, the betel-nut may fruit when it is only 6 or 7 years of age. In plantations they rarely fruit before the tenth or twelfth year. The trees subsequently put out in the plantation (just as the first set begins to flower) do not come into bearing for 20 years. There is no third planting except, as already stated, to fill up vacancies. Land formerly covered with betel-nuts, if re-planted with them, even after a rest of several years, in the form of mandar groves, does not, as a rule, yield until the palms are 20 years old. It will thus be seen that it takes at least 30 years before a betel-nut plantation comes into full bearing. The fruiting life of a tree may be put at from 30 to 50 or 60 years after maturity, and the total life of the tree might thus be stated at from 60 to 100 years.

The soil of the Bengal plantations is the ordinary grey sandy loam on which rice is grown. Occasionally the plantations are surrounded by a ditch and wall made of the soil thrown up from the ditch, but this appears to be more intended for protection than drainage. More inland, in the districts of Tippera, Dacca, Sylhet, Goalpara and Rangpur, the palm is grown on considerably higher land, and usually as special gardens or avenues in gardens, or along the high banks of the streams. In Northern Bengal and Assam the pand leaf is very often trained to grow on the Areca palm stems, so that the two industries are combined, while in the great nut-producing districts of the Sundribans the betel-leaf is never or very rarely grown in the nut plantations. In the lower portions of Sylhet and Cachar, on the other hand, betel-palm groves and pepper betel-leaf houses are very characteristic features of the river-banks. Taylor informs us that the average number of trees to a bigha in the Dacca district (two-thirds of an acre approximately) would be about 700, but he adds the palm is usually planted around gardens and huts and not in solid clumps.

Bombay Presidency.—The betel-nut may be said to be chiefly grown along the coast from Kolaba, Thana and Kanara to Goa. Interesting particulars will be found in the Gazetteers of these districts and more recently in Mollison's special Report on the Betel-nut, Pepper and Cardamom Gardens of Kanara, as also in his Textbook of Agriculture (l.c. 257-8). He there tells us that the Areca is cultivated chiefly by Haviks—a race of cultivators supposed to have come originally from Mysore. "It does not matter much," he writes, "whether the soil is naturally fertile or not, because the yield of the crops grown is mostly affected by the quantity and quality of manure directly applied. . . . In many gardens irrigation is not required even in the hot weather. At this time a trickling stream, fed from natural springs, may be seen running along the main channels or a

Perennial nāla passes by the main channels through the garden. The soil is thus kept continuously moist.” “The palms are raised in seed-beds and are once transplanted before they are planted out permanently. The first seed-bed is carefully prepared, the soil is dug, broken fine and mixed with leaf-mould. Fully matured nuts from old trees are specially selected for planting. These are planted about 9 inches apart in April. The seed-bed should be kept thoroughly moist. The shoots appear in June. The seedlings are transplanted in October into any moist place in the garden or along the watercourses about two feet apart and remain until permanently transplanted. This permanent transplantation is usually done towards the end of the rains. In the following March the trees are manured with leaf manure and the manure is covered with fresh-cut branchwood which is partially withered but which retains the leaves. The object of placing a layer of small branches above the manure is to break the force of heavy rain.”

“ The betel trees are manured as described every second year and come into bearing in ten years or so. The plantains are maintained for some years after the betel-palms are permanently planted, but in time are removed and cardamoms planted between the palms, and on the stems of the latter pepper-vines are trained. Betel trees are known to fruit freely for 30 or 40 years, and there is a popular belief that they are sometimes profitable much longer. On an average each tree has two bunches of fruit, sometimes three or four. But two good bunches yield as much as three or four inferior ones. The size of the bunch depends upon the manure used and upon the rainfall. A good bunch gives 200 to 300 nuts and a specially good one about 400. With unfavourable rain or cloudy weather in April or May many of the young nuts fall off and a smaller number of nuts on each bunch reach maturity. The trees produce flowers in March and April and the nuts are ripe in November or December, but to some extent the trees produce flowers and fruit out of season” (l.c. 259).

The flower spathes and leaf-sheaths are “valuable products in the garden economy. They are used to provide hoods for protecting the branches of betel-nuts from the rain. If unprotected the nuts rot. Two sheaths are used to make one hood. The hoods are made and tied on by professionals who come from Mysore territory and below the Ghats. A good workman can make 250 hoods per day and is paid Rs. 2 per 1,000. This operation and tying them on costs at contract rates Rs. 10 to 12 per 1,000 bunches and two meals per day. The men do not ascend and descend each tree. When once they have climbed up, by means of slight exertion they swing the tree and deftly catch hold of another and rarely descend to the ground for hours. These expert climbers also gather the fruit by cutting the bunches from the stem, getting Rs. 4 per 1,000 bunches and three meals per day ” (l.c. 260).

South India.—A good deal has been written on the subject of the special cultivation pursued in Mysore. Cameron (For. Trees, l.c. 324–6) practically reprints the account given in The Mysore Gazetteer when he says:—“Areca-nut gardens are a profitable source of income both to the cultivator and the State, the latter deriving a large revenue from a halut or custom duty levied upon the nut. The finest betel gardens are situated on the confines of the Malnad where there is a rich soil and plenty of water.” “It is necessary, during the rainy season, however, to drain off superfluous water by means of open
PROPAGATION IN SOUTH INDIA

ditches placed at intervals between the rows of trees, for although the areca requires a perennial supply of moisture at no great depth in the subsoil, it is keenly susceptible of being waterlogged.” “In topes exclusively apportioned to the areca-nut, the planting is mostly too close; 1,200 to 1,500 trees being allotted to the acre, exclusive of the banana trees.” “A full-grown tree is calculated to produce 250 to 300 nuts annually.”

Mr. D. B. Murti, in his Lecture on the Cultivation of Betel-nut in the Godavari district, says a man owning a plantation of 3 acres is considered rich. The plantations contain mangoes, plantains, cocoa-nuts, jackfruit, oranges, pomegranates, and these form a fringe around and also lines within, but areca-nuts are planted 10 to 12 years after the rows of other fruit trees have been established. Seed-nuts are selected specially from trees over 50 years of age because these form few but exceptionally large nuts. It is believed that such nuts ensure timely sprouting and steady growth of the future tree. The details of the nursery, of the transplanting, etc., followed in Godavari are similar to those already fully discussed. The harvest season is generally in the months of August, September and the first half of October.

Burma.—Mr. G. G. Collins has recently published the following brief account of the cultivation of Betel-nuts in Toungoo:—“The Toungoo district is noted for its cultivation of and trade in the betel-palm. This is confined almost entirely to the Karen tracts lying in the Kanni (Leitho), Tantabin, Kyaukkyi and Shwegyin townships east of the Sittang river.” “The gardens are formed particularly on the lower slopes of the hills which form the eastern boundary of the district and from which run the numerous streams that drain to the Sittang. The cultivated area covers at intervals a course of some 200 miles from North to South. The produce of the trees varies with the locality; a fair average may be 100 per tree, but as many as 400 to 600 nuts have been obtained from one palm.” “The cultivators of the betel-palm also grow oranges, many to a large extent, and the trade in both products in this district is very large. The price of the betel-nut at the gardens after drying varies from Rs. 80 to Rs. 100, and at the market town from Rs. 100 to Rs. 140 per 100 viss (viss = 3'65 lb.).

Diseases and Pests.—It may have been inferred that in the chief Indian area of production, viz. the Gangetic delta, the plant is cultivated on flat interfluvial tracts very little raised above inundation level, and has practically no labour bestowed on it during the half century or more that it continues to yield fruit. In other parts of India the palm is grown under a high state of cultivation with much attention and money devoted to it. These two extremes—utter neglect and careful treatment—should manifest, and perhaps naturally, widely different conditions of disease. Butler, in a paper on Some Diseases of Palms (Agri. Journ. Ind., i., pt. iv., 299-310), observes that fungus diseases are fortunately rare though a few have appeared in recent years, each apparently confined to a particular part of the country. He then gives details of the diseases found on the betel-nut palms of the Malnad district of Mysore and of Sylhet in Eastern Bengal. It would appear that in the former locality a fungal disease is known as kole roga or black rot, but that “up to the present it has not been found elsewhere and, as it does not appear to have extended much during the time it has been observed, it is probably favoured by the special climatic conditions of the locality where it occurs.” Butler is of opinion that the disease in question is caused by a fungus of the genus Phytophthora. The reader should consult the original paper for all necessary details. The practical aspects may be here summarised. The sporangia require to fall into water to ensure their full propagation, and hence the spread of the disease is closely dependent on conditions of moisture and rainfall. The disease originates on the flowering and
ARECA  
CATECHU  
Betel-nut 

fructing inflorescence, and for its growth it is necessary that moisture should exist at that period. He accordingly recommends steps being taken to secure a change in the period of harvest. The late crop of former years he regards as having been beneficial, and may be obtained by departures in the method of cultivation. So also improvements in the nature of the covers presently used to protect the inflorescence, he views as very desirable. Covers that leak, he adds, are likely to be more injurious than none at all.

Protection.

Betel-nut Protection.

Sylhet.

Speaking of the Sylhet disease, he says that the general symptoms are the same as those in Mysore kote roga, namely, the dropping of the nuts before maturity. Gradually the swollen green part below the leaves is seen to diminish in size. Withering of the outer leaves then follows, and finally the whole head dies and falls off. "The conditions resemble those which would be caused by drought or some general disturbances and not by a local disease at the crown of the palm. No trace of any parasitic fungus can be found in the earlier stages at the top of the tree. The stem is generally healthy. Below ground, however, matters are different. Here there is invariably a rot, either of the roots or of the below-ground part of the stem even in very early cases." Reasoning from analogy with other root fungi, Butler recommends the surrounding of affected portions by trenches. But to be effective, trenching must be undertaken as soon as the first disease appears in the garden. The trench should be two feet deep, about a foot broad, and drained in order to prevent water accumulating in it. It should entirely surround and cut off the first affected palm or palms.

[Cf. Pests and Blights of the Tea Plant, 1903, 413.]

Bombay.

White-ants.

A Borer.

Of Godavari, it has been said that white-ants often injure the palm materially by eating the rootlets. Of Bombay, Mollison (loc. 262) observes, "Betel-palms are not much affected with disease. A borer does considerable damage. It cuts a tunnel from the root upwards and in time reaches to the growing top. The damage there done is so considerable that the top withers and when wind blows breaks off and falls to the ground."

Bengal.

Plague.

Indolence.

Loss of Revenue.

Dead stumps.

Destruction of Tissue.

Causes of Plague.

Remedy.

The invasions by me in the great betel-nut area of Bengal left the impression on my mind that there was less to be surprised at in the severity of the plague that devastates the plantations than in the infrequency of its occurrence. It is next to impossible to imagine any industry existing at all under the conditions of abject neglect that prevail in the Bengal betel-nut districts. All that the owner of a plantation does is to lay the estate out on the principle of the greatest number of trees on the least space, and at the lowest labour and expense possible. He then builds his house, and he and his sons and grandsons settle down to a life of family disputes that not infrequently lead to lawlessness. He hires out his plantation to contractors who collect the fruits in any way they think fit, the owner all the while sitting by in a state of complete indifference and indolence. He neither drains, manures, nor cultivates his plantation in any form worthy of the name but lives in opulence until plague appears. When, if his property chances to be devastated, he gathers together unremorseful goods and leaves the district border to escape payment of the revenue or rent during the twenty years of renovation that may have to be faced.

After the most careful examination of numerous plantations (or rather jungles) of betel-nut palms in Eastern Bengal I failed to find any serious insect or fungal blight on the trees that were nevertheless seen to be dead and dying in every direction. The crown of leaves withered and was blown off, leaving a dead stump behind, until what was once a plantation looked like a harbour with thousands of masts. The destruction was not confined to particular plantations but had spread over the country like a great wave of infection in such a manner as to justify the name of "Plague" that had been given to it. On microscopic examination, the tissue of the dead and dying palms was found to be permeated with an organic agent of destruction in which it might be said that the fundamental tissue had invaded and devoured the fibrovascular. The condition, in other words, was very similar to that described under the name "Tyloes." As seen in Europe on the vine, the cucumber and other plants, that constitutional disease is believed to be induced when an undue amount of moisture is given to the roots, while the leaves are at the same time exposed to an abnormally dry, hot atmosphere or the reverse conditions. The cultivators in Bengal admit that plague follows when the soil becomes abnormally dried up, through failure of the customary showers in January, more especially if the hot months are ushered in by a cyclone. The remedy lies in more generous spacing, when laying out the plantation; more careful cultivation, in which drainage, irrigation and
THE NUT AND EXTRACT

manure are provided; and lastly an extension of the system of combination of betel-nut cultivation with that of other fruit trees. The cultivation of surface crops such as vegetables, ginger, tobacco, pepper-betel, etc., would also no doubt prove not only profitable but beneficial to the palms. They would retain moisture in the soil and preserve a healthy balance in its food materials. But in the country where betel-nuts are grown on a large scale and with the class of people who engage in that remarkable branch of agriculture, such preventive measures would perhaps be next to impossible, unless they could be made compulsory.

MANUFACTURE.—Preparation of the Nut.—It would take many pages to detail the various methods of preparation pursued in Bengal, Assam, Manipur, Burma, Madras, Mysore and Bombay. In some cases the shelled nuts are boiled, in others not; occasionally the nuts either before or after boiling are sliced or cut up into variously shaped pieces; lastly certain qualities of the nut are recognised according to region of production and variety of plant or degree of maturity at which collected. On this subject the authors of the Pharmacographia Indica (l.c. 532) say: “The varieties of the nut met with in trade are numerous; they may be classed as natural and artificial: the first class includes different varieties of ripe betel-nut produced by cultivation which have not undergone any preparation; the second class, all nuts, ripe or unripe, which have been treated by boiling or other process before being offered for sale.” Mollison observes that in Kanara the nuts after being boiled are dried in the sun and sorted into three kinds, viz. chikni, beta, and gotu. The first and the best quality sells at Rs. 6 to 7, the second at Rs. 3 to 4, and the third at Rs. 2 to 2½. Taylor describes the Bengal method of shelling and cleaning the nuts before being sent to market. Briefly it may be said the fruits are cut off the branches, collected in baskets and spread out to dry, most frequently on the roofs of the houses. They are never boiled, but are simply cut open and assorted according to size.

The Extract.—Mollison says—“The scraped nuts are boiled for about two hours in fairly large copper pots. A handful of lime or of the ash of the bark of malli (Terminatia tomentosa) is added to the water. The presence of lime causes the water to become red or red-brown in colour as the boiling proceeds. The water also becomes thick with a resinous extract from the nuts. The boiling is continued until the eye-bud or germ of growth from each nut comes out or becomes absorbed in the extract. The nuts are removed by a long-handled ladle (zâra). The ladle has perforations in its bowl which allow the extract to drain from the nuts back into the pot. The extract is again and again used for boiling fresh supplies of nuts, pure water as required being added from time to time to prevent the decoction becoming too thick and concentrated. The extract after being used for boiling repeatedly becomes deep red-brown and thick. It is then emptied into another broad-mouthed vessel which is placed under full exposure to the sun. The mass by evaporation thickens and Areca Catechu or kossa is the product.” Several other writers allude to this extract. In the Dictionary passages from The Thana Gazetteer, and from Baden Powell’s Panjâb Products will be found. Very little of a definite nature is known regarding it, however, further than that it is always prepared when the nuts are boiled and is used to flavour and colour inferior nuts. But no particulars are available as to the existence of a separate trade in the extract kossa itself.

Properties and Chemical Composition.—The reader is referred to the Pharmacographia Indica for full particulars under these headings.

Betel-nut

The Betel-nut Palm

Briefly it may be said that the chief use of the betel-nut is as an astringent and stimulating masticatory. To some extent it is employed in medicine, the unripe fruits are in India viewed as laxative and carminative, and a paste of the powder of the dry or burnt nut is used as a dentifrice. In Europe the ripe fruits have been employed as an anthelmintic and astringent. Most writers affirm that occasionally the nuts (especially when eaten fresh) are found to possess intoxicating and poisonous properties. This is believed to be an accidental peculiarity of certain trees which thus show a reversion to what may be the wild condition. This poisonous property has been ascertained to be destroyed by boiling, and hence no doubt has come into existence the system mentioned above of preparing the nuts for market by various methods of cooking. It has been ascertained that the active and poisonous principle present in areca-nut is an alkaloid Arecoline. The antidote to this, as recommended by Rumphius (in 1741 A.D.), is said to be salt, lime-juice or acid pickles.

Trade.

TRADE.—Betel-nuts are not only very largely produced in India but are imported from Ceylon, the Straits Settlements, Sumatra and China. In 1895–6, the year before the effects of the Bengal betel-nut plague became serious, the foreign imports stood at 58¼ million lb., valued at 36½ lakhs of rupees. Steadily these imports improved until in 1899–1900 they stood approximately at 90 million lb., valued at 62½ lakhs of rupees. These figures may be accepted as representing a loss to the Indian producer of 26 lakhs of rupees. This opinion may be confirmed in various ways. In my report on the ravages of the betel-nut plague it will be found that I have stated that in many plantations visited there was a loss of from 50 to 90 per cent. of the trees. The returns of the river traffic from the betel-nut area into Calcutta, showed for 1895–6 a decrease of 8 million lb., as compared with that of the three previous years. The trade still further declined for the two following years but revived very greatly subsequently, and has now been more than restored to its former magnitude. It will thus be seen that during the disturbed years above indicated production in Bengal decreased by the exact amount that the foreign imports increased, involving a loss during these years of some £200,000 per annum to the betel-nut growers of the province. But since 1900 the foreign imports have continued to increase, till in 1906–7 they reached 119,732,410 lb., valued at Rs. 1,15,35,030. The foreign exports were 280,782 lb. in 1896–7, and for the five years ending 1906–7 they were 375,050, 341,937, 320,176, 343,526, and 289,770 lb. To these amounts would have to be added the re-exports, which in recent years have varied from some 20 to 40 thousand lb.

The magnitude and importance of the Indian production of betel-nuts may, however, be judged of by the extent of the coasting trade. During the three years ending 1905–6 the inter-provincial exchanges have ranged from 57 to almost 64 million lb. of Indian-grown nuts valued at from 82 to 89 lakhs of rupees. Of that amount Bengal has exported from 32 to 37 million lb. Burma is the largest importing province, and has taken from 29 to 34 million lb. Of the internal trade mention may be made of Assam. It produces these nuts chiefly in Sylhet and Gauhati, but the large number of Indian coolies concerned in tea-planting are dependent on the supplies drawn from Bengal. Madras is supplied very largely by the Malabar Coast, and the exports of South India go mainly

90
to the Straits while Bengal exports to Burma. Judging by the costwise trade alone, the chief areas of production are Bengal, Bombay, Madras and Goa, mentioned in the sequence of their importance. A certain proportion of the quantities recorded as carried by rail and river appear again in the sea-borne traffic (the costwise and foreign exports) or they have been derived from the foreign imports, but allowing for all such necessary corrections, the transactions by land routes must be accepted as greatly augmenting any estimate that might be framed as to the total quantity and value of the Indian production. But over and above all published returns there is still a source of error (and in this case an important error) in the local or village cultivation and consumption which escapes registration entirely. As a deduction from the estimate that might be arrived at from the study of foreign supply plus Indian production, the Foreign Exports would have to be accounted for, say 250 to 350 thousand lb. These go mainly from Bombay ports and are derived chiefly from the coastwise imports from the other parts of that Presidency with a smaller supply from Goa and Madras. Madras is the next most important exporting province. Bengal, the chief producing province, exports very little to foreign countries. The Trans-frontier (land) traffic from India to Kashmir, Nepal, Bhutan, Manipur, the Shan States, etc., has during the three years ending 1906–7 been 53, 46, and 64 thousand lb.

From the published returns of foreign imports and Indian production, briefly indicated, it would seem safe to affirm that the annual consumption of betel-nuts in India itself cannot be far short of a valuation of Rs. 225 lakhs, or say £1,500,000. The price adopted in making that calculation has been obtained from the mean of the declaration value in the foreign imports and internal traffic for a period of five years. But if the foreign imports alone be considered, the price would seem to be from Rs. 5–78 in 1895–6 to Rs. 7–87 in 1898–9 and Rs. 6–98 subsequently per 100 lb. of nuts. These figures correspond sufficiently near with those given by O’Conor, viz. Rs. 6–5–8 per maund, risen recently to Rs. 7–8–0. The retail price may therefore be expressed at 2½ to 3 annas per lb. The following quotations from the Bombay market price list of different trade qualities may be regarded as amplifying the above average calculations:

**White Betel-nuts.**—Goa, Rs. 8 to 10 per cwt.; Mangalore, Rs. 14 to 22 per cwt.; Rupasi, Rs. 12 to 16 per cwt.; Calcutta, Rs. 12 to 13 per cwt.; Asigree, Rs. 12 to 14 per cwt.; Kanaarese, Rs. 16 to 20 per cwt.; and Severdani, Rs. 18 to 19 per cwt. **Red Betel-nuts.**—Malabari, Rs. 14 to 16 per cwt.; Kumpta, Rs. 12 to 18 per cwt.; Marorkhudi, Rs. 16 to 17 per cwt.; Goa, Rs. 24 to 32 per cwt.; Wasai, Rs. 20 per cwt.; Malwa, Rs. 12 to 13 per cwt.; Vingorla, Rs. 12 to 13 per cwt.; and Calcutta, Rs. 10 to 12 per cwt. It would appear that the poorer classes use various substitutes for the betel-nut, for example the seeds of *Calamus erectus*, Roxb.

At the base of the petiole is found a beautiful black horsehair-like *Fibre* known as the *Ejú* or *Comuta* Fibre. Within the sheaths is a layer of reticulated...
ARSENIC: WHITE, YELLOW AND RED ARSENIC

fibres said to be in great demand in China for caulking boats. It is also used for kindling fires and in Manipur to filter water. It has been recommended for ropes intended for use under water and even as covering for submarine telegraph cables. The coarsest fibre is only fit for brush-making. For this purpose the leaves are first washed and then soaked in an alkaline solution (Morris, Cantor Lect., Journ. Soc. Arts., Oct. 18, 1895, 931). Sandals are made from the leaf-sheath. [Cf. also Roxb., Obs. on Substitutes for Hemp and Flax, 1809—a paper which gives some results of a comparative test with ejù fibre.] The sago from the interior of the stem, although inferior to that obtained from the true sago palm (Metroxylon Sago, Rott.), is nevertheless an article of Food. It is the source of the Java Sago, which is of considerable importance throughout the Malaya, although the palm is chiefly cultivated for its sap from which palm-wine (toddy), spirit (arak), sugar and vinegar are prepared (see Mait Liquors, p. 760). A long and interesting account of the process of extraction of the sap (Simmonds, Trop. Agri., 248) will be found in the Dictionary (i., 303), and Tschirch (Indische Heil und Nutz-Pflanzen, 159–161, pl. 97) describes the uses and appearance of the palm in Java. The latter observes that it is not worth while to grow the palm for sugar because its production per acre is insufficient. He gives the yield for Java as about 8,000 lb. per hectare (say 2½ acres). The estimate quoted by Simmonds is about 6,600 lb. to the acre. Jumelle (Les Cult. Colon. Pl. (Aliment.), 27) says that about 400 trees can be planted to the acre and from each tree can be had 154 lb. of sago, giving the enormous total of 61,600 lb. to the acre. Roxburgh remarks that one palm gave about 150 lb. of good sago-meal. The palm will grow on soils where the cultivation of cereals could not succeed. "The palm dies after ripening its whole crop of fruit, and the stems, which speedily become hollow, are then useful for troughs and water-channels, lasting well underground" (Gamble, Lc. 728). [Cf. Milburn, Or. Comm., 1885, 310; "Durch Tropenpflanzer," iii. 1908, 509; and A. Wightill, Griff.; Talbot, Dist Trees, etc., 1902, 340. This is the dosdel, a palm which according to the excise reports is often tapped for toddy.

Arsenic.

White Arsenic.

Orpiment.

Sulphides.

Arsenic (Oxide), including Orpiment and Realgar; Ball, Man. Econ. Geol. Ind., 1881, 162, 592, 606; Holland, Rec. Geol. Surv. Ind., xxxii., 97. This metal is met with commercially in India in either of the three forms:—the Oxide, commonly called White Arsenic or Arsenious Acid, safed sambul, somal, etc.; the Sulphides, known as Orpiment, Yellow Arsenic, haritala, hsae-dan, etc.; and Realgar, Red Arsenic, mansil, etc.

White Arsenic is purely a manufactured article obtained by sublimation of the smelting of arsenical pyrites. The sulphides are natural minerals, through they can be artificially prepared. Of orpiment there are two qualities, (1) the medicinal and criminal form, consisting of smooth shining scales, which is chiefly imported into Bombay from the Persian Gulf ports, and (2) the coarser and less poisonous form, which occurs in opaque masses. The sulphides of arsenic are regularly drawn from Munsari in Kumaon, from Chitral and from Upper Burma and Yunnan. An interesting account of the orpiment mines of Chitral will be found in The Pioneer (Sept. 9, 1898). That from Munsari is brought by the Bhutias to the Bagesar fair. Orpiment is also carried from the Swat country and Kashgar to Peshawar, and from Herat to Kandahar. All three forms of arsenic have always been imported from Burma and China, and although white arsenic is now mainly brought by sea, the sulphides still form a valuable transit-trade from Western China through Upper Burma. There has been some trade, both export and import, in arsenic. The average export of Indian arsenic (excluding orpiment) from 1897 to 1903 was about 334 cwt., valued at £525, whilst the average import was 2,340 cwt., valued at £3,110. In 1906–7 the exports were 106 cwt., valued at Rs. 2,233, and the imports 1,925 cwt., valued at Rs. 44,196. The imports of orpiment into Burma from Western China averaged in 1897–1903, 9,551 cwt., valued at £11,470. The tendency seems to be for the trade to increase whilst prices fall.

It may be mentioned of white arsenic, that of all poisons it is the most frequently resorted to, especially in the Panjab, which has about 50 per cent. of the recorded cases of such poisoning. In the Annual Report for 1902 the Chemical Examiner, Panjab, observed that 64 per cent. of the cases of human poisoning in that year were with arsenic. However, by the Poisons Act of 1904 very wide
INDIAN WORMWOOD

discretionary powers were granted to the local Governments, subject to the control of the Governor-General in Council. Special restrictions are placed upon the traffic in white arsenic. Orpiment, besides being a Pigment and a Dye, is an essential ingredient in the manufacture of shellac, lac toys, Afridi wax-cloths, etc. [Cf. Tuleef Shereef (Playfair, transl.), 1853, 99, 156, 173; Watt, Ind. Art at Delhi, 1903, 211, 221-2, 291; Hooper, Rep. Labor. Ind. Mus., 1903-4, 36.]

ARTEMISIA, Linn.: Fl. Br. Ind., iii., 321-30; COMPOSITAE.

A. absinthium, Linn.; Heuzé, Les Pl. Indiast., 1895, iv., 343-9. The Absinthe, Wormwood, *afchantin, vilayati-afchantin*. An aromatic herb met with in Kashmir at altitudes of 5,000 to 7,000 feet; distributed to North Asia, Afghanistan, and westward to the Atlantic. This wormwood yields by distillation a dark green or yellow Oil having a strong odour of the plant and an acrid taste. In large doses it is a violent narcotic poison. In Medicine the whole herb is considered an aromatic tonic and anthelmintic, but in Europe is now relegated to the position of a domestic medicine. A liqueur consisting of an alcoholic solution of oil of wormwood with flavouring ingredients forms the Absinthe so largely consumed in France. Foster (Engl. Factories Ind., 1618-21, 338) alludes to "wormwood wine" among the articles provided for the Company's ships.

A. maritima, Linn.; Pharmacog. Ind., ii., 288. Wormseed, Santonin, *shih, kirmád, kirmádi-owa* (or kirmáni owa), etc. A very variable plant found in the Western Himalaya from Kashmir to Kumaon, altitude 7,000 to 9,000 feet, and abundant in Western Tibet on salt-plains between 9,000 and 14,000 feet. The Levant wormseed of European commerce comes from Persia, Asia Minor, etc., whilst the Barbary wormseed comes from Palestine and Arabia. The flower-heads are largely used for their anthelmintic, deobstruent, and stomachic- tonic qualities. Santonin is now well known to the Natives of India and is largely imported from Germany, but according to Dr. von Schroeder it is not poisonous to ascarides as was formerly thought, but merely drives them into the large intestine whence they can be removed. Wormseed is brought from Russia and also from Afghanistan and Persia, its value being about Rs. 2½ to 3 per Surat maund (37½ lb.); but much of the prepared santonin sold in the bazars is adulterated to the extent of three-fourths with gum, boracic acid, etc. Details of the trade are not available. Duthie observes that in the Himalaya ponies are fed upon this plant with relish, and he adds that "other species of *Artemisia* are mentioned as affording good fodder for sheep on the Panjáb Himalaya." The Kew Bulletin (June 1893, 127), commenting on this, observes that in localities where hardly any other vegetation exists, the use of the wormseed as a fodder plant might prove of value. Church reported on a bundle of dry leaves received at Kew from Duthie. The following is his analysis:

Percentage composition of *Artemisia maritima*:

<table>
<thead>
<tr>

<td>8-3</td>
</tr>
</tbody>
</table>

Church remarks that the plant contains rather less albuminoids, less digestible carbohydrates, and more fibre than the average hay of mixed grasses. It is, however, thrice as rich in albuminoids as the straw of European cereals. The harsh woody texture of the plant and its sickly odour would not commend its use as the chief ingredient in horse-fodder; but to any animals not deterred by these factors it might prove of considerable value under such special circumstances as obtain in barren tracts of the Western Himalaya. *A. parviflora* is also browsed by sheep and goats. [Cf. List of Himalayan Fodder Plants (excluding grasses), D.E.P., iii., 427.]

A. vulgaris, Linn.; Indian Wormwood, Flea-bane, *nágdoun, nágdoni, tataur, surband*, etc. A gregarious shrub found throughout the mountainous district of India and distributed to temperate Europe, Siam, Java, etc. One or two of the forms of this species, along with *A. Absinthium*, constitute the official wormwood, but by itself *A. vulgaris* is not an article of commerce. In Medicine it is held to have stomachic and tonic properties, and

the modern Hindus regard it as deobstruent and emmenagogue. It may be used as an inferior substitute for cinchona in intermittent fevers, and is probably one of the sources of the remedy known to the Muhammadans by the generic title of ajmanin. Said to be used in China in the preparation of an external application (moxa) employed in relieving pain (Bretschneider, Hist. Europ. Bot. Disc. in China, 1898, 234). [Cf. Hartless, Note, April 9, 1897; see Alkalis, etc., p. 50.]

**ARTOCARPUS INTEGRIFOLIA, Linn.**; *Fl. Br. Ind.*, v., 541; Gamble, *Man. Ind. Timbs.*, 652; *Urticaceae*. The Jack-fruit tree; *kánthád kánthád, káthád, panasa, phala, kantaka*, etc. A large evergreen tree cultivated in the warmer parts of India and Burma and occurring wild on the Eastern and Western Ghats up to altitudes of 4,000 feet. The dense mass of dark foliage and the huge fruits make this tree a prominent feature of most Indian villages.

Of the 40 odd species of *Artocarpus* indigenous to tropical Asia and the Pacific, only five are of economic importance in India. The four besides *A. integrifolia* are:—(1) *A. Chaplasha, Rosb.*; chaplash, sam, cham, pani, etc., met with in Eastern Bengal, Assam, Burma and the Andamans; (2) *A. hirsuta, Linn.*; the pat-phanas, anjalli, ayni, hebalsu, etc., which occurs in the Western Ghats up to 4,000 feet; (3) *A. inceia, Linn.*; the Bread-fruit, divy-halasa (divy-jack), rata-del, etc., an introduced South Sea species cultivated in S. and W. India, Ceylon and Burma, but unable to hold out against the Bengal winter; (4) *A. Lukocho, Rosb.*; the lukucha, dhea-phat, lovi, kamma-regu, myouk-lok, etc., found in Kumaon, Eastern Bengal, South India and Burma.

The bark yields a true **Gum** and the juice forms a useful **Cement**. *Cauotchouc* is obtained from all the above-named species, but the amount is very small (Hooper, *Rept. Labor. Ind. Mus.*, 1905–6, 26); that of *A. inceia* is employed as a glue in caulking canoes. A yellow **Dye** or **Pigment** is obtained by boiling the wood and sawdust (especially from the root of *A. Lukocho*), and this is employed in Burma, Madras, and elsewhere in dyeing the garments of priests (Aprt. Ledq., 1896, No. 4), but it is said not to dye with mordants (*Text. Mercury*, Jan. 25, 1896). The **Lac** insect is in Assam often obtained from *A. Chaplasha*. The bark yields a **Fibre**, that of *A. inceia*, being used apparently for clothing in Otaheite and other islands (Royle, *Fibrous Plants*, 341). The juice, leaves and root are employed in **Medicine**. The **Fruits** of all the above species are eaten occasionally, but that of *A. integrifolia* is of course most sought after. It is mentioned by almost all the early European writers, and in the *Ain-I-Akbari*, 1590 (Blochmann, transl., 66, 70). The name Jack-fruit was given by the Portuguese from the Malayalam *ismaka*. Kircher gives it the Chinese name of *po-lo-mi*. Varthéma (*Travels*, 1610 (ed. Hakl, Soc.), 159) calls it *ciecara*. The fruit is seldom eaten by Europeans owing to the smell of the ripe pulp, but the Natives regard it as one of the best fruits of the country. It is, as a rule, from 12 to 18 inches long, 6 to 8 inches in diameter, and should be called a *fructescence*. If the component flakes be fermented and distilled they yield an alcoholic beverage, and the roasted seeds taste not unlike chestnuts. The **Timber** of all the species seasons well, and is considered valuable, being used for canoes, doors, frames, etc. That of *A. hirsuta* is the anjeli-wood of commerce, and that of *A. integrifolia* is exported to Europe for cabinet-work, turnery and brush-backs. [Cf. Vertomannus, *Travels*, in *Hakl. Voy.*, 1811, iv., 585; Barber, *Memoirs*, 1519 (Leyden and Erskine, transl., 325); Garcia de Orta, 1563, Coll., xxxviii.; Linschoten, *Voy. E. Ind.*, 1598 (ed. Hakl. Soc.), ii., 20; Pyrard, *Voy. E. Ind.*, 1619 (ed. Hakl. Soc.), ii., 366; Clusius, *Hist. Exot. Pl.*, 1605, 281; Boym, *Fl. **ASBESTOS**; Ball, *Man. Econ. Geol. Ind.*, 518–9, 631; Holland, *Rec. Geol. Surv. Ind.*, xxxii., 99. A fibrous variety of amphibole which in Bombay has been called *shank-ha-polita* (wiek made of shells). It is reported to occur in Afghanistan, the Panjáb, Garhwal, Bhopawar (in Central India), Chota Nagpur, and Mysore.
TRAGACANTH AND HOG-GUMS

The average recorded yearly production in India would seem to be insignificant, namely about 5 to 6 cwt., valued at Rs. 40 to 48, but the great increase in the demand for fireproof materials has resulted in efforts being made to discover new and more profitable sources of supply (Min. Res., 1896-7). Recent discoveries in Central India and Rajputana seem likely to prove of value. In November 1899 two samples of asbestos found in the Jobat State, Central India Agency, were sent to the Imperial Institute, London, for analysis and report. The Director replied that both samples consisted of soft friable asbestos chiefly of very short staple. They were of inferior colour, even the so-called white variety being grey and impure. A commercial expert was of opinion that it would not pay to bring it to Europe, but that it might be found useful locally for fireproof packing, decorative work, etc. [Cf. Yates, Tex. Antig., 1843, 356-65; Textile Mercury, April 11, 1896; Hanusek, Micro. Tech. Prod. (Winton & Barber, transl.) 1907, 156-7.]

From this and perhaps several other species is obtained a Gum called katīra or gabina which exudes from fissures in the bark. This is known in Indian commerce as Tragacanth. It is further said that on the stem being cut across, the gummy substance shoots out of the medullary cavity in the form of pipe-Tragacanth. Aitchison observes: "This is collected in large quantities near Bzbd in Khorasan for exportation in all directions to India, Persia and Turkestan to be chiefly employed in the stiffening, glazing, and facing of local fabrics. Most of the gum sold in India as katīra is this and not the product of any Indian plant." Possibly another species (A. sarcoceola, Dymoch.; ansuzul, ansurul, gūjār, gūzahād, etc.) is the drug which was known as sarcoceola to Fliny, Dioscorides, Avicenna, etc. It is hardly, if ever, met with in Europe at the present day, although still used in the East. The gum is imported into India, and is one of the principal ingredients in the lēp (plaster) employed by Parsis to set fractured bones, etc. The average value is said to be about Rs. 3 per maund of 37½ lb. Aitchison is of opinion that without further knowledge of the plant than was derived from finding the fruit of an Atragatus amongst the gum and from an experiment with the seed, it would have been better not to identify this as a new species, since in all probability it will be found to be a form already described by Bunge. The drug consists of pale-yellow irregular grains not unlike crushed resin, and is said to be collected by being shaken off the tree onto a cloth. Eaten by ladies to improve their appearance and to give the skin a gloss.

Astragalus (Tragacanth) Substitutes: the Bassora or Hog-gums of India,—This is a group of gums resembling Tragacanth, but much inferior, the colour being most objectionable. The collective name in commerce is Bassora Gum, given because the gum of this class which first attracted attention is supposed to have been exported from Bassora. In India these gums are collectively known as katīra, though Aitchison observes that most of the katīra gums are non-Indian in origin. Chemically Tragacanthin and Bassarin are probably identical. The Indian Bassoras or Hog-gums are as follows:—

- Allanthus excelsa.
- Bombax malabaricum.
- Cochleospermum Gossypium.
- Moringa pterygosperma.

ATROPA BELLADONNA, Linn.; Fl. Br. Ind., iv., 241; Solanaceæ. Deadly Nightshade, sangyardur, angūr-shējā, sūchā, gīrbūtī, ustrung, yebraj, luckmūna. A coarse glabrous herb native of the Western Himalaya from Simla to Kashmir at altitudes of 6,000 to 12,000 feet; distributed to Europe and North Persia.

Gum.

ATROPA BELLADONNA

Lep.
AVENA SATIVA

Medicine.

The official parts of the plant are its leaves and the dried roots, which are powerfully sedative, anodyne and antispasmodic. The properties of the drug are so well known that it is unnecessary to detail them here. It appears that although the Himalaya might supply the world with belladonna, its cultivation has been but indifferently investigated. (Of. Leake, Agri. Journ. Ind., 1907, ii., pt. ii., 210–11; Paulus Aegineta (Adams, Comment., iii., 240), etc., etc.; Pharmacog. Ind., ii., 572; Fluckiger and Hanbury, Pharmacog., 455–9; Rept. Ind. Hemp. Drugs Comm., 1894, i., 172; etc., etc.)

Oats.

Habitat.—There are some 13 species, in addition to the cultivated one met with in India. Of the wild forms all occur on the Himalaya, their area extending from Baluchistan and Afghanistan in the west, through Kashmir, Kumaon and Nepal to the extreme east in Sikkim. The species A. uscura, Muro, in addition to its Himalayan habitat, occurs on the Khasia hills, the Nilgiri hills and the mountains of Ceylon. Nowhere are the wild Avenas found abundantly; a few plants here and there is their usual condition, though several (such as A. jutna, Linn., A. proetensis, Linn., and A. subspicata, Clairv.) are widely dispersed, being met with very nearly throughout the temperate Himalaya.

History.—None of the truly indigenous species are ever cultivated in India. And in fact it would seem that the Natives do not recognise them as worthy of distinctive names, hence they do not separately distinguish the species, and the following names may very possibly denote any Avena including the cultivated A. sativa: —jai, javi, jeli, jahi, gandal, ganer, ganhel, gozang, jandel, etc. There would appear to be no well-authenticated classic names for either the plants or the grains in India, Africa, Arabia, Egypt, Persia, China or Japan. The bromos of the Greeks and the avena of the Latins were names given to wild species, but there is no satisfactory evidence that either the Greeks or the Romans cultivated the Oats. Paulus Aegineta (Adams, Comment., iii., 78) says that the chapter in Dioscorides on this subject is spurious, and that Aegineta simply translated Galen. The plant seems, however, to have been known in Asia Minor during fairly ancient times. Caspar Bauhin (Theat. Bot., 1638, 470–1) describes and figures two forms, viz. alba and muda; and of the former he says that according to Serapion it is called churta by the Arabs. A similar reference is made by the Hortus Santitatis (1491) to Serapion, but I have not been able to verify the passage in question. The reference in Pliny to the Germans who lived on oatmeal porridge, would seem to imply that that was curious and interesting news to the Romans. The ancient Slav ovisú is connected with the Latin ovis, so that the word avena would therefore mean "sheep-weed." (Cf. Hehn, Kulturpl. und Haust., 1894, 539.) De Candolle (Orig. Cult. Plants (Engl. ed.), 373–6) gives the derivation of oats as from the Anglo-Saxon ata or ate. He then concludes his very interesting and instructive account of this plant as follows:—"As all the varieties of oats are cultivated, and none have been discovered in a truly wild state, it is very probable that they are all derived from a single prehistoric form, a native of eastern temperate Europe and of Tartary."

One or two popular writers in India affirm that oats were carried there in the wake of Chingiz Khan, and that they were well known to the Mughal Emperors. In the Ain-i-Akbari, 1590 (Blochmann, transl., 135), mention is made of oats in the chapter on Fodd. It has also been said that Warren Hastings, when Resident at the Court of Moorshedabad, experimented with oats on the grounds of the Mothu Jheel. Be that statement as it may, the cultivation of oats in India certainly dates from at least the beginning of the 19th century, and though still unimportant has been extended all over the country, especially in the vicinity of large towns and stud farms. The grain does not appear to fill sufficiently to justify the attempt being made to introduce it as an article of human

Fodder.
food, and moreover its liability to fall from the ears on its ripening, induces its being harvested when still green. In India, accordingly, it is used exclusively for feeding horses. If harvested late, the grains are shed and the straw loses much in feeding value. The crop is, however, of considerable value since the straw is recognised as being very much more nutritious than that of either rice or wheat.

Cultivation.—This is similar to that of barley. Duthie and Fuller say that with a copious supply of water, oats will give as many as three cuttings of green fodder, and thereafter make sufficient growth to bear a thin crop of grain. A large proportion of the Hissar oats area is treated in that fashion as a green fodder crop. An acre, Mr. Mukerji says, should yield 30 maunds of grain and 30 of straw. Mr. Mollison observes that the finest quality of grain is produced on the lower slopes of the Himalaya. The crop is grown to a considerable extent in Delhi, Hissar and Meerut districts and to a less extent in Poona, Ahmednagar, Satara and Ahmedabad. All the acclimatised forms grown on the plains of India produce long thin grain with much husk, and the weight per bushel does not usually exceed 35 to 37 lb.

In the plains oats are sown in September to October, or as soon as the rains have subsided. Mollison, for example, says of Bombay that oats are only grown as a rabi season crop, and always under irrigation. They grow best on well-drained friable soils of a fair depth. Very light sand and dense clay are not suitable. In fact, adds Mollison, “oats are grown on the same kinds of soil and under the same conditions as irrigated wheat and barley.” The seed should be broadcasted, and about 100 lb. to the acre will be required. The crop comes to maturity in 3½ to 4 months. The grain can be threshed out on a board or trampled underfoot by bullocks. Mr. Mollison says that a fair outturn on good soil would be 1,800 to 2,200 lb. grain and 25 cwt. straw per acre. Oats as given to horses in India are invariably crushed and mixed with other food substances. [Cf. Butler, Formaline Treat. of Oat Smut, in Agri. Journ. Ind., 1906, i., pt. iii., 257-9.]

Trade.—The imports are small and come for the most part in ships that bring horses. Oatmeal is also to a certain extent imported under the heading of “provisions,” but as it is not separately declared, no particulars can be furnished. But the exports are more considerable than would at first sight be anticipated. During the past 20 years or so they have fluctuated from 50,000 to 80,000 cwt., valued at from 1½ to 4 lakhs of rupees. In 1906-7 the actual figures were 55,518 cwt., valued at Rs. 2,26,022. The traffic is not, however, progressive. It goes very nearly entirely from Bengal and to Mauritius.

AVERRHOA BILIMBI, Linn.; Fl. Br. Ind., i., 439; Gamble, Man. Ind. Timbs., 119; Pharmacog. Ind., i., 248; Cooke, Fl. Pres. Bomb., i., 168; Duthie, Fl. Upper Gang. Plain, i., 132; Geraniaceae. The bilimbi, blimbi, belambú, pulich-chakkay, pulusu-kvéd-lu, vilimbi, kainojom, kala-zoun-si, etc. A. Carambola, Linn.; the kamaranga, khramk, kamrangá, kamrangá, tamarak, kamarakha, tamara, etc. This and the preceding are commonly cultivated in gardens.

These small trees, called, according to Garcia de Orta, 1563 (Coll. xii.), balimba in Malaya and carambolas in Malabar, are fairly extensively grown for the sake of their fruits. It is customary to read of their having been introduced by the
Portuguese from America. The kermerick is not only mentioned in the Memoirs of Baber (Leyden and Erskine, transl., 325), of a date (approximately 1519 A.D.), or about 27 years after the discovery of America, but it is described in such terms as to leave no doubt whatever as to its identity. Baber gives his account of this fruit in a list of "Vegetable Products Peculiar to Hindustan," and makes no sort of suggestion of its having been only recently introduced. These facts, when taken in conjunction with the existence of a Sanskrit name, may be regarded as throwing grave doubts on the supposed American origin of the karmaranga. The fruits of the *Bittinb* ripen about the middle of summer and are used in pickles and curries. The flowers also are sometimes preserved. Of the *Cavemola*, the leaves, roots and fruits, having antiscorbutic properties, are used as cooling medicines. The fruits ripen about January, and when stewed are very palatable. The Natives sometimes eat them raw. When unripe they are astringent and are used as an acid in dyeing, or to remove iron-mould, owing to their containing much potassium-oxide. The Timber is said to be employed in the Sundribans for building purposes and for furniture. [Cf. Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), ii., 33; Acosta in Clusius, Hist. Exot. Pl., 1605, 286; Jacobus Bontius in Piso, Ind. Utiri re Nat. et Med., vi., 102; Rheede, Hort. Mal., iii., tt. 43-4; Buchanan-Hamilton, Stat. Acc. Dinaf., 162; Taylor, Topog. Stat. Dacea, 50; Mooden Sheriff, Med. Med. Med., 75-6; etc., etc.]

**AVICENNIA OFFICINALIS.** Linn.; Fl. Br. Ind., iv., 604; Gamble, *Man. Ind. Timbs.*, 546; Pharmacog. *Ind.*, iii., 82; *Verbenaceae*. The White Mangrove, *bina* (bani), mada, venkandan, karungandan, tivar, oepata, thame, lambey, etc., etc. A small tree or shrub of the salt marshes and tidal forests of India and Burma; found also in the Andaman and Nicobar Islands and the Malaya.

The bark of this tree is astringent and used by tanners (*Agri. Ledg.*, 1902, No. 17, 48). The ashes of the wood are used to wash cloth. The green fruit mixed with butter and boiled is made into a plaster for softening and maturing humours and to heal smallpox ulceration. The timber is brittle and employed only for firewood; it is reported as used in the Andamans in the construction of oil-mills, etc.

It is proposed to treat the Bamboos from the practical rather than the scientific standpoint, and accordingly to deal with them collectively instead of under their separate genera. But many of the purposes for which bamboos are utilised are met also by the Canes (*Calamus*, p. 202), by the Reeds, and other basket and wicker-work materials (*Baskets*, p. 115). The Canes proper are climbing palms, and the Reeds are species of grasses which, from the industrial point of view, are very nearly identical with the smaller bamboos. The Reeds proper are the species of *Phragmites*, as also certain species of *Arundinaria, Andropogon, Arundo, Ischaemum, Saccharum* and *Typha*. But many basket-materials are not grasses, and the link is thus given that carries the attempt
to classify these industrial substances away completely from the Bamboo and its associates into Mats, until it becomes logically impossible to separate Cotton, Silk and Wool—the chief matting materials—from the Bamboos, the Canes and the Reeds.

The following are the chief Indian genera and species of the Bambuseae as recognised by botanists, together with the more valuable special properties of each:

Arundinaria aristata, Gamble: khnap or u-shp, a thorny shrub of the Khasia and Jaintia hills, employed to tie thatch. [Cf. Ind. For., 1888, xiv., 309.]

A. Hookeriana, Munro: a cespitose species of the Eastern Himalaya—the singhali, prong, etc.; affords an edible seed. [Cf. Ind. For., 1888, xiv., 310–4; For. Adm. Rept., 1903, 9.]

A. intermedia, Munro: the nigali, titi nigali, parmiok, prong nok, etc. An East-Himalayan species, alt. 7,000 feet. Is an excellent hedge plant, the culms of which are strong and used for fishing-rods, baskets, mats, etc. Is largely exported from Darjeeling to the plains.

A. Khasiana, Munro: the namlang (or u-kadac namlang), a species of the Khasia hills, alt. 5,000 to 6,000 feet. Is often specially cultivated and used for wattle-and-daub walls. A. Pratuli, Gamble; Naga and Jaintia hills. A graceful climbing plant which has six stamens and is known as sampi, kena, etc. It is used in basket-work and in hut-building, etc. A. Mauri, Gamble, another climbing species, may also be mentioned. It occurs in the Jaintia hills and is known as beneng. Is used split as a binding material in hut-building.

A. racemosa, Munro: the maling, physem, miiknu, mehem, pheroung, pat-khu, etc. A Darjeeling gregarious species extensively employed in making and for roofs of Native houses, fences, garden supports, etc. Largely used in Darjeeling as fodder for ponies (Ind. For., 1888, xiv., 308–9).

A. spatshflora, Trin.: the high-level ringal, garu, deo ringal, etc., of the N.W. Himalaya (from the Suture), alt. 7,000 to 9,000 feet. Is the common undergrowth of deodor and pine. Often flowers gregariously. A. Wrightiana, Nees; the chevari—a shrubby species of the hills of Southern and Western India, specially abundant on the Nilgiris. Largely used for mats, baskets, walking-sticks, etc.; exported to Bombay and all over India. The young shoots are eaten and the grain has often proved of much value.

Bambusa arundinacea, Wild. The Spiny Bamboo or kanta bans, behor, bana, katanga, kalok, vae, ketu, kature, kotoka, goha, dongi, moga bogs, nai bans, vedura, penti-vedura (hollow bamboo), mungil, kyakatwa, etc. This tall, graceful bamboo is both wild and cultivated all over India and Burma, except in the Himalaya and Sub-Himalaya and the valleys of the Ganges and Indus. It is scarce in the Central Provinces but not uncommon in Gujerat. Very frequent in Orissa and the Kurnatok, both as a small and a large variety, and abundant in the Konkan and on the Western Ghat ranges. In the Deccan it occurs in the valleys (as it also does throughout South India), ascending the Nilgirs to alt. 3,000 feet. Scarce in Northern and Eastern Bengal and Assam, but becomes common in Burma from Pegu and Martaban to Tenasserim.

Gamble tells us that it flowers about every thirty years and is reproduced by seed, but several writers in the Indian press say only twice in a century. A forest of surpassing splendour is transformed into one of desolation and death, soon followed by fire, until the charred stems, dust and ashes are all that remain. But seeding would appear to take place in sections. A writer in the
THE INDIAN BAMBOOS

Gardeners' Chronicle describes the manifestation of 1862 as having commenced in Travancore, extended to Malabar in the following season, and in the next year to Coorg and Mysore.

The seeds, which somewhat resemble wheat, are edible, and have in certain years proved of great value in supplementing food-supplies, more especially since flowering very frequently accompanies seasons of famine or scarcity. Speaking, probably of this grain, Church (Food-Grains of Ind., 102) gives the nutrient value as 87. He then remarks: "The food value of bamboo grain, after the removal of the husk, is high; its defects are due to the low proportion of oil and mineral matter." The analysis, he says, shows 73-7 per cent. of starch, 11-8 albuminoids, 11-0 water, 1-7 fibre, 1-2 ash and 0-6 oil. The young shoots (kalla bâna) are greedily eaten and somewhat resemble asparagus; they appear above ground in August. The leaves are very largely employed as fodder, more especially for buffaloes and elephants. The leaves and tender twigs are also used medicinally, being supposed to possess emmenagogue properties. The silicious deposit within the joints, known as Tabâshir, though found in most, if not all bamboos, was first observed in connection with this species.

The Culms, which attain a height of 80 to 100 feet, and are 6 to 7 inches in diameter, are very largely employed (although this is by no means one of the best bamboos), but they are rather crooked and often knotty. At the same time the densely interlacing thorny branchlets make it difficult to extract the felled culms, hence it is not a species that would be cultivated in the commercial supply of bamboos. But as a hedge it has often proved of great value, and as Mr. Gamble says, except explosives nothing would have much effect against it. It is often badly attacked by a small hemipterous insect, an aphis which has been described under the name of Oregna bambusæ (Stebbing, Injurious Insects, 20-2). This attacks the leaves in such multitudes that it causes a sort of Manna to form. [Cf. Taylor, Topog. Stat. Dacca, 1840, 61; Pharmacog. Ind., 1893, iii., 585-92; Jasper Nicholls, Journ. Bomb. Nat. Hist. Soc., 1893, viii., 298; also Ind. For., 1895, xxxi., 90-5.]

B. Bâlooa, Roxb. The bâlooa bâna, bâloukâ, borô-bâna, sil bardia, tekbâria, wamnah, beru, betwa, etc. This well-marked and most useful bamboo is a native of the plains on the eastern side of India. The culms are 50 to 70 feet high and 3 to 6 inches in diameter; nodes swollen with a whitish ring above and hairy below. It is probably the best and strongest species for building purposes and is greatly esteemed in Calcutta, but it is not a handsome plant and would hardly be chosen for ornamental purposes. It is much used for scaffolding and is very durable if well seasoned by immersion in water, a process said to protect it from subsequent attack by Rostichus beetles (Working Plans, For. Jatpâi, 1898, 22.)

B. nutans, Wall. The pichle, biaâhulâ, nal bâna, mukial, makal, mahlu, mahl, paoshi-ting-ying, jotia, deobâna, wa-malang, sering-jat, etc. A moderate-sized graceful species, found on the lower Himalaya from the Jumna to Assam and Eastern Bengal, doubtfully wild anywhere west of Sarada but common near villages and along roads and canals in Dehra Dun. In Sikkim it is met with up to alt. 5,000 feet. Culms 20 to 40 feet high, 13 to 3 inches in diameter, and having internodes 15 to 18 inches long. Strong, straight, hard, good and much esteemed, and since they rise from the ground well apart, plantations of this species can be easily and profitably worked (Kanjilal, For. Ft. School Circ. U. Prov., 1901, 367).

B. polymorpha, Munro. A common species in the upper mixed forests of the Pegu Yomah and Martaban, often associated with teak and distributed westward to Assam and Eastern Bengal. The culms, which are found in dense clumps, are 50 to 60 feet high and 3 to 6 inches in thickness, much branched above and curling downwards. The species is known in Burma as kyâthan-wa (kyâ-thon-wa), in Assam as betiá, and in Bengal as jôma betiá; is considered one of the best bamboos for walls, floors, roofs of houses, etc. [Cf. Ind. For., 1876, i., 22; 1896, xxii., 70; 1897, xxii., 131, 263; 1903, xxix. (flowering of), 244-5, 513-6; Alpin, Reptl. Éxp. Shan States, 1887-8; Ind. and East Engineer, 1897, 166, etc.]

B. Tûlda, Roxb. The Common Bamboo of Bengal, tûlda, jowa, dyowa bâna, muk, mukor, kirani, matela, peka, mîrtinga, miitenga, wati, wamnâ, wagi, nal-bâna, deo-bâna, bijûlû, jat, jao, ghora, thîva, thâk, etc. This occurs in Central and Eastern Bengal, Assam and Burma, also on the hills of the Northern Circars and probably in Orissa. It is cultivated throughout Eastern Bengal

Common Bamboo of Rice Country.
and Burma, and is perhaps the most common bamboo in the rice country of Bengal and Assam. It is, however, somewhat difficult to distinguish from *B. indica*, and the two plants are consequently often much confused and the same vernacular names given to either indiscriminately. It flowers gregariously over considerable areas, but single flowering clumps are not unusual. The culms are green, streaked with yellow; they attain a height of from 20 to 70 feet and 2 to 4 inches in thickness. They are regarded as strong, but not so much so as those of *B. Buxtonii*.

**B. vulgaris**, *Browd*. In Bengal this is the *bdains* or *bdains*, that is, "Female Bamboo"—a name which in South India is also given to *B. arundinacea*. In other parts of the country it is the Golden or Yellow Bamboo, *barida*, *sun-drograi*, *kuluk*, or *kalak*, or *vamsa-kulaka*, *kulna*, *wda*, *wanet*, etc. This cosmopolitan species is cultivated and run wild over the warmer parts of India and Burma; its original country is uncertain, but it is found in Java, Mauritius, Madagascar, Algeria, the West Indies, Mexico and Central and South America, etc., etc. The culms are bright green or striped green and yellow, polished, shining. They attain a height of from 20 to 50 feet with a diameter of from 2 to 4 inches. The nodes are hardly raised but have a ring of brown hairs. The species is used chiefly in basket-making and to some extent in house-construction. [Cf. Lisbon, Bom. Grasses, 1896, 140; Talbot, List Trees, etc., 1902, 347; Firminier, Man. Gard. Ind. (ed. Cameron), 1904, 321.]

**Cephalostachyum capitatum**, *Muiret*. The *gopian*, *gope*, *payong*, *silea*, *sillea*, etc. A shrubby semi-scandent bamboo found in the North-East Himalaya and in the Khasia, Jaintia and Naga hills. It is a graceful plant which often forms dense thickets. The wood is used by the Lepchas in preference to that of any other kind (for making bows and arrows), and is also regarded as good for baskets. The joints of the culms are often 2½ feet long. The leaves are employed as *Fodder* and the seeds are eaten in times of scarcity.

**C. pergracile**, *Muiret*. Is known as *latang*, *madang*, *tina*, *kengwa*, etc. A deciduous arborescent bamboo common in Burma, and after *Dendrocalamus strictus* is there, perhaps, the most abundant of all species. It occurs also in Chota Nagpur and Assam and is being cultivated experimentally in South India. The culms are largely used for building purposes, floating timber and mat-making. In Burma the joints are employed for boiling the *kaunyin* or glutinous rice, the effect being to produce a long mould of boiled rice which can be carried about and eaten on journeys. In Manipur I observed my coolies invariably cooked their food in joints of green bamboo. The fact of their being green and the presence of the fluid within, seemed to render the fire incapable of burning these wooden cooking-pots.

**Dendrocalamus Brandisii**, Kurz. This is sometimes confused with *D. giganteus*, and, like it, is often called *wabo*. Its proper names are *kyelowa*, *wawoy*, *wawak*, *wakhi*, etc. Mr. Alpin (Rept. on the Shan States, 1887-8) calls it *kyello bamboo*. It is a lofty tufted evergreen species with ashy-grey culms from 60 to 120 feet in length and 5 to 8 inches in diameter. It is found in the tropical forests of Pegu and of Martaban up to alt. 4,000 feet, chiefly on calcareous rocks. It is said to flower sporadically and not to die off after flowering. *Nisbet* (Burma under Brit. Rule and Before, 1901, i., 381) says the culms are employed for boat masts.

**D. giganteus**, *Muiret*. This truly gigantic grass is a native of the Malay Peninsula but much cultivated in Burma, where it is known as *wabo* and in Assam as *woroa*. It is used in Burma for posts and rafters in house-building, for carts, etc., and the joints for poles, boxes, flower-pots, etc. The large culms (often 120 feet long and 25 to 30 inches in circumference) are said to fetch Rs. 2-4 each, or in quantity, Rs. 150 to Rs. 180 per hundred. At the Colonial and Indian Exhibition, London, I had extra fine culms cut into short lengths and prepared as umbrella stands, when they readily fetched 5s. to 10s. each, according to size. [Cf. Vartheena, Travels, 1510 (ed. Hakl. Soc.), 218-9.]

**Hamiltoni**, *Nees & Arn.* In the lower North-West hills this is called *chye*; in Darjeeling *tama*, *pao*, and *pa-shing*; in Assam and Burma *kokua* or *kalua*, *wabo*, *peeka*, *fonay*, *wanoke*, *wabo-miyantewa*, etc. It is a large bamboo that flowers sporadically and also gregariously. It occurs in the North-East Himalaya, Assam, Khasia hills, Sylhet and Upper Burma, and is distributed to

Tea-shade.

Water-pail Bamboo.

D.E.P., iii., 72.

D. Hookeri, Munro. The seiat, ussey, sejai, sirong, denga, ukotang, patu, tili, kawa ule. A large bamboo with long curving branches, met with in the Khasia and Jaintia hills, alt. 2,000 to 5,000 feet, in the Daphila hills, also Sikkim, and is distributed to Bhamo in Upper Burma. The culms are from 50 to 60 feet high and 4 to 6 inches in diameter, walls about 1 inch thick and internodes 18 to 20 inches long. The culms are used in making water and milk pails (chungsas).

D. longispathus, Kurz. A large and handsome bamboo of East Bengal and Burma, chiefly near streams. It is known as the khang, ora, wa-yu and talaqu. Wa-ya in Burmese means "Stinging Bamboo," a name given in allusion to the irritating hairs on the sheath. The culms reach to 60 feet high; internodes 10 to 24 inches long and 3 to 4 inches in diameter, with the walls half an inch thick. It often roots at the nodes, and the culm sheaths are papery and more or less persistent. It is not much appreciated as a building material, though used when better kinds are not available. [Cf. Madras Admin. Rept. (numerous passages), 1888–9 to 1898.]

Sikkim Milk-pail Bamboo.

Churns.

Poison.

D.E.P., iii., 72.

D. sikkimensis, Gamble. The pugrany of Darjeeling, wodah of the Garo hills and the tiria, vola in Nepal. A large bamboo, with caspito-seams and few culms, but these 50 to 60 feet or more high and 5 to 7 inches in diameter. It occurs on the hills of the North-East Himalaya—Sikkim and Bhutan—at altitudes of 4,000 to 6,000 feet, also at Tura in the Garo hills, and is cultivated in several localities. It is the largest and perhaps the most beautiful species in Sikkim, where its thick culms are preferred for making the chungsas (or pails) in which water and milk are carried and butter churned. But the leaves have the evil reputation of being poisonous to cattle and horses.

D. strictus, Nees. This is the most common, most widespread and most universally used of all Indian bamboos. It is the "Male Bamboo," the bons, buns kapan, bons khard, karai, mathan, mat, bur mat, salia bons, halpa, vadur, bhiru, kark, kal mangal, khibi bidaru, sadhanapa-vadur, kauka, myinina, etc. It is deciduous, densely tufted, gregarious, has strong often solid culms, which average from 30 to 50 feet high and 1 to 3 inches in diameter. It occurs on all mountains and on all the dry hills throughout India except the Western Ghats, Eastern Bengal and Assam. In South India and Burma it reaches a large size and has hollow culms, while in the drier Deccan hills and the Siwaliks it is smaller but has nearly solid culms. Flowering is usually gregarious: the flowers appear in the cold season, the seed ripens in June and is shed, but the husk remains. After flowering, the plants die and are replaced by seedlings.

Col. Doveton (Ind. For., ix., 529) gives an account of the Indian uses of this bamboo in connection with the Central Provinces, that might be consulted as it is characteristic of the species wherever found. Amongst other uses, he mentions rafters and battens, spear and lance-shafts, walking-sticks, whip-handles, the manufacture of mats, roofing, sieves, hand-punahs, umbrellas, chairs, vessels for holding grease and oil, bows, arrows, and cordage, etc., etc. When converted into charcoal it is in request for the finer smiths’ work. The dry stems are also used for torches and the production of fire by friction. The leaves are much sought after as food for buffaloes and even for horses. The seed is used in times of famine as a food-grain, and the young and tender shoots are also largely eaten as vegetables (Rec. Bot. Surv. Ind., 1903–4, ii., 29, 156, 190). In another paragraph particulars will be found of the recent and highly interesting discovery of manna (saccharon) seen on this species. [Cf. Agri. Ledg., 1900, No. 17.]

D. sikkimensis, Gumble. The pugrany of Darjeeling, wodah of the Garo hills and the tiria, vola in Nepal. A large bamboo, with caspito-seams and few culms, but these 50 to 60 feet or more high and 5 to 7 inches in diameter. It occurs on the hills of the North-East Himalaya—Sikkim and Bhutan—at altitudes of 4,000 to 6,000 feet, also at Tura in the Garo hills, and is cultivated in several localities. It is the largest and perhaps the most beautiful species in Sikkim, where its thick culms are preferred for making the chungsas (or pails) in which water and milk are carried and butter churned. But the leaves have the evil reputation of being poisonous to cattle and horses.

D. strictus, Nees. This is the most common, most widespread and most universally used of all Indian bamboos. It is the "Male Bamboo," the bons, buns kapan, bons khard, karai, mathan, mat, bur mat, salia bons, halpa, vadur, bhiru, kark, kal mangal, khibi bidaru, sadhanapa-vadur, kauka, myinina, etc. It is deciduous, densely tufted, gregarious, has strong often solid culms, which average from 30 to 50 feet high and 1 to 3 inches in diameter. It occurs on all mountains and on all the dry hills throughout India except the Western Ghats, Eastern Bengal and Assam. In South India and Burma it reaches a large size and has hollow culms, while in the drier Deccan hills and the Siwaliks it is smaller but has nearly solid culms. Flowering is usually gregarious: the flowers appear in the cold season, the seed ripens in June and is shed, but the husk remains. After flowering, the plants die and are replaced by seedlings.

Col. Doveton (Ind. For., ix., 529) gives an account of the Indian uses of this bamboo in connection with the Central Provinces, that might be consulted as it is characteristic of the species wherever found. Amongst other uses, he mentions rafters and battens, spear and lance-shafts, walking-sticks, whip-handles, the manufacture of mats, roofing, sieves, hand-punahs, umbrellas, chairs, vessels for holding grease and oil, bows, arrows, and cordage, etc., etc. When converted into charcoal it is in request for the finer smiths’ work. The dry stems are also used for torches and the production of fire by friction. The leaves are much sought after as food for buffaloes and even for horses. The seed is used in times of famine as a food-grain, and the young and tender shoots are also largely eaten as vegetables (Rec. Bot. Surv. Ind., 1903–4, ii., 29, 156, 190). In another paragraph particulars will be found of the recent and highly interesting discovery of manna (saccharon) seen on this species. [Cf. Agri. Ledg., 1900, No. 17.]
One of the chief European uses for this bamboo is the manufacture of lanceshafts. For this purpose solid stems of uniform thickness are essential. But apparently they are only here and there completely solid. Thus the supply is unequal to the demand. Split up and again united they are made into fishings��d. For bamboo furniture the hollow stems are now largely utilised. In India it fetches from 8 annas to Rs. 1–8 per hundred in the forests, but the transport charges to the coast are the chief items of expense. Gamble estimates the total annual production at possibly 100 million culms. [Cf. For. Admin. Rept. C. Prov., 1892–3, 13–4; Lisbon, Bomb. Grasses, 1896, 141–4; Lovегrove, Ind. For., 1900, xxvi., 433–42; Smythies, Ind. For., 1901, xxvii., 126; Kanjiл, For. Fl. School Circ. U. Prov., 1901, 369; Church, Food-Grains of Ind., supр., 1901, 7; Brάnthwaite, Ind. For., 1902, xxvii., 233; Muriel, Ind. For., xxix., 507–8.]

Gigantochloa macrostachya, Kurz. The tekserah, мали, madayuwa, wanet, wabrat, etc. An evergreen bamboo with striped culms from 30 to 50 feet long and 2½ to 4 inches thick. Native of Assam, Chittagong and Burma. G. vеrticillата is the beautiful striped species often cultivated in India but introduced from the Malay. Gamble suspects G. mаrvTeniiа, Kurz, the kula of Bengal and талагуwa of Burma, may have to be placed under Оxytenantherа. Melocanus compactiftrs, Benth., Hook., f. This arborescent, tufted and scandent evergreen occurs in Eastern Bengal and Burma, viz. from Sylhet and Chittagong down to Martaban, but is frequent only between alt. 4,000 and 6,000 feet. It is in Burma known as wa-nwe, in the Kachin country as nаchinuа, in Chittagong as lota, and in Sylhet as daral. The culms are largely used for basket-work, and when split in the green state may be reduced to such fine and pliable strands that they may be woven. It is the material employed in the construction of the shoes worn by the Kachin, Shan and Chinese traders seen in Bhano, and in the characteristic lacquered ware of Upper Burma. The seed is large, edible and mealy, somewhat resembling the chestnut. [Cf. Ind. For., 1902, xxviii., 422; Ind. Art at Delhi, 1903, 223.]

Meloсa пambusoides, Ten. This is sometimes called the bamboo-bearing bamboo and is known by the following vernacular names—мali, metanga, пaλи, tаrа, wаtι, агtrεм, тυrιh, wαтрαu, luγαυυгυa, ραγυ-tullа, hayинυa, etc. Is often called the Terai bamboo. An arborescent evergreen, with distant culms, arising from the ramifications of an underground rhizome. Met with throughout Eastern Bengal and Burma. In Chittagong it is perhaps the most prevalent species, and is universally employed for building purposes and mat-making. It is very largely exported to Lower Bengal, and according to the forest returns about 16 million culms are yearly required in the Gangetic Delta. It is, in fact, from the Indian standpoint, one of the most valuable of bamboos. Though thin-walled is strong and durable and has the great advantage of being straight and of possessing only very slight knots. It is doubtless the pαλи and aυгorя bamboo referred to by Lewin, who observes that white-ants will not attack it. Gregson says the young shoots are often killed by a beetle— Cvптrfuchelus longipes (Ind. For., xxv., 420). The fruit is large, edible and occasionally germinates and makes as much as 6 inches growth before it drops from the stem (Staрl, Trans. Л.nn. Soc., 1901—5, vi., 409–23). Tabashir is very often abundant in the stems (Roξb, Pl. Ind., ii., 197).

Ochiandra travancorica, Benth., ex Gamble; τρακάλι (Braνдiа), ἵλο[ν, (Bourdillon). A shrubby gregarious reed or bamboo, met with on the mountains and plains of South India (in Tinnevelly and Travancore districts), up to alt. 3,000 to 5,000 feet. It has exceptionally large flowers and fruits and as many as 120 stamens in one spikelet, united more or less into a tube. The culms attain a height of 20 feet, and the internodes are sometimes 5 feet in length. T. F. Bourdillon, Conservator of Forests, Travancore State, has furnished much useful information regarding this species. It flowers, he says, gregariously every 30 to 35 years, then dies down. The shoots when 6 to 9 months old constitute a splendid paper material. For some five years or so a paper-mill was run in Travancore which used this material almost exclusively. The fibre has been pronounced superior to esparto but the expense of chemicals killed the industry, as it seems a larger quantity was required than with other paper materials. [Cf. Ind. For., 1899, xxv., 152.]

Оxytenantherа nigroсiliatа, Муво; ψωδά (And.) ωάshυι (Гarо), bolαnгι bάνς (Orissа). A tufted evergreen species found in Orissa, Chittagong, Burma, the Andaman Islands and Malay Peninsula. Used in house-building and for basket-work.

The Umbrella-handled Bamboo.

**THE INDIAN BAMBOOS**

O. Stocksl., *Munro.* The koda, *ur schme,* etc., a slender bamboo of the Konkan. Talbot (List Trees, etc., 1902, 348) says it is commonly cultivated along the coast but is rare in the Ghat forests. It is a strong bamboo, used for punting-poles, Native umbrellas and baskets.

*Pseudostachyum polymorphum,* *Munro;* *tingling,* *purhiok,* *paphok,* wachall, *bajal,* *tolti,* *nai,* *bawa,* etc. Large shrubby or semi-arborescent bamboo, has culms arising singly from a long, creeping, jointed rhizome. Tall and branched at the top only, thus often taking support from neighbouring trees. Young shoots come away freely and are very straight. This species occurs in the Eastern Himalaya, Assam and Upper Burma and ascends the hills (to alt. 5,000 feet), but is most abundant and prolific in moist valleys or under the shade of trees. It is a very valuable bamboo, and in Sikkim is considered the best sort for the basket-work used on the tea estates, etc. The culms are easily split and the laths flexible and durable. It is also largely utilised in the manufacture of mats and for tying the rafters of huts.

*Telnostachyum Duflooa,* *Gamble.* A moderate-sized tufted bamboo, tending to become scandent. Occurs throughout Northern and Eastern Bengal and from Bhutan through Assam, Sylhet and Chittagong to Upper Burma. There are two forms (possibly two species), a large and a small. The following vernacular names have been recorded for these: the larger form—*dolwu,* *dulooa,* *nakela,* *pajola,* *syowa,* and the smaller—*siklu,* *baya,* *thakka,* *pura,* *waba,* etc. The culms are used as water-pails and in the manufacture of umbrellas, also for basket and mat-work, and in the manufacture of the small boxes used to carry *pán.* It is also employed locally for building purposes. Lewin (Hill Tracts of Chittagong, 1869, 139) speaks of the large kind as much employed for making the mats used in loading vessels with cargo.

T. Wightli, *Bedd.* The *huda,* *wontenugyi,* etc., is a tall semi-scandent bamboo found on the slopes of the Western Ghats from North Kanara to Cape Comorin (alt. 3,000 to 5,000 feet). In North Kanara, according to Talbot (List Trees, etc., 1894, 206), it is much used in the construction of temporary bridges.

*Thyrsostachys siamensis,* *Gamble.* This is called “The Umbrella-handle Bamboo,” or the “Monastery Bamboo” (see *kyauug-wa*) because of its being commonly cultivated in the monastery gardens, especially in Kyaukse and Meiktila. One of the most elegant of bamboos because of the regularity of its nodes. It is caspitoise and deciduous; the culms become 25 to 40 feet high and 1½ to 2 inches in diameter; are straight and not branched till high up but are covered with the persistent old sheaths. It is found in Burma from Mandalay to Tenasserim; also in Siam. It is largely exported from Moulim and used for umbrella handles, for which it is well qualified, being light, strong and straight. [Cf. Mason, *Burma and Its People* (ed. Theobald), ii., 99; Firminger, *Man. Gard. Ind.* (ed. Cameron), 1904, 321.]

**GENERAL STATEMENT OF THE PROPERTIES AND USES OF BAMBOOS.**

Few plants are more valuable to man, especially to the inhabitants of tropical countries, than the various species of the arborescent grasses collectively denominated the Bamboos. The *Flora of British India* describes 117 species as met with in India, and refers these to 15 genera. All bamboos may be viewed as of economic and industrial value, but the majority do not differ very materially from one another. It accordingly follows that a general statement of the properties and uses of the bamboos collectively may be of value, especially when taken in conjunction with the fairly detailed enumeration of the specific peculiarities of the better-known forms already furnished.

**The Culm or Stem.—** It may be said that under most of the genera indicated one or more species of gigantic or even arborescent grasses have been described by botanists, each of which might popularly be called a "Bamboo." Many authors, however, speak of *Bambusa arundinacea* as "the Bamboo," an expression which is quite incorrect, since the Spiny Bamboo of South and West India and Burma is by no means either the

most useful or the most abundant species in India as a whole. It is quite customary also to read of Bambusa vulgaris rendered as "The Common Bamboo," whereas in India, at least, that cosmopolitan cultivated species is hardly a common plant. In the rice-producing areas it might in fact be more correct to speak of Bambusa Tuld as "the common Bamboo," and as far as Bengal is concerned that certainly is the most abundant species, although B. Balcooa is nearly as plentiful and ever so much more useful. On these grounds the baku bāns would be pronounced "The Bamboo" by the people of India. The term "Male Bamboo" is given to any solid (or nearly solid) bamboo used for spear or lance staves and for walking-sticks, though it is more particularly applicable to Dendrocalamus strictus. Arundinaria Prainii and Oxytenanthera Stocksii have also, however, more or less solid culms.

The home of the giant forms of bamboo is the tropical and extra-tropical forests; in the temperate zones they dwindle down to mere under-shrubs, until they become scarcely distinguishable from other grasses. Arundinaria densiflora might be described as the smallest and Dendrocalamus giganteus (or D. Brandisii) the tallest of bamboos. Some species have their stems of nearly one thickness throughout, and possess at the same time very long joints; such are specially designated as umbrella bamboos because suitable for umbrella handles. Of this nature may be mentioned Arundinaria Wightiana, Oxytenanthera Stocksii, Phyllostachys bambusoides, and Thyrsostachys liamensis. In this connection it may be observed that a Calcutta firm, who manufacture umbrellas on a large scale, have to import from China the canes they use as handles because India does not appear able to compete in quality and price with the imported article. Other species form long thin tubes such as Arundinaria falcata, and are, in consequence, described as huka-tube or fishing-rod bamboos (Ind. For., 1889, xv., 92, 141). While still others have very thin and uniform shells with large cavities, and are in consequence readily adaptable for water-pails, milk-churns, drinking-jugs, and the like. Of this nature may be mentioned Bambusa pallida, Dendrocalamus sikkimensis and Teinostachyum Dullooa. Of a very different kind are those specially valued because of the ease with which they can be worked up into mats and baskets, as, for example, the various species of Arundinaria, Bambusa vulgaris, Cephalostachyum capitatum, Dendrocalamus Hamiltonii, Melocalamus compactiflorus and Pseudostachyum polymorphum. Burmese lacquer-ware consists very largely of neatly made boxes, trays, etc., of bamboo wicker-work coated and polished with the thiti varnish (Ind. Art at Delhi, 1903, 218–24). Lastly, certain bamboos are prized in house and boat construction or for scaffolding, because of their great strength. These are Bambusa Balcooa, B. nutans, B. Tuld, Dendrocalamus giganteus, D. strictus and Melocanna bambusoides. Mr. Hannan (Textile Fibres of Comm., 145) says: "The stems of Bamboo when spliced are known in the brush trade as the Bamboo fibre. The fibres used are about an eighth of an inch in width and 6 to 7 inches in length. They have a good elastic bending property . . . This material is also known to the trade as "Patent Bass.""

The bamboo stem, as in grasses generally, consists of a more or less hollow culm, with transverse solid joints called nodes. The thickness of the woody shell and the length of the internodes varies exceedingly in
the different species. One peculiarity is preserved by all bamboos, namely, the rapid growth of the young shoots. This is a most important provision, for a branched shoot could never penetrate through the crowded mass of mature culms. Having in about a month reached its full height and thickness, the shoot commences to produce its branches and branchlets, and thus weighted, it curves into the graceful plume which is the elegant and familiar feature of most species.

As a rule the bamboo is gregarious, establishing itself so thoroughly over certain portions of wild forest tracts that it very nearly exterminates all other forms of vegetation. Seen from a height, nothing could be more lovely, but, to the traveller who for days together may have to clear a path for himself, the interminable monotony, the twilight shade and death-like stillness, broken only by the sighing of the grating culms, make the bamboo jungle dreary in the extreme. In mixed forests, an occasional clump has a most pleasing effect. It supplies the traveller, moreover, with some of his most essential materials of equipment. Indeed, where bamboos are plentiful tents may be dispensed with, for, through the expert handling of that material, the camp followers, armed with large knives, can in a remarkably short time erect a comfortable hut and furnish it with beds, tables and chairs, all constructed from the bamboo. Sir J. D. Hooker (Him. Journ.) observes that it took “the Leptchas about twenty minutes to construct a table and two bedsteads within our tent.” Lewin (Wild Races of South-Eastern India, 1870, 28–30) says: “The hillman would die without the bamboo, and the thing he finds hardest of credence is that in other countries the bamboo does not grow, and that men live in ignorance of it.” A writer in The Pall Mall Gazette published in 1893 a charmingly told story of bamboo and its uses. He said the Orient was wreathed in bamboo; it was the one characteristic common to all the East,—bamboo was in fact symbolic of the East. Mason (Burma and Its People (cd. Theobald), 1883, ii., 102–3) gives a brief sketch of the varied uses of the bamboo, in which the methods of procuring fire from that material may be found specially interesting.

Popularly, bamboos may be divided into those which grow in separate clusters or clumps, and those which send up their shoots singly from an underground root-stock, and thus form continuous patches of perhaps many miles in extent. The former are characteristic of the tropical, and the latter of the extra-tropical or temperate forests. Each clump bears from 30 to 100 culms, which attain a height of from 30 to 100, or even 130 feet. The creeping bamboos are often exceedingly valuable. Of this class may be mentioned *Pseudostachyum polymorphum*—an East Himalayan and Burmese form—and *Melocanna bambusoides*, one of the most valuable species and one which is extensively exported from Chittagong. Of this kind may also be mentioned *Bambusa nutans*—a Darjeeling bamboo. The distance apart of the culms is a feature of commercial value, since the difficulty of removal of ripe culms from dense clumps is a serious disadvantage in some bamboos. A few are climbers (such as *Arundinaria Prainii, Cephalostachyum capitatum* and *Melocylamus compactiflorus*), their festoons and pendulous boughs passing gracefully from tree to tree.

For about two-thirds of its lower portion, the culm of most bamboos is unbranched, or possesses only very short and inconspicuous branches. On escaping from the ground the shoot attains very rapidly its full dia-

meter and appears like a great scaly cone, clad in large embracing sheaths. Solid-stemmed bamboos are, as a rule, much smaller than hollow ones, but bamboo culms may be said to range from the thickness of a goose's quill to more than a foot in diameter. Until the branches have been fully developed the culm is not mature. The branches are produced from below upwards, and with their appearance the stem gradually matures. A good deal has been written as to the rate of growth of the shoot, but up to the present exact and definite figures, even for the important species, cannot be obtained. It is probable that an average of three inches per day would not overstate the growth of the young shoots of the more important bamboos. This seems also, in the majority of species, to take place chiefly at night and to continue for a month pretty uniformly, being increased if anything by fine clear days, and retarded apparently by damp and cloudy weather. The period of sprouting is generally about the beginning of the rains. Repeated cutting of bamboo-shoots considerably weakens the stock, while the cutting of full-grown haulms does no more injury than mowing does to grass. Indeed it is believed that too much cutting of shoots results in early flowering of the stock, and in most cases death to the plant. This fact has an important bearing upon the question of the application of the bamboo for the manufacture of paper, since young and not mature culms are necessary for that purpose. The number of shoots produced yearly from each clump varies according to the vigour of the individual and the peculiarities of the species. It is believed that the larger species produce 12 to 20 and the smaller 30 to 50. If we assume 10 a year, that would mean 300 culms in 30 years, which is the mean age of most species. The greatest possible variability exists in the colour and markings of bamboo culms. Some are pale-coloured, others dark-green, some bluish, others yellow, or again others are variegated. Solidified buds are sometimes developed into formidable recurved spines, or below the sheath a whorl of rootlets are produced which harden into spinescent bodies. These are popularly called the spiny bamboos. For the purpose of live fences the spiny bamboos are specially valuable, such as B. arundinacea and B. Bambusoides. The last mentioned is split and made into mats and sugar sacks in Java. Most bamboos show a tendency to flatten above the nodes; especially is this the case with Phyllostachys, the genus that affords the "square" bamboo of China. The Whangee canes are obtained from P. nigra. [Cf. Or. Comm., 1813, ii., 545; Hobson-Jobson (ed. Crooke), 1903, 969; Kew Mus. Guide, No. 2, 78.]

Durability of the bamboo depends, in the first instance, upon the culms being cut when mature. Specific peculiarities render some culms more durable than others, as, for example, the thickness of the woody sheath, and the amount of silicious matter deposited within the tissue. In this latter respect bamboos vary exceedingly. Long immersion in water greatly enhances the durability, rendering the stem less liable to the attacks of insects, owing to the sap, which they are fond of, being quickly extracted.

Flowering of the Bamboo.—A great deal has been written regarding this exceedingly curious and interesting subject. All the species commence to flower when in full leaf, but as the inflorescence expands the leaves as a rule fall off, until when in complete flower the clump or certain portions of it are leafless. In some cases special flowering culms are produced, at other times every culm flowers, the flowering portion of the entire clump dying off after the seed has been matured. In a few instances
the plant continues to flower as a perennial, while some bamboos are entirely annual, flowering and dying down to the ground every year. With all the larger species the flowering stage is reached after a prolonged period of vegetation, variously stated at from 25 to 50 years, and is almost regularly followed by the death of the whole stock. But the most curious circumstance in the flowering of bamboos may be said to be that while certain species are sporadic, others are gregarious. That is to say, a few plants here and there flower in the one instance, and all the plants of the same species flower simultaneously in the other. In the alphabetical enumeration above the reader will find occasional mention of this feature. According to some writers the gregarious flowering is due to specific maturity being attained at a certain age, when flowering ensues on all the plants derived from the same stock. According to others, flowering is directly a result of climatic conditions. Both opinions may be true, and this is probably the wiser solution of the phenomenon—in other words, a bamboo may not flower before it has attained a certain age, but its flowering may be retarded or accelerated by climatic influences. It is an undoubted fact that the flowering of the bamboo is decidedly influenced by the causes which bring about famine, for the providential supply of food from this source has saved the lives of thousands of persons during several of the great famines of India. Sleeman (in 1836) suggested that it might save the complete destruction of the bamboos of a district to introduce seedlings obtained from the same species found in remote localities. Whether or not this would have the desired result cannot as yet be stated. But it appears certain that it is immaterial whether cuttings are taken a few years or many years before the flowering; the parent as well as plants raised from it by cuttings, will flower and die simultaneously. Indeed it has been shown that cuttings taken a year or so before the flowering, if unable to produce flowers, nevertheless die with the rest. [Cf. Brandis, Ind. For., 1900, xxv., 10–25; Bean, Kew Bul., 1907, 228–33.]

Propagation of the Bamboo.—This may be effected:—1. By Seed.—The slowest but most satisfactory process. Some species germinate while the seed is still attached to the plant, the young seedlings dropping from the parent when about 6 inches in size. Nothing is known as to the period of vitality of the bamboo seeds, but if carefully collected and matured in the usual way, they may be sent from one part of India to the other in good condition. But this, of course, applies only to those which fall from the plant before germinating. Seedlings, however, require 10 to 20 years to attain a growth sufficient to admit of full cropping; the period varying slightly according to the species grown and the locality of production.

2. By Cuttings.—This is the process most frequently adopted in artificial production. The lower part, say 3 feet in length, of a growing half mature stem is placed in the ground shortly after the commencement of the rains. This is most frequently cut off so as to leave, if possible, a portion of the rhizome attached. The cutting should be made a little below one of the nodes and buried so as to include two nodes. Sometimes the cuttings are laid lengthwise along the ground on a specially prepared soil, and the sproutings at each node with their rootlets are afterwards severed and transplanted to their final positions.

Fibre as a Paper Material.—“Of all the fibre-yielding plants known to botanical science, there is not one so well calculated to meet the
pressing requirements of the paper trade as 'Bamboo,' both as regards facility and economy of production, as well as the quality of the 'paper-stock' which can be manufactured therefrom; grown under favourable conditions of climate and soil, there is no plant which will give so heavy a crop of available fibre to the acre, no plant which requires so little care for its cultivation and continuous production." These are the opening sentences of Mr. Routledge's most useful and interesting pamphlet on Bamboo as a Paper-Making Material, published in 1875 (also Bamboo and Its Treatment, 1879). I had the pleasure of meeting Mr. Routledge during his visit to India. There seemed then a possibility of doing something with bamboo. He spared no pains to test his theories and expectations. Unfortunately he died shortly after having learned that there were practical as well as physical and chemical difficulties that seriously opposed the growth of a trade in this new paper material. These may be briefly summarised as follows:

1.—The young shoots only being serviceable for paper-making, three serious difficulties arise:—(a) the bamboo shoots appear from June to July and are in condition during August and September, but by the end of October are too old; (b) the stock suffers severely from the removal of the shoots; (c) each clump can yield only about three or four shoots a year.

2.—Experiment seems to have failed to induce the bamboo to produce a continuous supply of shoots throughout the year.

3.—A large percentage of the old stems requires to be left on the stools, otherwise the plants are killed, and this same danger exists in complete removal of the young shoots. Hence methodical working of the jungles becomes essential, thus considerably increasing the charges of collection and transport. Sir George King demonstrated that if all the shoots be removed for three successive years the plant is killed. This danger may however, be averted for a time by systematic working of the clumps, but it appears to be ultimately certain to ensue.

4.—During the months in which the bamboo shoots appear, the climate of the most important bamboo tracts is such that labour could not be obtained. In fact, bamboo forests occupy, as a rule, uninhabited districts rendering the labour question, apart from the dangers to human life, one of the most serious difficulties.

5.—The freight and transport charges incidental to all raw products which have to be conveyed for long distances are very considerable. In fact, owing to the scattered nature of the clumps which form bamboo jungles, human labour would be the only means of collecting the material to centres from which it could be conveyed to the factory.

6.—A most unexpected difficulty, which in itself almost renders the bamboo unsuitable for paper-making, exists also in the hard adpressed hairs which cover the scales and young stems. It has been found impossible to remove these, and they are not only dangerous to the men employed, but injure the paper seriously. [In passing it may be added that in Java these hairs are reputed to be used as a criminal poison. Gamble points out, however, that the difficulty in the hairs does not exist in Melocanna.]

7.—As demonstrated in Travancore with perhaps the most likely bamboo (Ochlandra travancorica), the amount of chemicals required is prohibitive.

Mr. M. Hill (Ann. Rept. Board Scien. Adv. Ind., 1905-6, 92-3) gives a more hopeful view of the prospects of bamboo as a paper material. He
BAMBOOS

Tabáshir

there observes, "It is considered that the manufacture of paper pulp would be practicable from a commercial point of view; the prospects of an export trade for unbleached bamboo pulp appear to be favourable, having regard to the excellent quality of the pulp prepared under favourable conditions. It is estimated that a ton of unbleached bamboo pulp could be produced for £5 10s. including manufacturing costs, interest and miscellaneous charges. This cost, supplemented by the freight to England and sundry dues, would be increased to £7 10s. as the price delivered to London or Liverpool. Considering the quality of the pulp, a profit should be realised, since wood pulp is valued at £8 to £9 a ton. The manufacture of bleached bamboo pulp for export does not, however, appear to be promising chiefly in consequence of the high cost of importing bleaching powder and the deterioration of this chemical in a warm climate. The value of the pulp for local use in a paper mill in Burma is considered undoubted, and the manufacture of paper from bamboo offers favourable possibilities as a new industry for Burma."

Wiesner (Denkscht. Akad. Wiss. Wien. Math.-Nat., 1902, lxxii., 7, 8), quoting Karabacek (Das Arabische Papier, 29), also Giles, says that the modern Chinese paper "is made from bamboo fibre, the bark of the Brüssonettia papyrifera and rice straw." The late Sir Dietrich Brandis (I.c. 25) seemed, moreover, to think that in spite of all the disadvantages, "Bamboo paper has a future in India." He urged the necessity for a thorough inquiry into whether or not, by special cultivation, the plant could be induced to afford shoots more freely and for a longer period, without injury to the rhizome, and whether it would not be possible for mature culms to be used in paper-making. [Cf. Journ. Soc. Chem. Industr., 1904, xxiii., 265.]

Medicine.—Tabáshir.—In the interior of the hollow stems of most bamboos, chiefly Bambusa arundinacea, a silicious and colloidal substance is found, known in the bázars of India as Tabáshir; Bánasa rochana or Tavak-kshira in Sanskrit. This has erroneously been called Bamboo Manna by some writers, thereby obscuring the circumstance recently established that certain species produce a true manna on the outer surface of their culms. The following may be given as the chief vernacular names for the substance found within the stems:—Tabáshir, bans-lóchan, bans-kapúr, thistoriyá, banasa-mithá, vás-nuníthá, munga-luppu, veduruppu, moleuppa, bidaruppu, tavakshírá, váchá, vathégá-kiyo, vathégasd, vasan. In the Dictionary will be found a brief sketch of the history of tabáshir. This has since been amplified by Dymock in his Materia Medica of Western India; by Sir D. Brandis in the Indian Forester of 1887; by the authors of the Pharmacographia Indica and by many correspondents in the Indian press. There are two kinds of tabáshir known in the bázars, viz. kabúdi, blue; and safed, white; the former is only pale blue. It is largely used by Hindus and Muhammadans, and is considered cooling, tonic, aphrodisiac and pectoral. It is an ingredient in many compound medicines which are given in different lung diseases, but from its chemical composition it must be quite inert. Cohn (Beiträge sur Biolog. der Pflanz., 1887, 365-406) may be said to regard it as the residuum of the water which fills the young joints. Sir David Brewster, in 1819, supported the opinion that the deposit within the stems was a consequence of disease set up by an insect. Brandis views (though incorrectly) the deposition as a natural process in the metabolism of
BAMBOO MANNA

Edible

**BAMBOOS**

Edible Leaves, Seeds and Shoots.—In the brief abstract of information given above as an alphabetical enumeration of the more important species of Indian bamboos, mention will be found of those that are specially valued as fodder. Some are highly prized (especially for horses), others viewed as very indifferent fodders, and still others (such as *B. nanum*) used mainly as cattle medicines. It has already been stated that in times of scarcity bamboo grain has saved the lives of thousands of human beings. Many instances are on record of the providential flowering of the bamboo in times of famine. The grain is pounded in the ordinary way in order to remove the husk, then milled until reduced to a coarse meal or flour. In that form, either by itself or after being mixed with rice or *juiar*, it is baked into cakes (*chapatis*) and thus eaten. The young shoots constitute a most important article of food all over India, nearly every bamboo being eaten in this stage; but the larger species are most generally used. Freed from the sheaths and hairs, they are cut up into small pieces and eaten in curries. They are also pickled or boiled into preserves. The young shoots of the smaller species if boiled in water with a little salt resemble an inferior quality of asparagus. [Cf. Nisbet, *Ind. For.*, 1895, xx, 98–100; also Wallinger, xxvii., 226–8.]

**Chemical Composition.**—The most complete analysis yet published of bamboo grain is that given by Prof. A. H. Church (*Food-Grains Ind.*, suppl., 1901, 6), which shows in 100 parts: water 13·5, albuminoids 10·8, starch 7·1, 6, oil 0·6, fibre 2·1, and ash 1·4. “The above-stated percentage of albuminoids, calculated from the total nitrogen present in the grain, gives us the nutrient ratio 1:6·7, the nutrient value being 83·5.” This was the result obtained from the examination of a sample of *B. tulda*. Church adds that the grains were much larger than those of *B. arundinacea* though similar in chemical composition. Prof. T. Thomson of Glasgow found the ash of bamboo grain to consist of silica 90·50 per cent., potash 1·10 per cent., peroxide of iron 0·90 per cent., alumina 0·40 per cent., moisture 4·87 per cent., loss 2·23 per cent.

**Manna.**—In March 1900, Mr. A. E. Lowrie, Forest Divisional Officer, Chanda, sent me a sample of bamboo manna. This was chemically analysed at my request by Mr. D. Hooper and his results published in *The Agricultural Ledger* (1900, No. 17). Mr. Lowrie wrote as follows:—“About the middle of last month I went through the area of *Dendrocalamus strictus* seeded forests and found that, though most of the bamboo clumps were far advanced in seed, small stretches were still flowering, and strange to say, in the drier portions of the forest on poor soil, very stony and chiefly laterite. It was while passing through one of these tracts that I noticed the culms in the clumps streaked all the way down with what appeared to me to be a white brittle gum, similar to what one sees exuding from *Odina Woodier*. On asking some of the Gonds (local men) who were with me, what it was, they could not tell me and had never seen it before. I at once collected some, and on tasting it, found that it was perfectly sweet. The men then began collecting it by handfuls. I also collected some and send you a tinful in case you would care to have it. On reaching camp I got hold of a number of the villagers, both Gonds and others, and on inquiry they told me they had never seen or heard
of this gum. I passed through a number of similar stretches in which the bamboos were covered with the gum. This sugary deposit only extended for about five feet along the culms and was entirely absent towards the tops; it was found both at the nodes of the bamboo as well as on the stems between the nodes. I am sure this has nothing to do with any insect deposit, nor has it been caused through the aid of insect punctures in the stem of the bamboo, as I made a careful examination of a number of culms. The culms also were old ones, one, two and three years old." Mr. Stebbing, however, reports that he had found the leaves of *Bambusa arundinacea* so attacked by an Aphis as to cause a manna to fall in drops on the stems. Hooper found that the manna furnished by Mr. Lowrie consisted of a saccharose related to, if not identical with cane-sugar. [Cf. with Hobson-Jobson (ed. Crooke), 863.]

**Timber.—** Bamboos form the most important portion of the minor forest produce of all forest divisions, and one that increases in value every year. Gamble estimates that the Indian annual consumption of bamboos must be something like 150 millions per annum. The forest administration Annual Reports issued by the various provinces of India afford useful particulars as to the supply drawn from their respective producing areas. It would occupy a volume to enumerate even by name all the uses to which the mature bamboo stems are put. To the inhabitants of the regions where the bamboo luxuriates, it affords all the materials required for the erection and furnishing of ordinary dwelling-houses. Certain species are more serviceable for posts, others for matting and basket-work, etc., etc., but if one or two species be used every requirement in house construction and furnishing may be met. Perhaps one of the most curious is the employment of specially prepared slips of bamboo for the purpose of letter-writing. M. Chavannes (*Les Livres Chinois*, etc.) has shown that in ancient times (or prior to the discovery of the art of paper-making in 105 A.D.) the stationery of China was mainly of this nature. Stein (*Ancient Khotan*, 1907, 358) has moreover shown that the oldest manuscripts discovered by him (3rd century) were written on specially prepared pieces of wood made up on the pattern of the older bamboo slips (see under Leather, p. 636; also *Paper and Paper Materials*, p. 862). The reader had better also consult the account of the economic uses of the Bamboo as given in the *Dictionary*.

A century ago the manufacture of carbonate of soda from the ashes of certain saltworts was an important industry. Attention was accordingly early directed to India as a source of supply for Great Britain to supplement that obtained from Spain. Roxburgh, Royle, Baden-Powell and many other writers in succession described the existing trade and discussed its possible developments. Roxburgh (*Fl. Ind.*, ii., 61) practically speaks of the future of the Indian barilla trade as being of national importance. He explains that one species of *Salicornia*, one of *Arthrocenum* and one of *Salsola*, which are extremely abundant plants on the Coromandel Coast, might be made to yield barilla sufficient to make *Soap* and *Glass* for the whole world, since labour is cheap and population abundant. That opinion was written before the date of the famine that removed fully half the labouring classes of Coromandel (1791–3). It need hardly be said, however, that the discovery of Le Blanc’s method of preparing sodium carbonate chemically from common salt not only destroyed these and all other similar expectations of a remunerative trade in barilla, but

**Barilla.**

World’s Supply.

**Soap and Glass.**

Expectations Falsified.
BARILLA INDUSTRY OF THE PANJÁB

revolutionised the world's necessities and demands for the salt. At the present moment were the available lands not only of Coromandel but of all similar suitable tracts in India to be devoted exclusively to the production of barilla, they probably could not supply a tithe of the present demands for sodium carbonate.

Baden-Powell (Pb. Prod., 1868, i., 86) gives an instructive account of the barilla industry of the Panjáb. Very little of importance has since been written on this subject and the following abstract may, therefore, be taken from that work:—"The process by which this substance is prepared is carried on during the month of October and three following months. The plant after being cut down is allowed to dry. The next step is to dig a pit of a hemispherical shape, about 6 feet in circumference and 3 feet deep. One or more vessels with holes perforated are inverted and placed in the bottom of the pit, the holes being kept closed until the alkali begins to flow, when they are opened by a stick previously arranged for that purpose. The dry plants are gradually burnt, and during the process a liquid substance is found to run down into the inverted vessels. After this has taken place, the residue is stirred up by means of a flat piece of wood and kept covered over for three or four days till it cools. Care must be taken not to allow water to get to the molten liquid, otherwise the whole mass would blow up. In the inverted vessels will be found a pure form of khdar sajji (sometimes called lota (pot) sajji) and in the bottom of the pit an impure form containing a mixture of ashes."

In the Dictionary more recent papers are reviewed. The Deputy Commissioner of Multán says that in that district the plants are collected in January and February. He then observes that the land on which barilla-yielding plants grew was in 1883-4 leased for Rs. 7,907. The Settlement Report of Shahpur District contains an interesting account of the barilla industry in which it is stated that the farming of the monopoly fetches upwards of Rs. 8,000 a year. The quantity of sajji manufactured is said to be about 10,000 maunds. In Montgomery and Jhang the khdar (or khangan khdar) plant is Malacynlon recenueum, and this is supposed to yield the finest quality of sajji; the inferior qualities are believed to be made from the various species of land, of which the gora land is the best (salsola suhita).

In Sind the plant that yields the best sajji is said to be known as land. This grows wild all over the province and springs up spontaneously after a copious fall of rain. The process of manufacture pursued in Sind differs from that described in connection with the Panjáb in the circumstance that earthen pots (loti) are not employed. The industry flourishes most at Kutchi in Khelát, where over 5,000 maunds are annually prepared. In Shikápur a like quantity is made, and in Thar and Parker about 3,000 maunds are annually turned out. There seems also to exist a fairly extensive manufacture of sodium carbonate at Aden from the so-called Aden Balsam (sueda multifora).

The publication of the article "Barilla" (in the first volume of the Dictionary) led to a correspondence on the subject of a possible extension of the industry. In 1888 the Madras Government asked the assistance of the Director of Agriculture in the Panjáb. The result was that Mr. J. R. Drummond, then Deputy Commissioner of Karnal, was invited to draw up a report on the Panjáb saltworts actually in use in the manufacture of barilla, and this was furnished to the Madras Government. After considering the information procured from various sources, the conclusions arrived at by the Government may be put thus:—

1. It was cheaper and more convenient to obtain sodium carbonate from alkali deposits in the soil (such as the well-known dhobi's earths of various parts of the Presidency) than to burn saltworts and manufacture barilla.

2. The imported pure salt could be had at such a low price that it was doubtful whether either method was likely in the future to compete successfully.

Indian Saltworts.

The following may be given (in continuation of the observations under Alkali Soils—Réh, p. 51) as an alphabetical enumeration of the better known saltworts of India, in which all those that might be successfully tried in reclamation of réh efflorescence have been shown, as well as those actually employed in the manufacture of barilla.

Arthrocnemum Indicum, Nees. The jadu palang, machola, ghuri, chil, umari, koia-pipal—a native of the salt marshes of Bengal, Madras and Bombay.

List of Chief Plants.

D.E.P., 1., 328.
**BASKET-WORK MATERIALS**

**INDIAN SALTWORTS**

**Indian Salicornia shrub**

Halocharls violacea, Bunge. A small diffuse annual common in the Peshawar Valley, Western Panjab, Salt Range, and Baluchistan.

**Haloxylon recurvum, Bunge.** The khārd, khārī-lani, etc.—a straggling bush plentiful in the C and W. Panjab plains and Salt Range, also found in Sind, Deccan (Coimbatore) and Burma. This is the most important barilla-yielding species. H. multijorium, Bunge, and H. saltaticum, Bunge; the former occurs in the Panjab and the latter in Sind. They seem to be used as adulterants or substitutes for *H. recurvum.* [Cf. Agri. Journ. Ind., l.c.]

Salsola brachialtsa, Roxb. The *quoleu, uma-rī-kīrāi*—a shrub chiefly found on most salt marshes in Bengal, South India (Tanjore), etc.

**Salsola teetida, Del.** The *lanā, shora (shorga), lana, ella-kura,* etc.—a saltwort much valued as fodder for camels and employed in the *Hari-rūd* in the Panjab from Peshawar Valley south-westwards.

**Suaeda fruticosa, Forsk.** The *lunak, choti-lani, lūmch, ushak lani*—a sub-erect shrub of N.W. India throughout the Panjab. Used mainly as an adulterant in barilla. *S. monolec, Forsk.*—a shrubby species met with on the coast of the S. Deccan. *S. multijorum, Moq.*—*morā, khārī-lani, geria, kiray, rava kada,* a shrub met with on the coasts of Bengal, Bombay and S. India. *S. maritima, Dumort.*—*lant, khārī-lani, lana, yella kiray, tia or ella-kura,* A herbaceous species (occasionally shrubby) met with in the Upper Gangetic plains from Delhi to the sea-coasts of Bengal, Bombay and the Deccan. The leaves are eaten, especially in times of famine. Drummond says that most references by authors to *S. multijorum* should be taken as denoting this plant. [Cf. Kew Bull., 1891, 96-7.]

The above heading embraces several distinct crafts, but since the materials employed are often identical, collective treatment may perhaps be the most satisfactory. The opening paragraph of the article Bambous has already set forth some of the leading ideas that prevail, such as the separation of the Bamboos (*Bambuseae*) from the Canes (*Calamaceae*) and from the Reeds. But there remains the even more difficult task of designing a classification for the basket materials that are neither reeds nor canes, and for the matting materials that are often grasses, reeds, canes or even bamboos. It is proposed to get over this difficulty by furnishing in this work several articles that conjointly may embrace the whole of these somewhat diversified crafts and materials. These will be *(a)* Bamboos: *(b)* Calamus: *(c)* Basket and Wicker-work—the reeds for the most part: *(d)* Cyperus or Grass-Matting: and *(e)* Mats and Matting. But over and above these collective articles, certain substances that have other and more important uses than as materials for baskets and mats will be discussed in their own alphabetical position, and references to these are accordingly given in the collective articles so that the reader may have little difficulty in discovering the products necessary to complete special enumerations.

Throughout India basket-making in some form is practised, and very largely so by the gipsy class. In the rural districts it is of the crudest possible kind, the baskets produced being intended purely and simply for agricultural purposes. Here and there, however, basket-making, as a consequence of special materials and facilities, attains a fairly high position, and in one or two instances even becomes artistic and ornamental. The following may be mentioned as the chief materials used and the centres of their utilisation, taken up in the alphabetical sequence of the scientific names of the plants concerned:

**Acacia arabica**—Agricultural baskets (see p. 8).
**BASKET MATERIALS**

**Alnus nitida.**—The _alder or shrol, udish_, etc., twigs used in tying loads, in construction of rope-bridges and of crude baskets.

**Arundinaria** spp. (see _Bamboos_, p. 99).

**Bambusa** spp. (see _Bamboos_, pp. 99–101 et seq.). Along the foot of the Himalaya from east to west, bamboo basket-making is an important industry. The combined hat and umbrella of the Assam and Burmese cultivators, as also the highly artistic hats of the Shans, are made of bamboo. In Bengal, ingenious and often neatly constructed fish-traps and bird-cages are also constructed of bamboo. The traffic in these articles is by no means insignificant.

**Borassus flabellifer.**—Fancy baskets, etc. (see p. 170).

**Cajanus indicus.**—Agricultural baskets (see p. 200).

**Calamus** (see pp. 201–4.) Cane baskets of great strength are largely produced in Bengal, as for example in Patna, Pubna, etc. These are formed of entire canes wound round and round and held in position by tie-bands. Fancy cane-work is largely produced in Poona, Ratnagiri, Kanara, etc. In Bengal a small colony of Chinamen are engaged in the production of cane-chairs, baskets, etc. In Shimoya in Mysore and in several localities in Coorg cane-work of some note is turned out.

**Caryota urens** (see p. 286).

**Corypha umbraculifera** (see p. 129).

**Dendrocalamus asper**.—The _bankati, sukan_, and _I. Gerardiana_, the _kati, khenti_, etc., are fairly extensively employed by the hillmen to tie loads and make baskets, etc.

**Melocalamus compactiflorus.**—The bamboo most highly prized for lacquered boxes and trays (see p. 103).

**Parrotia Jacquemontiana.**—The _paher or pishor, killar, spikecha_, etc., of the N.W. Himalaya, is a most useful shrub, the twigs of which are extensively employed in binding loads, making strong (though not very durable) baskets and in constructing the so-called rope-bridges ( _jhulas_ ) which are thrown across the mountain torrents. Occasionally twigs of _Cotoneaster, Indigofera, Olea_, and _Salix_ are mixed with _Parrotia_, and in other parts of the Himalaya the grass _Tschemum_ is mainly used for these bridges.

**Phoenix** (see pp. 384–5). Beautiful cigar-cases are plaited in Madras from specially prepared strips of the leaves of this palm. The leaves, which are known as _bhutra or khushab_, are also woven or plaited into fans, baskets and ropes, etc. The leaf-stalks ( _khari_ ) make excellent walking-sticks, and split up they furnish a material which is woven into exceedingly strong crates and baskets. W. H. Gee ( _l.c._ 15) says that in the Panjab the manufacture of fans from the date-palm is universal, and that there is a fair export in these articles from Peshawar. Fans are made largely in Rohtak and Karnal. In Delhi also there are two factories for date-palm fans. The leaf is soaked in water for a short time and some of the leaflets cut off and plaited in with those that remain, thus forming the fan. They are then stained according to certain patterns. A man can make about twelve such fans a day. In most parts of the country where one or other of the date-palms is plentiful the leaves are largely employed in the construction of baskets, as a rule in the bee-hive shape. These are produced in the Madras and Bombay Presidencies and in the Panjab, Sind, Baluchistan and Afghanistan. In the eastern parts of Bengal, matting used in houses is almost always of _khafir (Phoenix)_ and is sold at about Rs. 6 per 100 square yards. [ _Cf._ Gee, _l.c._ 6, 14.]

**Phragmites** (see _Mats and Matting_, p. 777).

**Pseudostachyum** (see _Bamboos_, p. 104).

**Rhus Cotinus.**—The Elm-leaved Sumach or _tinga, phan_, etc.; shoots employed in coarse basket-making.

**Saccharum arundinaceum** (see _Muni_, pp. 929–30).

**Salix.**—Several species of Willow. There does not appear to be in India any generic name like osier which denotes the specially grown shoots used in basket-making, but _bed or bent_ are very general names, and others such as _bin, bis, bisi, blesh, baish, bhains, bes_, etc., all denote willows. Although never so successfully worked up as in Europe, the willows of India are of the greatest possible value to the people. The _kiitas_ or load-baskets carried on the back by the hillmen are very generally made of willow, and the long willow-baskets used in conveying apples and pears from Kullu and Kashmir to the plains are well known. The _kiita_ is a pointed basket so
BASKET AND WICKER-WORK

Mahua designed as to throw the chief weight on the shoulders. In some of the jails and asylums of India admirable willow baskets and chairs are now produced, but this is apparently a modern industry. Willow twigs, when procurable, are largely used in all rural parts of the country for wattles, weirs, dams and fences. The bark is often stripped off the twigs and used in place of string, the twigs being then converted into charcoal, which is viewed as of special merit.

Tacca pinnaflida.—The dhai, diva, periya, kando, kanni-kund, touk-ta, etc. An investigation recently conducted at the Imperial Institute into the possibility of this plant being used as a braiding material, resulted negatively. But the tubers are fairly extensively eaten by the hill tribes of Chota Nagpur and the Central Provinces. [Cf. Forster, Pl. Esc., 1786, 59; Rumphius, Herb. Amb., v., t. 114; Nicholls, Excise Rept. C. Prov., 1878—9, app. D.]

Tamarix.—The jau affords long flexible twigs that are very generally employed in the manufacture of baskets, brooms and wattles, especially in South Panjáb. Stein (Ancient Khotan, 1907, 332 et seq.) makes repeated reference to the tamarisk as seen in the ruins of Khotan, the specimens being found in association with other objects of date 3rd to 5th centuries. Wattle wattlings of tamarisk plastered over were one of the chief methods of forming partitions in house-construction. The pens used by these ancient peoples were also made of tamarisk wood.

Tridicum, Oryza and other straws are worked up into fancy baskets, as for example in Hazara and Nepal. W. H. Gee (loc. cit.) observes that the wheat-straw baskets of Hazara are of two kinds, viz. mandhas and parotas. “The former cylindrical and narrow at the base, the latter with straight sides; both are often worked in coloured designs and cost from Rs. 0—4—0 to Rs. 1.” Collins (Arts and Manuf. Beng., 1890, 6) says that “in the Patna and Bhagalpore Divisions fancy baskets of coloured grasses are made by high-caste ladies. . . . Fancy straw baskets are made in Purnea district. Leghorn hats are made of the straw of spelt wheat (see p. 1084).

Typha (see Mats and Matting. p. 777).

Vetiveria zizanoides.—The khas-khas (see p. 1106).

[The following special works may be consulted in amplification of the particulars here given regarding basket-ware: — Hoey, Monog. Trade and Manuf. N. Ind., 1880, 72—5; Kipling, Ind. Fb., in Journ. Ind. Arts, 1885, i., 80; Lawrence, Valley of Kashmir, 1895, 250, 372; Stuart, Man. S. Kanara, 1895, ii., 149; Kew Bull., 1899, 200; James, Basket Makers of California, 1901; O. T. Mason, Smithsonian Inst. Ann. Rept., 1902, 185—548 (plates 10 to 248); etc., etc.]

BASSIA BUTYRACEA, Roxb., As. Res., 1805, viii., 477—85, with coloured plate; also Fl. Ind., ii., 527; Traill, Proc. Roy. As. Soc., 1838, 115—7; Gamble, Man. Ind. Timbs., 448; Fl. Br. Ind., iii., 546; SAPOTACEAE. The Indian Butter Tree, phulvárá, chíra, chíra, cheuli, chíri, yel, etc. The butter is called chiéra-ke-pina, phalel or phulwa. A large deciduous tree of the Sub-Himalayan tracts from the Ganges to Bhutan, ascending to altitudes of 15,000 feet.

MAHUA OR ILLUPEI TREE

Oudh and Kumaon to Gujarat, Kanara and Burma. It ascends the hills to altitudes of close on 4,000 feet and is often cultivated.

B. longifolia, Linn.; Gaertner, Fruct. et Sem. Pl., ii., t. 104; Lamk., Illust., t. 398; Roxb., Fl. Ind., ii., 523; Wight, Illust. Ind. Bot., ii., t. 147; Rec. Bot. Surv. Ind., ii., 185; Gamble, Man. Ind. Timbs., 448; Cooke, Fl. Pres. Bomb., ii., 92; Fl. Br. Ind., iii., 544. This evergreen tree is met with from the Konkan southwards and replaces B. latifolia in South India. It is most frequently met with in cultivation. The Tamil, Telegu and other South Indian names mentioned above more especially refer to it, such as ippa, yeppa, pinna, illipi, ippi, hippe, mi, meze, etc.

Habitat.—The mahua, though met with in a purely wild state in many parts of India, is of the greatest possible value to the inhabitants of large tracts of country where it exists in a state of semi-cultivation. It prefers dry sandy and even rocky soil to rich low-lying and inundated lands. Apparently it is self-sown, the seedlings being in some parts of the country protected for a few years (Ind. For., 1880, v., 468). But by the casual visitor, it would appear, seedlings are not readily detected. Hamilton in 1788 (l.c. 305) says that neither he nor any of his friends had ever seen an infant plant. Several writers have recorded the same observation. Mr. Sly (Commissioner of Settlements and Agriculture in the Central Provinces) does so in his Annual Report for 1902–3, and adds that in the absence of reproduction it is only a question of time for many villages to lose a most valuable addition to their food supplies. Numerous writers deplore the disappearance of the tree from regions where it formerly grew. Others urge, and with much force, that every effort should be made to extend rather than to contract its cultivation. As a protection against famine few schemes are to be more highly commended (for many parts of India) than systematic cultivation of mahua where suitable lands are available.

History of Mahua.—It seems highly probable that the economic information published from time to time regarding the mahua tree is fully applicable to all the above-mentioned species, each in its own area being the mahua or illupei of popular writers. From the industrial standpoint there is in fact no very sufficient reason for their different values. The most remarkable fact regarding the mahua is that it appears to have escaped the notice of all the early European travellers—Marco Polo, Vasco da Gama, Garcia de Orta, Varchéma, Linschoten, Tavernier, Rheede and Rumphius are silent regarding this most valuable tree. It was, however, well known to the classic authors of India. Its best-known Sanskrit name is madhuka. Susruta describes the spirit obtained by the distillation of the flowers, and the oil from the seed is mentioned by Chadradatta. Ibn Batuta, who travelled in India in 1332, calls it mahua and remarks that the sun-dried flowers taste like figs (Dymock). In the Memoirs of the Emperor Baber, written from 1494 to 1529 (Leiden and Erskine, transl., 1826, 325), the meluks or gal-chekan is said to be a wide-spreading tree of whose timbers the houses of the Natives of Hindustan are chiefly constructed. Mention is also made of the spirit extracted from the flowers, of the dried flowers eaten like raisins, and of an oil extracted from the kernel. Thivenot (Travels Levant, Indostan, etc. (Engl. transl.), 1687, iii., 94), speaking of Golconda, tells us that clumps of a tree called "Mahowa" were placed along the boundary of the territory of the "Mogul." The Ain-i-Akbari, 1590 (Blochmann, transl., 70), refers to it as yielding a fruit known as gilawndah, which Abu Fazl adds is employed in the preparation of an intoxicant. The botanical and other writers mentioned above in connection with each species, carry the history of the products of these plants up to the most recent dates, and it may be added that only the more important, and especially those not mentioned in the Dictionary, have been quoted.

THE MAHUA TREE

BASSIA

Mahua
Flowers

Economic Value.—It may be said that there are two great products of the
tree, (a) the Edible Flowers and (b) the Oil-yielding seeds. The Dictionary
should be consulted for the minor uses, and these may therefore be disposed of
here very briefly. A Gum or gutta (the milky sap hardened) flows from incisions
or abrasions on the stem (see p. 627). [Cf. Pharmacog. Ind., ii., 358–60 and 361
for its chemical properties and uses.] In some parts of the country ringing
of the stems is practised just on the setting of the fruits. When this is done
the gum may be obtained in abundance. The bark is employed as a Dye. The
flowers, the oil, the spirit distilled from the flowers, and the bark are all used
medically. Lastly the timber has some merit, but the trees are, as a rule,
too valuable to allow of their being killed for this purpose.

The Flowers.—The mahua shows its leaves from February to April.
The cream-coloured flowers appear as great clusters (of 30 to 50) near the
ends of the branches, from March to April, and are soon followed by the
young leaves. Preparatory to the harvest of flowers the people clear
the ground below the trees by burning the weeds and smoothing the soil.
About March the flowers begin to come to maturity, and every morning
just after sunrise the succulent corolla-tubes fall in showers to the ground.
This continues till the end of April, each tree yielding from 2 to 4 maunds
of flowers, but usually the fall from a single tree is complete in about 7
to 10 days. Mukerji (Handbook Ind. Agri., 291) says the yield of each
tree is from 5 to 8 maunds. A drying-floor is prepared in a position
central to a selected batch of trees. The ground is smoothed and beaten,
etc.; on this the flowers as collected day by day are spread out to dry in
the sun. In a few days they shrink in size, change in colour to a reddish-
brown, and their peculiar sweet smell becomes more concentrated and its
resemblance to that of mice more intense. But the mahua that is intended
for sale is not dried to the same extent as that set apart for home con-
sumption, and naturally so since the loss in weight is considerable. But
mahua is eaten extensively while fresh—in the dried form it is cooked and
eaten along with rice and other grains or food materials. Before being
eaten the dry corolla tubes are beaten with a stick to expel the stamens
(jili); the quantity required is then boiled for six hours or so and left to
simmer until the water has been entirely evaporated and the mahua
produced in a soft juicy condition. Tamarind or still seeds and gram are
frequently eaten along with mahua. By the better classes it is fried with
ghi (butter) or with mahua oil. It is extremely sweet, but the power to
cat and digest this form of food is an acquired one, so that few Europeans
are able to consume more than one flower without having disagreeable
after effects. Sometimes the mahua is dried completely, reduced to a
powder, and mixed with other articles of food. In that condition it is
often baked into cakes. Sugar may also be prepared from the flowers or
they may be distilled and a wholesome spirit prepared, the chief objection
to which is its peculiar penetrating smell of mice. Nicholls estimated
that in the Central Provinces 1,400,000 persons use mahua as a regular
article of food, each person consuming one maund per annum—an amount
that would set free about 1½ maunds of grain or about 30 per cent. of the
food necessities of the people in question. This at the lowest estimate
comes to one quarter of a million pounds sterling which the tree presents
annually to these provinces. It would serve no purpose to speculate as
to the corresponding total supply for all India; the above illustration
of one province exemplifies its extreme value.

Mahua, in times of abundance, may be purchased at a very small figure,
but normally it costs about 12 annas a maund. As a rule the surplus

118
FLOWERS AND SPIRIT

over local necessities is sold. The chief purchasers are the distillers, and the additional revenue thus derived greatly enhances the value of the tree. Some few years ago the experiment was attempted in Bombay of the Forest Department becoming the vendors of the available surplus and selling to the trade. The object in view was the protection of the poor and ignorant people, who it was believed often got but a fraction of the actual value of their produce. At that time also there was a fairly brisk new export trade in mahua, which went apparently to Europe to be used for distillation. It is generally believed that the action of the French Government in closing their ports to mahua ruined the foreign traffic and accordingly the exports shrunk to small proportions, the article being at present exclusively used in Europe to feed pigs—a purpose recommended originally by E. Lockwood (Journ. Linn. Soc., xvii., 89).

Mahu'a Spirit.—As already indicated, the art of distilling these flowers is a very ancient one in India. Susruta mentions mahua spirit. The Ain-i-Akbari alludes to it. Hove (who travelled in Bombay in 1787, 142) tells us that the mauva (as he calls it) affords when distilled a pure and very pleasant but remarkably strong spirit. This he observes is often poisoned with Datura, and accordingly he concludes, “I would advise the Company to send out orders to their Settlements to inspect the common liquors more minutely and they would not lose half the troops which they commonly do on this side of India.” Williamson (East Ind. Vade Mecum, ii., 153) tells us that in 1810 the number of shops for the sale of mahua and other spirits was “absolutely incalculable.” Thus India had little to learn from Europe either in the art of distillation or in the habit of alcoholic consumption. The registration and supervision of the traffic which had been inherited by the Company and by the Crown became a necessary evil.

One of the best accounts of mahua spirit is that by Archibald Keir (As. Res., 1788, i., 309-19). That article was written in Chatra in Ramgar after a most careful personal study of the subject. Dr. Gibson (Hooker’s Kew Journ. Bot., 1853, v., 90) tells us that in Gujarat and Rajputana every village has its spirit-shop, and he adds that the Government duty on the spirit distilled at Caranja, opposite Bombay, came to something like £80,000. He then observes that the spirit prepared was something like Irish whisky but had a strong smoky and rather foetid flavour.

The aroma is the chief disadvantage to the spirit, but it is understood that a gentleman who experimented in Monghyr very extensively with this issue, succeeded in producing a spirit quite free from the objectionable smell. Lockwood tells us that he had ascertained that six gallons of spirit could in Europe be produced from one hundredweight of mahua. More recently it has been found that as much as 7-6 gallons per cwt. can be produced, the yield from molasses being only 5{1/4} gallons, and much less from barley, potatoes, etc. [Cf. Manson, Journ. Agri.-Hort. Soc. Ind., 1886, vii., 83-5.] He tells us that the spirit is called daru and much resembles Hollands both in appearance and taste, but unfortunately it retains the sickening flavour of the flowers. The method of distillation is similar to that pursued in all other countries, save that in India it is less scientific and correspondingly more wasteful (see Eleusine, p. 521). For preparation of vinegar from mahua flowers, see p. 1109.
BAUHINIA
PURPUREA

The Seed, Oil and Butter.—From the remotest antiquity it has been known that the seeds of this plant contain a large quantity of an exceedingly good edible oil, which owing to the ease with which it solidifies is often called Mahua Butter. The oil from B. butyrosperma is generally upheld as more valuable than that of the other three species, chiefiy because it solidifies almost immediately after being expressed from the seeds. Roxburgh (As. Res., viii., 477-85) has given a full account not only of the butter of B. butyrosperma but of the oil of B. longifolia, the last mentioned being from the pen of the Rev. Dr. John. In the Journals of the Agri. Horticultural Society of India numerous papers have appeared urging the desirability of an extended production and use of these oils (1848, vi., 219-22, also app. lxix, cxiv.; 1861, xii., 345, n.s.; 1869, i., 394-7; 1886, vii., 76-92; etc.). Instructive and useful are also the articles by Lockwood in the Journal Linn. Soc. (1878, xvii., 89); in the Dictionary (1885, i.); in The Agricultural Ledger (1899, No. 12); and in Mukerji's Handbook of Indian Agriculture (1901, 290-1), which carry the subject up to the most recent and very admirable paper by G. M. Ryan (Ind. For., 1903, xxix., 543-9). This, among other features of interest, sets forth particulars of a new trade that seems of growing value to India.

The seeds (nuts), he observes, are commonly known as mohoti, and are collected about the end of May to beginning of June. There is a considerable local demand for them all over the country, but apparently a practical margin for export is annually available. Ryan puts the price of the seeds at Rs. $4\frac{1}{2}$ per cwt., which shows a net profit to the trader of 13 annas. During the past five or six years the foreign traffic has rapidly expanded, and stands now at about 500,000 cwt. It would seem that these nuts are consigned to Hamburg and Antwerp, and the supplies are drawn from Bombay, Rajputana, Central India, Central Provinces and even the United Provinces. A difficulty would appear, however, to exist in Europe in the disposal of the cake, which in India is used as a manure. [Cf. Leather, Agric. Ledg., 1897, No. 8, 23.]

The oil of the mahua proper (not mahua butter) is greenish-yellow, and is largely eaten all over India, and in addition is used to adulterate ghi. It is sometimes called doló oil. In South India the solid form is called illipi butter. Here and there a fair quantity of soap is made from this oil. The oil is also largely burned by the hill tribes, who express it crudely from the seeds. Apparently the only limitation to the uses of the oil is the want of enterprise in its extended production.

Indian Economic Species.

**B. angulina**, Roxb. The nag-pát, nāvīlī, sahatingnagrik—a climber of N. and E. Bengal, Sikkim, Chittagong, Martabans, Burma and South India, etc.

**B. macrostachya**, Wall. The gunda-gilla—an extensive climber found in the forests of Sylhet and Assam.

**B. malabarica**, Roxb. The amli, karmi, gourbati, laba, amli-taki, kattara, cheppura, korala, kundapula, etc.—a bushy tree met with in the Sub-Himalayan tract, from the Ganges to Assam, and in Bengal, Burma, and South India.

**B. purpurea**, Linn. The koiral, koilár, etc.—a moderate-sized deciduous tree of
THE MALU FIBRE

BAUHINIA VARIEGATA

the Sub-Himalayan tract from the Indus eastward, also of Central and South India and Burma.

B. racemosa, lam. The kachná, banraj, kaimu, katmanlí, areka, are, asatri, aipta, palan, etc.—a small crooked tree met with in the Sub-Himalayan tract from the Ravi eastwards, in Oudh, Bengal, Burma, and Central and South India.

B. retusa, lam. The kuri, kandla, laba, etc.—a moderate-sized deciduous tree of the N.W. Himalaya from the Beas eastward, to Simla, Garhwal, Kumaon and Central India.

B. tomentosa, lam. The kachnár, asnduro, chámal, etc.—an erect shrub met with in the U. Provinces, and throughout India to Ceylon and Penang.

B. Vahili, w. & A. The malghan, chekur, sikh, borla, sungun rik, jom, lama, shioli, moulan, etc.—one of the most useful of Indian climbing Bauhinias. It is found all along the lower Himalaya from the Chenab eastward, in N. and C. India and Tenasserim. [Cf. Hooper, Rept. Labor. Ind. Mus., 1904-5, 25.]

B. variegata, lam. The kachnár, kólar, rakta kánchán, kurmang, sániga, kundol, akó, kóvidara, búcchín, etc.—a moderate-sized deciduous tree found in the Sub-Himalayan tract from the Indus eastward and throughout the forests of India and Central India. It is largely cultivated in the plains as an ornamental tree.

Most of the species yield a Gum which seems to be known by a generic name, sem-ki-gond. It is as a rule too little soluble in water to be of great value. That from B. retusa (semá gond) is very like gum arabic. It is eaten by the poorer classes and is used to waterproof terraced roofs, and also medicinally as an external application to sores. By some Native practitioners it is regarded as emmenagogue and diuretic. In the report by Dunstan, republished in The Agricultural Ledger (1900, No. 12), it is pointed out that the gum absorbs more than twice its own weight of water, and that a 10 per cent. solution yielded a thick mucilage which could not be manipulated. Several firms of brokers were asked to report on the gum. The estimated value was from 10s. to 20s. per cwt. They did not consider the gum of any commercial importance. It must, therefore, be regarded as mainly of local interest. The export from Dehra Dún amounts to about 2,500 maunuds per annum, and the local valuation is about Rs. 1–8 to Rs. 2–8 per maund.

Several species are reported to yield Oils, e.g. B. acuminata, B. tomentosa, etc., but information as to their economic use (if any) is wanting. The bark of B. purpurea is used in dyeing and TANNING and that of B. racemosa in dyeing. The latter produces at first a dirty red colour, but the dyed article having been worked up in mud for some hours subsequently appears black or nearly black (Note by Conservator For., E. Circ. Burma, 1896). Bauhinia is, however, principally noted for the Fibres afforded by one or two species. A cordage, strong but not durable in water, is made from the inner bark of B. racemosa. According to Dodge, this being very tough has been employed in India in the construction of certain bridges across the Jumna. The stems are usually cut in July or August. Concerning the strong cordage prepared from the bark of B. Vahili a full account is given in the Dictionary (i.e. 424) and need not be repeated here. It is a very important article with the hill tribes. The malu fibre is one of the few that will stand to be dried, bleached and worked up along with wool (Watt, Rea. of Brit. Ind., 1894, 15). In certain districts ropes are made from it in two ways. Either real fibres of the branches are extracted and twisted into ropes or the branches are simply split up and used as natural ropes. They are known in the Panjáb as udála and are extensively employed for tying slates and thatch on to roofs (See, Monog. Fibrous Manuf. Pd., 1889-90, 5). The shoots are said to grow as much as 50 feet long in one year.

Whilst it may be said that most of the species enumerated above are used in some way in Native MEDICINE, almost every part of B. variegata is so used. The bark, flowers, and root are triturated in rice-water for use as a cathartic. A decoction of the root is given in dyspepsia, the flowers are taken with sugar as a laxative, and the bark is regarded as tonic and anthelmintic. The medicinal use of the gum of B. retusa has already been mentioned. B. tomentosa is said to be antisyphilitic and to be useful in liver-complaints. The aerial parts of B. vahili are demulcent and the seeds tonic and emollient.

The aerial leaves of B. malabarica are used as Food in Burma and Bombay, and elsewhere the young shoots are eaten as a vegetable. The flowers of B. purpurea are used in curries as a pot-herb or are pickled. The leaves form a cattle-FODDER. The buds and seeds of B. racemosa are eaten by
Natives and the leaves are relished by buffaloes in N. India. The seeds of *B. Vahlii* are eaten raw or fried, and the young pods of this species and also of *B. variegata* are cooked and eaten by some of the hill tribes. The timber of *B. purpurea* is used for agricultural implements, but of the other trees of this genus the wood is mainly useful for burning. The leaves of *B. Vahlii* are made into cigarette-covers (*bidis*)—those of the former are said to be exported to Sind and Persia, while the latter in the Thana district alone bring a revenue of Rs. 1,500 a year. Those of *B. Vahlii* are made into cups, platters, etc., and the bark of this climber, as of *B. maeveostachys*, is used for matchlocks. Finally, the leaves of *B. racemosa* are worshipped at the Dasara festival.

**BEADS.**—These may be referred to three groups:—

1. **Mineral**, including glass and stone-beads, alabaster and metal ornaments, etc.

2. **Animal**, including bones, corals, pearls, shells, etc.

3. **Vegetable**, including flowers, fruits, seeds, etc.

**Mineral.**

1. In the mineral group there is a large import trade, especially from Italy, in glass beads. The value of the trade in 1902–3 was Rs. 16,61,325, representing 14,437 cwt. of goods, and in 1906–7, 22,520 cwt. or Rs. 24,02,442 (see Glass, p. 503). A considerable internal trade is also done in the cheaper kind of stones which are collected on the mountains of India and Burma, as also brought across the northern land frontier (see Gem Stones, p. 506). Small beads made of various metals are also common, the more elegant being gold beads mixed with precious stones or coral.

**Animal.**

2. Personal ornaments derived from the animal kingdom are chiefly Cowrie and Conch shells (see Shells, p. 980), feathers of birds, skins, furs, horns, bones, the smaller pearls, etc. Such information on these subjects as can be here given will be found under the respective articles, Birds' Skins and Feathers (see under Birds, pp. 138–42; Bones, p. 169; Hides, p. 630; Horns, p. 645; and Pearls, p. 557).

3. In the *Dictionary* (i., 430–8) will be found a complete enumeration of the various plants of which certain parts are used for beads, rosaries, garlands, etc. In the more important instances the domestic uses will be found under the plant-names in their proper alphabetical positions—Adhatoda, Egle, C01x, etc., etc. [Of Vieux, *Agri. Ledg.*, 1906, No. 6.]

**BÉCHE-DE-MER; Sea-slug; Tripangs; Suala, Swallow, etc., names given to various forms or qualities of the Edible Holothurian; Thurston, Mar. Fa. Rameswaram, Mod. Cent. Mus., see, ser., 1887, No. 1, 15, etc.

**Habitat.**—These edible Sea-slags are found on the coast of the Mediterranean, the Eastern Archipelago, Mauritius, Ceylon and Zanzibar, whence they are occasionally brought to Bombay for re-export to China. Several species are found on the shores of the Andaman and Laccadive Islands and on the Burmese coast, particularly that of the Mergui Archipelago, where they are collected from the Nicobar Islands, the Maldives, the Gulf of Manar, etc., cured and sent to China via Burma and Madras ports. It is, however, mainly from New Caledonia, Tahiti and the Fiji Islands that China is supplied.

**Preparation.**—Very little of a satisfactory nature is known regarding the Indian and Burmese species and qualities; the methods of collection, curing and drying; system of packing and exporting; chief towns concerned in the trade; seasons of collection, prices, etc., of these edible products. In fact very little of a practical nature has been described since Capt. Andrew Cheyne wrote his account—an abstract of which will be found in the Dictionary. Mr. Thurston tells us that "The Tripangs are collected by Natives, as they lie on the mud at low water, and placed in a caldron which is heated by a charcoal fire. As the temperature rises in the caldron, the still living animals commit suicide by ejecting their digestive apparatus, etc., and become reduced to empty membranous sacs, which, by loss of water consequent on the temperature to which they are exposed, shrivel up considerably. At the end of twenty minutes or half an hour the boiling process is stopped, and then the same process is repeated for a similar
time. Finally, they are arranged in order according to their size, and are then ready for shipment to China."

Trade.—The tripang is highly esteemed as an article of food by the Chinese and Japanese epicures. Minced down it is made into a thick gelatinous soup. It is seldom used by the Europeans in India, but is reported to be a favourite article of diet with the colonists of Manilla. The trade returns usually record a fairly large traffic to and from India and Burma. The foreign imports of India during 1901–6 averaged about 28,000 lb., valued at Rs.10,000, and these came from Ceylon, the Straits Settlements and Hongkong, and were consigned to Madras and Burma. In 1906–7 the actual imports were 6,744 lb., valued at Rs. 2,796. Formerly, of the exports of Indian Bêche-de-Mer an average of about 100,000 lb., valued at Rs. 24,000 a year, went from Burmah and Madras to the Straits Settlements. But within recent years the trade seems to have been declining, the exports in 1903 having been approximately 32,000 lb., valued at Rs. 6,000. Since then, however, they have fluctuated greatly, and in 1906–7 were 44,408 lb., valued at Rs. 14,343. [Cf. Barbosa, Coast E. Africa and Malabar (ed. Hakl. Soc.), 165; Forrest, Voy. Merqui, 1783, 83; Milburn, Or. Comm., 1813, ii., 305; Raffles, Hist. Java, 1817, i., 203–8; Royle, Prod. Isinglass, 1842, 54; Crawfurd, Dict. Ind. Isl. and Adj. Count., 1856, 440; Collingwood, Rambles of a Nat., 1865, 150; Mason, Burmah and Its People, 303, 728; also (ed. Theobald) i., 20; Hunter, Imp. Gaz., x., 295 (Expt. from Nicobar).]

BEES: BEES’-WAX, BEES’-DAMMAR AND BEES’-HONEY.—It has to be admitted that in India Bee-culture takes a remarkably subordinate position. Whilst met with occasionally on the hills, it is a completely neglected industry on the plains as a whole. This circumstance is doubtless an expression of the influences, whatever they may have been, that consigned horticultural and dairy operations to village artificers rather than to farmers or agriculturists proper.

The religious sentiment against taking life may doubtless have had a restricting power, and perhaps the climate and the seasons of flowering, together with the nature of tropical vegetation, may have been ascertained to be unfavourable, and thus have acted prejudicially against the establishment of regular bee-culture. But while there is no organised industry, bees exist plentifully here and there all over India and Burma, in a wild or semi-domesticated condition, and supplies of both honey and wax are plentiful and of fair quality. It seems to be generally upheld in India that bee-culture is impossible in regions where species of Strobilanthes do not abound.

The following may be given as the chief honey and wax-yielding bees and the products derived from them, together with the references to standard works regarding the same:

(a) Apis dorsata, Fabr.: Bingham, Fa. Br. Ind. (Hymenoptera), i., 557. The Wild Bee or Rock Bee of India: the voua, khago, kongi or kong, dangara, surang, bhammar, mahal, mahuk, bhavra, lycus, aghya, age, toqri, tagara, bhaga- mohu, pedda-pera, peria-them, piesei-tenai-egalu, malai-teni, pya-gyi, etc.

Habitat.—Found throughout India and Burma, but rarely ascending the hills to altitudes above 2,000 feet. It would seem to be most prevalent in localities where species of Strobilanthes abound, and is reputed to move from one locality to another with the somewhat spasmodic flowering of the plants on which it seeks for its supply of honey, etc. Bingham remarks, "So far as my observation goes, Apis dorsata, Fabr., the largest of the three species, in

Largest Indian Species.
its wild state builds its combs exclusively more or less in the open—that is to say, on the undersides of the branches of large trees, in caves or under over-hanging rocks, in buildings, etc." The combs are three to five feet long, and two feet or more deep; they consist of cells that are 4½ to the inch. Only occasionally is the comb, side by side to the frame, built. Some of these combs weigh as much as a zemum, and an average one gives from 10 to 20 lb. of honey and from 2 to 3 lb. of wax. Mr. J. D. Douglas's note in the Dictionary (l.c. 435) furnished the following reasons against the systematic cultivation of this species:—

1. It builds naturally in the open. 2. It makes as a rule but one comb, so that honey cannot be removed without destroying the brood. 3. Its comb though large is not so great in cubic capacity as the combs of the ordinary domestic bee of Europe (A. mellifera). 4. It is only met with in tropical countries. It may be added that it is a vicious, intractable insect.

(b) A. Indica, Fabr.; Bingham (l.c. 558); the Indian Semi-Domesticated Bee: the Hill Bee; the Tree Bee of Indian writers, or sathpuria, sath, eateri, satpada, mohury, mohri, aira, ngap, yung, manchtilur, doar, doyar sadhi, saide, kol, tudir-jen, aduku theni, thord egatu, pya aung, etc.

**Habitat.**—Found throughout India and Burmah and ascending the hills to 9,000 feet. In the high altitudes of its area, such as Bhutan, Hazara, Kashmir, Khalsa hills and Simla, the insect seems to become larger than when met with in the plains and lower hills. Unlike A. dorsata it does not as a rule live in the open, but chooses hollow trees, overhanging caves, crevices in walls, etc., and shows a preference for proximity to human dwellings rather than for the hearts of forests or the faces of inaccessible rocks. There are several combs, one above the other, hence the name sathpuria or seven-layered. The cells are about 5½ to 6 to the inch. The yield of honey from a fair-sized hive would be from 10 to 40 lb., and of wax from 2 to 10 lb.

Mr. G. Minnken, in a report published in the Dictionary (iv., 268), gives an interesting account of the degree of domestication practised on the Himalaya, and that may be here epitomised since it is fairly representative of the bee-culture of India. In Beshahr, he says, houses—one, two or three stories high—are often specially kept for rearing bees. In these, small recesses are made in the walls, two feet apart and closed on the outside by a wooden panel in which an entrance hole is made. A man is usually in charge of each such bee-house, whose duty it is to prevent over-swarming. This is effected by giving each colony ample room, and sometimes by clipping the wings of the queen. He has also to keep the apiary well stocked with early swarms, and to guard it against the rapacity of bears, martens, hornets, caterpillars, etc. Stocking is most generally effected by capturing wild swarms and bringing these to the apiary. But where bee-culture on a large scale is not contemplated, it is customary for the hill people to provide one or two recesses in the walls of the ordinary dwelling-houses in which a few swarms may be reared. In the Simla district it is believed the best honey is procured in localities where *Pleconanthus rugosus* (the pekh) abounds.

The Bashahr system is followed in Chambo, Hazara, Jholum, Kangra and Kullu. The swarms are looked for in the jungles, and carried off to the zamindar's house. In Kashmir, a honey-bee—manchtilur—is almost completely domesticated, and seems to be a variety of *A. indica* hardly separable from *A. mellifera*. In the Khalsa hills a somewhat similar semi-domestication exists, the swarms being captured in the jungles and kept in small boxes under the eaves of the houses.

(c) A. florea, Fabr.; Bingham (l.c. 559). This is the smallest of the three Indian bees, but with *A. indica* is much more closely allied to the European honey-bee (*A. mellifera*) than to the Indian rock bee (*A. dorsata*).

**Habitat.**—It has been collected in Bengal, Assam, Burmah, Madras, Malabar, Central Provinces, Central India, the United Provinces and on the Himalaya from Kumaon and Sikkim. It might in fact be viewed as a slightly more tropical species which displaces to a large extent the western and northern *A. indic*.

It has been called Flower Bee by some writers, and appears to be the *kotiyal, lamai, tudbi, zinya, kol-tala, kombuth, thodji-para, pullu-egatu or pullu-tenagatu, yra-egatu*, etc., etc. Its combs consist of cells that are nine to the inch. It would appear frequently to build in the open a single comb suspended from branches of trees or rather thorny bushes, especially near river-banks, but sometimes it selects cavities in walls or hollow trees, or builds under the cornices or other protecting parts of houses. It is a comparatively harmless insect, and about the size of the domestic fly. It is probable that the mohri or
BEES'-WAX

The honey it affords is but small in quantity, and when found on trees is thin in quality. It appears to improve when produced within large combs in protected hives. In Burma (Kachin country) a sort of domestication has been attempted apparently with this species, though with little success. According to some writers its honey is superior to that of the other two species. In Burma as a whole, however, A. dorsata is regarded as the most valuable insect, though it is never domesticated in any way.

II. BEES'-WAX.—This substance is best known by the following names—mom, sinh, mena, min, mozhukin, mainam, mozhuka, lelin, phayoni, and in the classic—madhujam, siktha, shama, etc.

The observations already made regarding the species of bees met with in India afford incidentally certain particulars regarding wax. It may, however, be useful to disregard the individual insects and to bring together provincially the particulars available regarding the centres of supply. The season for making wax would appear to be the hotter months, viz. April to June. The separation of the honey from the wax is usually done in the crudest manner possible by the persons who collect the combs. Refinement is rarely practised, but adulteration is not usual, and although under the Indian sun it might be readily bleached, Indian wax is rarely so treated, but on the contrary is purposely coloured with turmeric. It is made up in balls, rolls, cakes or blocks, sometimes moulded and at times even as much as 2 feet in diameter and 6 to 9 inches in thickness.

Hooper's paper (ib. 82-100) should be consulted for fuller details, but the following abstract may be useful:

Bengal.—Supplies are drawn by Calcutta from the Sundrihans, Chota Nagpur, Chittagong, Darjeeling, Bhutan and Nepal. It would appear that average qualities realise from Rs. 53 to as much as Rs. 75 a maund. It is largely consigned to Singapore and the Straits Settlements.

Assam.—The dealers in wax reside in Sylhet, and they derive their supplies from the Khasia hills and wild tracts beyond the frontier. Naga wax is usually sold in rolls cast in bamboo moulds. Assam wax is of inferior quality as a rule.

United Provinces.—The right of collecting honey and wax is leased, but a decline in the supply has recently taken place. It is drawn from the Eastern Dun Forests, Kharí, etc. The trade is chiefly in the hands of traders resident in Saharanpur. It fetches about 11 annas a pound, the imported foreign bleached wax realising about 9 annas.

Central Provinces.—It has been stated that the forests of these provinces are capable of yielding 300 maunds of honey and 100 maunds of wax annually. In Chadgarh bees are so plentiful that it is impossible to beat the forests for big game. Ratgarh hill has been described as a "hive of bees." The following are the chief localities of supply in alphabetical sequence of names—Betul, Chanda, Chhindwara, Damoh, Hosangabad, Jabalpur, Mandla, Nimar, Raipur, Sambalpur and Wardha. Wax fetches locally, according to quality and season, from 3 annas to 12 annas per pound. There are said to be two seasons for collecting—April to May, and again November to December.

Panjab.—Bee-culture and the collection of honey and wax from wild bees seems to be confined to the hilly country. The districts most famed are Bashahr, Chamba, Hazara, Jhelum, Kangra, Kashmir, Kullu, Simla, etc. Certain species of bee supplies the Hills.

Wax.
particulars have already been given of these localities that need not be repeated. The Bashahr supply comes usually to about 20,000 lb. of wax that is sold at the annual fair of Rampur. In Hazara, bee-keeping is practised for the sake of the honey, and the wax obtained appears to be largely used up locally. In Kangra it is said 2 to 3 maunds of the annual productions are employed by the brass and coppersmiths in moulding their wares. In Hazara the honey is collected in November, in Kullu during July and again in October, while in Chamba the seasons are May to June and September to October, and in Kashmir it is gathered from September to October. The hives contain from 20 to 40 lb. of honey and 2 to 4 lb. of wax.

**Afghanistan.**—Kuram Valley and Afghanistan.—Bees are believed to be extensively kept by the hill people, and the produce is to some extent exported to India.

**Rajputana.**—Honey and wax are collected at Ammer, Baojari, Dewari, Mandla, and Tedgarh, but the supply of wax is very small.

**Bombay.—**The honey and wax of this Presidency are drawn mainly from Khandesh (Satpura mountains largely) and the Deccan. The chief localities are Belgaum 1,500 lb.; Dharwar, 1,500 lb.; Kanara, 3,000 lb.; Panch Mahals, 4,000 lb.; Ratnagiri, Satpuras, 500 lb.; Satara, 500 lb.; Salsette, etc. The figures denote the approximate annual supply. Locally it fetches from 4 to 10 annas a seer (2 lb.); the Bombay maund in some returns is 28 lb., and the price of wax per such maunds is quoted at Rs. 14 to 20; in other cases the maund is 40 lb. and the price returned as Rs. 25 to 30. The wax is said to be usually about one quarter the value of the honey. The exports from the Presidency go mainly to the towns of Bombay and Goa.

**Bevar.**—The districts most noted are Ellichpur, Mangrul, Melghat, and Wun. The supply is not large, and the local price is about 4 annas a pound.

**Madras.**—Bees are met with on all the mountains and low hills of the Madras Presidency, but the following are the chief centres of supply in alphabetical sequence of their names: Bellary, 800 lb.; Coimbatore, 8,000 lb.; Cuddapah, 3,500 lb.; Ganjam, 1,000 lb.; Godavari, Kistna, Karnul, 6,000 lb.; Madura, Malabar, 200 lb.; Nellore, 500 lb.; Nilgiri, North Arcot, South Kanara, Trichinopoly, and Vizagapatam, 700 lb. The figures give the annual supply of each of the places named. The Madras maund is 25 lb. and wax is said to sell at from Rs. 10 to Rs. 20 a maund, but it is often to be had at 4 annas (say Rs. 5 a maund) or it may fetch as much as 12 annas a pound.

**Burma.**—Following the system pursued with the provinces of India, the following may be mentioned as the centres of Burmese supply:—Bhamo, Chindwin, Katha, Mandalay, Minbu, Pyinmana, and Tenasserim. In the Upper Chindwin there seems to be a prosperous trade in honey and wax. It is brought for sale in the Kabaw valley. In the lower Chindwin, Mankadaw is the mart. It is probable that the total supply from the Chindwin comes to something like 4,000 lb. to 6,000 lb. (viss = 3 lb.). The rate at which it is sold comes to about 10 annas a pound, but in the towns a much higher figure is quoted. In Tenasserim it averages from 9 annas to Rs. 1-5 a pound. It is impossible to give even an approximate estimate of the Burmese total production, but wax is largely imported, so that there cannot be a margin for export.

**Chemical Investigations.**—Hooper, concluding his report on the extensive series of samples that had been placed in his hands for chemical examination, says: "In studying the tables of analyses"—drawn up as the result of the investigations conducted in the Indian Museum—"two very interesting facts will be revealed. The first is the lower acid value of Indian bees-wax; this indicates a different ratio between the erotic acid and myricitin compared with that of waxes from other parts of the world, and the second is the uniformity in composition of the secretion of the three kinds of Indian bees representing the Apis family. The appearance of the wax from the three species gives no clue to the origin, and although there are two or three somewhat abnormal deviations from the average on account of the high saponification value and the wide range of the iodine value, there is very little, if any, suspicion of adulteration. The wax from the combs of *Apis dorsata*, *A. indica*, and *A. florea* is, therefore, practically
identical in composition, and a combination of the wax of one species with
that of another cannot be regarded as a fraudulent admixture. It must
be admitted, however, that the Apis dorsata, because of the much
larger comb it manufactures, is the chief source of the bees’-wax of
the country.” “It is satisfactory to record that out of 64 samples
collected from different parts of India only 3 were really adulterated,
or less than 5 per cent. of the total, and there is no evidence that the
sophisticated wax was a native product or was manufactured in the
country.”

Uses of Wax.—It is perhaps hardly necessary to mention the uses
of wax. The introduction of paraffin and other composition candles has
removed, to a large extent, the demand for wax to be used as votive
 offerings at the temples and churches. Jahangir (Memoirs (Price, transl.), 3)
alludes to camphorated wax lights used in the palace. It is, however,
required by the silver and goldsmiths, also by brass and copper foundry-
men, to give finishing touches to their moulds and to be subsequently
liquefied and dispelled by the molten metal poured into the matrix.
There is a considerable demand in Burma for it, accordingly, in
the workshops that turn out the brass idols of Buddha. Wax is
also fairly extensively employed as a resist in certain stages and
methods of calico-printing (Ind. Art at Delhi, 1903, 229–30, 259–67).
Lastly, it is largely used by the shoemakers of India. In Medicine
wax is extensively employed in the preparation of ointments and
plasters.

Recently some interest has been observed in a substance called
“propolisine,” derived from the propolis of bees (see below) by dry dis-
tillation. It is said to destroy all known bacteria without danger to
human beings.

Wax Trade of India and Burma.—During the past twenty years the
exports of wax have practically remained stationary. The highest figures
occur in 1905–6—viz. 8,593 cwt., valued at Rs. 7,31,320, and in 1894–5,
namely, 7,487 cwt., valued at Rs. 7,05,247 the lowest in 1896–7—viz.
3,142 cwt., valued at Rs. 2,76,190. In 1906–7 they were 8,162 cwt.,
Rs. 5,96,009. The major portion of these exports go from Bengal,
and the chief receiving countries in 1905–6 were Germany, 2,854;
the United Kingdom, 2,609; Belgium, 988; Straits Settlements, 622;
United States, 408; France, 406; all other countries making up the
balance of 8,593 cwt., the exports for the year. [ Cf. Milburn, Or.
Comm., ii., 315.]

III. BEES’-DAMMAR.—Bingham, Fa. Br. Ind. (Hymenoptera),
i., 559–64; Cooke, Guns, Resins, etc., 1874, 95–7; Hooper, Agri. Ledg.,
1904, No. 7, 79 et seq. The Dammar Bees, as the little insects that afford
this substance are called, belong to the genus Melipona, or, as it has been
called, Trigona. A resinous substance employed by several species of this
genus in forming their nests, is an article of commerce. It has been said
to be chemically allied to propolis, the substance used by the domestic bees
to repair injuries to their hives or to stop up useless and objectionable
openings. These very minute and stingless bees are met with all over India
and Burma. Among the collections recently brought together some 40
samples of wax, honey, etc., were identified, through the insects that accom-
panied them, as being the product of species of Melipona. These came
from the following localities, the figures denoting the number of separate samples to hand: Almora (2), Basin, Belgaum (2), Betul (3), Chhindwara, Coimbatore (4), Damoh, Dehra Dun (4), Dharwar (2), Kanara (2), Khandesh (3), Madura, Nellore, Nilgiris (2), Panch Mahals, Raipur (2), Ratnagiri (3), Rawalpindi, Sambalpur, Singbhum, South Kanara (2), Tenasserim and Tinnevelly (2). It will thus be seen that these insects are practically distributed all over India and Burma, and perhaps to a greater extent than was known to Bingham when he wrote his *Hymenoptera*. That distinguished author describes twelve species, of which *Melipona toveiceps* of Tenasserim is the most interesting, since it affords (or at all events, is the chief source of) the resinous substance known as *Pwé-nyet*. The following are the vernacular names for the specimens of *Melipona* recently procured: —kunti, kote, kuntali, poye, nasari, bhinkwa, bankwa, misri, nasrijen, kosuteni, kalliada, musuruteniga, moye byak, etc., etc.

**Pwé-nyet.**—The insects referred to are said to build nests in hollows within trees, crevices among rocks, and sometimes in holes in stone walls, etc. The interior surfaces of the nests are lined with a resinous substance, and the entrance is often formed into a beautiful projecting funnel also composed of a resinous substance—the product for which these insects are valued. When the nests are small, the resinous substance (or bees"dammar) is not collected, but in the case of *A. toveiceps"* the trumpet-shaped structure of resinous wax which very often forms the entrance to the nests” projects from the hole in the tree for a foot or more. "Horne gives an interesting account of the finding of the nest of *M. vaferoensis*, and states that the hollow in which it was built was coated all over with a layer of black wax, and that the cells, containing a dark honey of excellent flavour, were globular in shape, pendant side by side from the roof." *M. vaferoensis* is apparently the only Indian species that has been systematically described. Whether the forty odd samples indicated above are one and all derived from this or from several species has not as yet been ascertained. Horne’s description of the resinous lining and the comb says that it is a peculiar compound of various resins and gum-resins. In a fresh state it may be moulded to any shape. Its constants were determined as well as its solubility in alcohol and ether. He promises a full report in the future, but for the purpose of comparison has carefully studied the resins and oleo-resins of *Hopca, Valeria, Camarum*, and *Dipterocarpus*. So far, therefore, Hooper seems to confirm the popular opinion that *pwé-nyet* is composed of certain gums and resins collected by the insects from trees. Speaking apparently of the wax of the combs, Hooper further observes: "The wax of the species of *Melipona* has quite a different consistence and composition compared with that of the true bees. The blackish colour, sticky consistence and higher melting point, acid and iodine values readily distinguish it." According to Groshoff and Such (Pharm. Weekbld., 47, 933), the substance consisted of a mixture of 8 parts resin, 12 parts wax with 4 parts of an impurity insoluble in alcohol. The resin melted at 60° and the wax at 60°. But it is not quite certain whether they had examined the true wax or the *pwé-nyet*.

**Uses of Pwé-nyet.**—"The resinous product collected and used by the bees in making their nests is called ‘pwé-nyet’ by the Burmese, and after boiling in water and mixing with earth-oil or petroleum, it is largely used for the caulking of boats. The right of collecting ‘pwé-nyet’ is sold by the Local Government in Burma and Tenasserim yearly, and forms one of the sources of revenue under Minor Forest Products” (Bingham, l.c. 560).

**IV. BEES'-HONEY.**—The best names for honey are shahad, madh, madhu, sahu, saht, polée, tén, jenu, piya-ye, etc. The honey-bee would be shahd-ki-makhi.

It is not necessary to deal with this subject in detail after the treatment already given to Bees and Wax. The regions of production of the latter are

**DEP., iv., 268-71.**

**Honey Production.**
necessarily those of the former. Occasionally, however, the wax is neglected and the production and sale of the honey becomes the important aspect. Honey is a plentiful wild product over the greater part of India, and is obtained also from bees in a state of semi-domestication, chiefly in the hills of the Panjab. It is highly appreciated as an article of food by the inhabitants of many parts of India. It is also employed to preserve fruits, and in the Khasia hills, apparently, human bodies are sometimes temporarily preserved in it. At certain seasons, due doubtless to the flowers visited by the bees, or possibly to the species of insect, the honey has intoxicating and even poisonous properties. The honey of the various species of Indian bees, mentioned above, at all events varies considerably. The most abundant is that of *A. dorsata*, which provides the greater portion of the honeys of the United Provinces, the Central Provinces, Berar, Bombay, Madras and Burma. This is the insect of the Kundahs, the honey of which is collected in March and again in September. The March crop is the best. Mr. A. Mervyn Smith published in the *Statesman* in 1895 a most instructive account of the Honey and Wax collection of the Kundah country. As this is representative of the operations pursued in the Nilgiri hills, in the Wynad, in the Sattyamangalam hills and elsewhere, a fairly extensive passage may be abstracted:—

"A strong stake was driven into the ground 15 or 20 feet away from the edge of the precipice, as a purchase for the rope, as it was being lowered down the face of the precipice. One end of the cane-ropes had a double loop, in which a Ko-ramber seated himself, his feet being supported by a short stirrup of bark. A light, reed-like bamboo, 20 feet long, armed with a reaping-hook at the end, served to cut the combs from the rocks. A small landing-net below the sickle received the combs as cut. A light cord, running through a loop about 10 feet above the head of the gatherer, and fastened to the sickle-end of the rod, enables the gatherer to use the rod as a derrick, which he can raise, lower, and swing to any position, without being inconvenienced with the weight of the combs in the net. When the net is full, he empties the contents into a large close-framed basket lined with leaves, which is suspended from a separate cord; and this basket is drawn up when filled. The occupation of gatherer is extremely dangerous and requires steady nerves. In many cases the men are suspended 400 feet from the top of the cliff, with many hundreds of feet below them to the bottom of the precipice. These cane-ropes are immensely strong and stand more rough usage than one made of fibre, and they are also extremely light. The suspending rope is shifted about from place to place in answer to signals with the hand from below. Immediately the bees are disturbed, they crowd round the gatherers in myriads. The men are literally covered with a coating of bees from head to foot and present a most curious appearance, just as if they were covered with rusty chain armour, each link of which is in motion. The pungent smell of the wood-smoke from the bodies of the gatherers has a kind of paralysing effect on bees and prevents them stinging. The flight of bees thus disturbed could be distinctly seen, from which came, half a mile off, and resembled a flight of locusts. We could even hear the humming noise made by the irritated insects. In about two hours all the combs within reach had been collected and the ropes were drawn up."

The next most important honey is that of *A. indica*, an insect found here and there all over India, but semi-domesticated in the Khasia hills and the mountains of the United Provinces, of the Panjab and of N.W. Frontier Provinces. It is accordingly the chief source of the honeys of Assam and the Panjab, and possibly also of Bengal. The third form is hardly a commercial article, though when found in sheltered positions it is said to be remarkably good. It is the honey of *A. florea*. This is met with in the Central Provinces, Bombay, Berar, Madras and Burma. Lastly, some of the species of *Hellepona* afford honey. This is incidentally alluded to by Hooper all through his review of the information recently collected by the Reporter on Economic Products. He tells us that it is often tainted with a peculiar odour, and has a bitterish and acid taste. It has, however, a considerable reputation in many parts of India for its medicinal properties. In some parts of the country (Nellore) the honey of the dammar-bee is said to be intoxicating, and in Kanara it is reported that the insect is semi-domesticated. [Cf. *Institutes of Manu*, iii., 119; v., 41; viii., 131, etc.; Barbosa, *Coasts E. Africa and Malabar* (ed. Hakl. Soc.), 167; Lawrence, *Valley of Kashmir*, 1895, 366; *Journ. Board Agr.*, 1898, 335–9; *Bee-keeping, Imp. Dept. Agr.*, *West Ind.*, 1901.]
BERBERIS
Barberry

BENINCASA CERIFERA, Suvi.; Fl. Br. Ind., ii., 616; Cucurbitaceæ. The White Gourd Melon, petha, kumhra, etc., an extensive climber cultivated in India; native of Japan and Java.

Sown at the beginning of the rains or in the hot weather, it continues fruiting until the close of the rainy season. The fruit excretes a waxy bloom which it is said can be made into candles. The seeds yield a mild, pale Olt. The fruit possesses alterative and styptic properties, and is popularly known as a valuable antimercurial. It is also used as a vegetable and in curries or is made into a kind of candied fruit called heshmi or heshin, sold at about 3 lb. to the rupee.

There are twelve species of Barberry mentioned in the Flora of British India. They are not easily distinguishable, and the vernacular names are therefore probably indiscriminate. The products are common to five or six Himalayan species and may be dealt with collectively. The chief are the following:—

B. aristata, 00.; chitra, simlû, kasmal, isena.
B. asiatica, Roxb.; kilmora, matê-kias, chitra, etc.
B. Lycium, Noge; kashml, choitra, ambar-bâris, etc.
B. vulgaris, Linn.; kashml, bedana, ambarbâris, etc.

Habitat.—The entire Himalayan districts between 6,000 and 10,000 feet, also the Nilgiris, Ceylon, etc. The bushes often constitute thickets many miles in extent.

A dye is obtained from the roots and stems, which is sometimes used in tanning and colouring leather. It would seem that the colour exists chiefly in the bark and in the young wood immediately below the bark. In the older wood there is less than better quality of dye. Barberry is perhaps one of the best yellow dyes in India, and the supply is inexhaustible. The seeds yield an oil.

The principal use of the barberry is, however, in medicine, the parts employed being the stem, dârhalad, the fruit, zirishk or zirishk, and the root-bark. A watery extract is prepared from the stem and root, called ruset or rasout (Taleef Shereef (Playfair, transl.), 1833, 87). It is worthy of notice that this extract has the same beneficial effects in the treatment of ophthalmia which have been ascribed by certain Greek and other early writers to mamiras. The plants now known in India as mâmîrân seem, however, to be Coptis teeta, Wall., Corydalis Gowaniana, Wall., and Geranium Wallthiænæm, sweet. The juices of these are still used as applications to the eye, and two of them, at least, contain berberine. In later times the barberry appears to have been extensively sought by European oculists, and it seems to have been the origin of the Lycium, whereof the empty pots were found in Herculaneum and Pompeii.[Cf. Fluckiger and Hanbury, Pharmacog., 33-5.] Barberries-sticks, 1 inch thick and 12 to 18 inches long, are fairly extensively exported from Kangra and thence carried all over India (see Coptis, p. 405).

Trade.—Various preparations of the barberry are used in fevers, the advantage claimed over quinine being that repeated doses of berberine do not cause depression and deafness. The fruit is given as a cooling laxative to children, and the stems are said to be diaphoretic and laxative in rheumatism. The berries are dried like currants, and thus brought down to the plains. The trade value of dârhalad is stated by Dymock (Mat. Med. W. Ind., 28) to be Rs. 3½ per maund of 57½ lb. ; of ruset, Rs. 8 to 9 ; of zirishk, Rs. ½ per lb. Mooden Sheriff (L.c. 15), however, quotes the wholesale price of ruset as Rs. 35 per maund, and the retail price as Rs. 2½ per lb. He says that the fruit (zirishk) may be had at Rs. 6 per maund (wholesale), or 6 annas per lb. (retail). Kanny Lall Dey gives the price of the extract (ruset) as 8 annas per lb.

130
BIRCH BARK

BETULA UTILIS, Don.; Fl. Br. Ind., v., 599; Gamble, Man. Ind. Timbs., 668; Pharmacog. Ind., iii., 359; Cupuliferæ. The Indian Paper Birch, bhūj-pattra or bhūj-patar, börj, shák, takpa, phuspat, bhūr-japatra, etc., is a moderate-sized deciduous tree forming the upper edge of arborescent vegetation in the Himalaya (14,000 feet).

By some of the hill tribes the bark is regarded as more durable than paper, and it is well known as the material upon which the ancient Sanskrit MSS. of Northern India were written. It is widely used for writing medicinal charms and is said to be found in every druggist’s shop. Its uses are, however, varied; for wrapping up parcels, for surrounding hookah-stems, for umbrellas, for water-tight roof-lining, and apparently sometimes also for clothing. Minute strips are used in certain forms of tie-dyeing. [Cf. Ind. Art at Delhi, 1903, 256.] The younger branches are plaited into twig bridges. It has also certain aromatic and antiseptic properties. The leaves are lopped for cattle-Fodder, and the timber is extensively used in the inner arid Himalaya for building, since it is elastic, seasons well and does not warp. [Cf. Taleef Shereef (Playfair, transl.), 1833, 48; Lawrence, Valley of Kashmir, 1895, 68-9, 79; Journ. Soc. Chem. Induct., 1900, xix., 1141.]

Another species, B. alnoides, Häm.; pījā uddish, shādūl, shākhšin, etc., of the outer Himalaya, the Khasia hills and Burma, has a bark which constitutes an important article of FooP with the Lahüpas in the mountain-tracks of N.E. Manipur. In the upper tracts of Kulu, where earthenware vessels are procurable with difficulty, the outer bark is peeled off in long strips and bound around water-pots as a protection. The Timber is valued in Nepal for strength and durability.

Bezoar.—This is the padzahr or pazzahr of the early Persian writers, a name which usually denotes an antidote or alexipharmic. The word comes into English through the Arabs, who wrote it bazahr. The true bezoar is a stone or concretion found within the bodies of certain animals, more especially the Persian Wild Goat (Capra veyagrus) (Blanford, Fa. Br. Ind. (Mammalia), 503) (see p. 743).

Sources.—Moodeen Sheriff (Ind. Pharm., suppl., 68-70) says there are many kinds or qualities, according to the animal from which procured, such as Goat-, camel-, fish-, snake-bezoar, etc. The last mentioned is generally called Snake-stone. But there is no foundation for the very general belief that snake-stone is procured from the head of the snake (see p. 141). Some writers classify the bezoars into animal and mineral, the last being a fossil form and possibly often a coprolite. So also numerous references are made by writers on this subject to false or artificially prepared bezoars, fabricated apparently from calcined bone. Certain towns are famed for their bezoars, such as Diu and Golconda.

Chemical Examination.—Dr. Davy was apparently the earliest author to examine these stones chemically, and his description of them has been drawn upon by the majority of subsequent writers. Taylor formed nine groups, three being phosphates (of lime, magnesium, or of ammonium and magnesium), one oxalate of lime, and the five others mostly mechanical or obstructive accumulations such as hair, vegetable-fibre, ambergris, etc. Milburn observes that the genuine Oriental bezoar is commonly of an oval form and between the size of a hazel nut and a walnut; the larger it is, the more valuable. It is externally smooth and glossy, and is composed of several layers. The colour most prized is a shining olive green. It has a peculiar smell but no taste. Can be scratched easily by a penknife, and when applied to the tongue or any moist surface adheres firmly and absorbs the moisture. The supposed virtue as alexipharmics depends upon this power of absorption, but in Europe it has been proved that they have no special chemical or mechanical merit in support of their varied reputation. [Cf. Watts, Dict. Chem., 1883, i., 584.]

BIRDS: Blanford and Oates, Fa. Br. Ind. (4 vols. on Birds); Jerdon, Birds Ind., 1862-4; Henderson and Hume, Lahore to Yarkand, 1873, 170-304; Hume, Scrap Book; also Nests and Eggs; Oates, Birds of Burmah; Barnes, Birds of Bombay.

From the standpoint of utility the study of the birds of India might
THE ECONOMIC BIRDS OF INDIA

be referred to several sections of which the following, taken up in alphabetical sequence, may serve to exemplify the chief facts and products of value:

1. Birds associated with Agricultural and Horticultural operations, either beneficially or injuriously. W. L. Sclater (Ind. Mus. Notes, ii., 119) gives the following as the chief insectivorous or helpful birds:

   Accipitrinae, the Hedge Sparrows; Brachypterygini, Ground Babblers; Caprimulgidae, Goatsuckers; Certhiidae, Creepers; Corvidae, Rollers; Crateropodinae, Babbling Thrushes; Cuculidae, Cuckoos; Cypselid, Swifts; Dieturidae, Drongos or King Crows; Hirundinidae, Swallows; Laniidae, Shrikes and Minivets; Liorechidae, Ioras and Green Bulbuls; Megapidae, Bee-eaters; Motacillidae, Wagtails and Pipits; Muscicapidae, Fly-catchers; Paradisornithinae, Crow-tits; Ploceidae, Woodpeckers; Pittidae, Ground Thrushes; Ruticollinae, Redstarts and Robins; Saxicoline, Chats; Sylvia, Warblers; Timelinae, Solitary Babblers; Trogonidae, Trogons; and Euphidae, the Hoopoes.

   In addition to these the following partake of a mixed diet, and are partly insectivorous and partly fruit and grain feeders:—Alaudidae, Larks; Brachypodinae, Bulbuls; Biceidae, Flowerpickers; Fringillidae, Finches; Cisticolidae, Cranes; Zinioidea, Waders of all sorts; Nectarinidae, Sun-birds; Oriolidae, Orioles; Otididae, Bustards; Pooine, Tits; Passeridae, little Birds; Rallidae, Rails; Siblina, Sibias, White-eyes, etc.; Sittidae, Nuthatches; Sturnidae, Starlings and Mynas; Tetroidea, Partridges; Turdidae, Thrushes; and Turdacea, Button Quails.

   It is highly important that the majority of the above-enumerated families of birds should be protected against ruthless destruction. The conditions and necessities of India are, however, very different from those of Europe that legislation, easy of application in the latter, often becomes next to impossible in the former, where the customs of the people, their complex vested interests, their immense numbers and the vastness of the territory they occupy, are facts of supreme moment in the enforcement of even urgently needed legislation. To Surgeon-General George Bidie, C.I.E., is due much of the credit for bringing about the existing Indian legislation for the protection of birds. In 1887, however, the Government of India brought into force a law for the Protection of Wild Birds and Game” (Act xx. of 1887): this allowed Local Governments to define Wild Birds and to fix the required close season within which it became illegal to possess or sell certain birds. But as its operations were more or less restricted to Cantonment and Municipal limits it exercised little repression on the most objectionable aspects of the traffic, namely, the slaughter of plumage birds in the rural tracts. Accordingly first the Madras, then the Bombay and finally the Panjab Government sought permission to extend the provisions of that Act. Philanthropic institutions and individuals also continued to press on the attention of the Government of India the desirability of amending the Act. After a full consideration of all the circumstances and evidence His Excellency Lord Curzon in Council issued a Notification (Sept. 19, 1902) which prohibited the taking by sea or by land out of British India skins and feathers of all birds other than domestic except (a) feathers of ostriches and (b) skins and feathers exported as bona fide specimens illustrative of natural history. Thus an effectual check has been given to the reprehensible and destructive traffic, for since no foreign market is now open to the fowler, the trade is practically destroyed. [Cf. Journ. Bomb. Nat. Hist. Soc., iv., 124.]

   But fortunately few of the purely insectivorous birds are either attractive in plumage or in demand as edible birds. The exceptions are all the more regrettable, viz. (a) The Blue Jay or Indian Roller, Coracias indicus, the nilkant, sasbuk, tis, pada pitta, katu kadei, etc.—one of the most abundant and typical of Indian birds. It is sacred to Siva and a constant associate of the homestead and village lands. Its brilliantly coloured blue plumage led to its wholesale destruction, many thousands of skins being annually sent to Europe. (b) The Purple Sun-bird or Honey-sucker, the shakat khora, jagi jagi, than kudi, etc.; recently a deplorable trade had been organised in exporting the skins of this beautiful and most useful bird. Happily the roller and the sun-bird will no longer be trapped and snared, for the loss of the foreign market practically means the discontinuance of the demand.
CAGE BIRDS

With regard to the second group it is probable that some of them do more harm than good to the crops amongst which they are to be found. Their protection is not, therefore, so necessary, and those of them that are utilised economically or industrially will be dealt with in further paragraphs.

2. Birds often Reared in Cages, etc.—F. Finn (Cage-Birds of Calcutta, in Journ. Bomb. Nat. Hist. Soc. (reprinted from The Ibis), xiv., 564-78) furnishes full particulars on this subject, and to that valuable paper the reader is accordingly referred.

The following alphabetical enumeration gives the names of the birds most frequently seen in confinement in India, as also the reference (within brackets) to Blanford, where a full account of each species will be found:—

Acanthis fringillostris, the Indian Linnet (ii., 228).
Acridotheres tristis, the Common Myna (i., 537). Babor, Emperor of India (Memoirs, 1519-25, 319), and Abul Fazl in the Ain-i-Akbari (Jarrett, transl., iii., 121) call this the shārak, and the latter characterises it as an astonishing talker. [Cf. E. H. A., Times of India, March 25, 1899.]
Caecealis chucar, the chukor or Himalayan Partridge (iv., 131).
Cardpoeaeus erythrinus, the Indian or Rose Finch (ii., 219).
Coturnix communis, the Rain or Grey Quail (i., 114).
Chloropsis aurifrons, the hurrība or Gold-fronted Green Bulbul (i., 234).
Citoecina macrura, the shama (ii., 118).
Dendrocitta rufa, the Indian Tree-pie (i., 30).
Dissemurus paradisaeus, the bhimraj or Larger Racket-tailed Drongo (i., 325).
Dryonastes chinensis, the Black-throated Laughing-thrush (i., 74).
Eudynamis honorata, the Indian Koel (iii., 228). The Ain-i-Akbari (l.c. 121) observes, “Romance sings of its loves as of those of the bulbul.” The Emperor Baber (l.c. 323) describes it as the nightingale of India.
Euilbes intermedia, the Nepal or Talking Myna, The Indian Grackle (i., 511). This seems to be the pindāveli or meina in Baber’s Memoirs, and which in the Ain-i-Akbari is said to imitate the human voice and to speak with great distinctness. [Cf. Thevenot, Travels in Levant, Indostan, etc., 1687, iii., 68.]
Francolinus pondicerianus, the titar or Grey Partridge (iv., 139).
Galerita cristata, the chendul or Crested Lark (ii., 337).
Garrulax leucopholus, the White-crested Laughing-thrush (i., 77).
Hirudococyx varius, the Brain-feaver Bird, The Common Hawk-cuckoo or kupak (iii., 213).
Melanerpes bimaculata, the Calandra Lark (ii., 323).
Molopistes bengalensis, the Red-vented Bulbul (i., 271). [Cf. E. H. A., l.c., 1898.]
Dec. 7, 1898.]
Palaeornis cyaneecephalus, the Blossom-headed Paroquet (iii., 251).
P. nepalensis, the Large Indian Paroquet, chandra (iii., 248).
P. torquatus, the Rose-ring Paroquet, tata (iii., 250). Baber (l.c.) alludes to this bird.
Pomatorhynus schisticeps, the Scimitar Babbler (l., 116).
Turtur communis, the Turtle-dove (i., 42).
T. risorius, the Indian Ring-dove (iv., 46). Of the imported birds a long list might be given, but it is only necessary to say that a fairly large trade exists in canaries brought from the Straits and China: the Java Sparrow (Manila oregirra) has become acclimatised and the Malayen Lorkieet is extremely popular. It would appear that Cockatoos were imported into India as long ago as in the time of Jahangir, for Mr. Finn tells us he has seen a picture of that period depicting a yellow-crested species. The same observer points to the significant fact that there is a larger percentage of insectivorous and frugivorous birds reared by Indian bird-fanciers than in Europe, a circumstance that has led to the creation, as a village craft, of the practice of collecting and selling live insects, white-ants, etc., for these birds. Some years ago it was suggested that one solution of the periodic plague of locusts that here and there annually invades India would be to collect, dry and export these insects as food for the cage-birds of Europe. No one would seem, however, to have acted on that suggestion. [Cf. Agri. Ledg., 1893, No. 2.]

FALCONS, FALCONRY AND HAWKING.—The bird that was formerly (and to some extent is still) most prized for hawking is Falco peregrinus, the shāhān Falcon, the male of which is called kohīa and the female kohī. In

Nikitin (a Russian who travelled in India from 1468–74) mentions the fact that the Grand Duke Iwan III. sent a present of falcons to the Shah of Shirvan. The Ain-i-Akbari (Blochmann, transi., 293–4) gives many particulars of interest. In fact a very extensive series of authors might be quoted in support of the antiquity in India both of the training of and hunting with hawks. Jerdon gives a most interesting account of the Indian methods. As this is reproduced in Blanford’s Fauna of British India (iii., 416–7) it can be consulted by those interested. Montgomery Martin (Hist. Topog. and Stat. E. Ind., ii., 148; iii., 189, 579) speaks of the falconer as the mirshkari. In the Kangra Gazetteer (1897, 99) we read of Hindu traders called paprásas, who come from Amballa and Patiala to purchase hawks, which they teach and then sell at a profit in the plains. The Madras Mail (July 5, 1898) gives many details (derived chiefly from Oates) regarding the catching and rearing of hawks in South India. [Cf. Thevenot, Travels in Levant, Indostan, etc., 1687, iii., 38; Taleef Shereef (Playfair, transl.), 1833, 140.]

3. Birds, Edible.—This is necessarily a very large and important aspect of the study of Indian economic birds. It is readily referable to two sections, viz. domesticated and wild. The former embraces the varied assortment of birds usually classed as “poultry” and the latter corresponds to the “lesser game.” In the Dictionary the edible birds have been discussed under the following groups:—

(a) Ducks, Teal, Geese and Swans.—This corresponds to the

Anseres or Natatores. Blanford, l.c. iv., 411–71; E. C. Stuart-Baker, Journ. Bomb. Nat. Hist. Soc., xi. to xv. The domestic duck and goose are the most important birds of this assemblage, but the common wild, Nettium crecca (Blanford, l.c. iv., 443) is universally eaten, and sometimes reared (or fed up) in a state of semi-domesticity. In Madras Presidency immense flocks of domestic ducks are herded on the flooded fields, their eggs being an important article of export to Burma. [Cf. Ainslie, Mat. Ind., 1826, i., 441; Campbell, A Successful Duck Farm, in Agri. Gaz. N.—S. Wales, 1898, ix., 1377–82; Monier-Williams, Buddhism, 525.]

(b) Game Birds; Hume and Marshal, Game-Birds of Ind.; W. L. Selater, l.c. ii., 117–21. This includes examples drawn from many families such as the Bustards, Cranes, Ducks, Pheasants, Pigeons, Plovers, Quails, Rails, and Snipe.

Selater gives the following as the birds commonly eaten or brought to market:—Calandrella brachyactyla, the baghaira Ortolan; Charadrius fulva, the Golden Plover; Chalcites strynerus, the Gadwall; Ciconia leucoccephala, the manikjor or Beefsteak Bird; Columba intermedia, the kabutar or Black Rock Pigeon; Coturnix communis, the Batch or Gray Quail; Crocypus phoenicophaerus, the hurrial or Green Pigeon; Dafila acuta, the Pintail; Euodotis edwardsi, the todkar sohan or Bustard; Francolinus pictus, the Painted Partridge; Francolinus calidus, kalatit or Black Partridge; Fulvia wrynea, the White-eye; Falguinae rufa, the Red-crested Pochard; Gallinago gallinaria, the Common Snipe; Gallinago stenura, the Pin-tailed Snipe; Gallopardus spadiceus, the Red Spur-fowl; Gallus ferrugineus, the jungle-murgi or Jungle Fowl; Gallus sonnerati, the Gray-fowl; Grus antiquae, the sarus or sarus-Crane; Houbara Macqueen, the Houbara Bustard; Hydropassus chirurgus, the Pheasant-tailed Jacana; Nettapus coromandelanus, the Cotton-teal; Ortygornis galavis, the banitar or Kyal Partridge; Paco cristatus, mor or Peacock (Taleef Shereef, l.c. 158); Pterocles existus, kuhar or Sandgrouse; Querquedula cisticola, the Blue-winged or Garganey Teal; Sypheotes bengalensis, the charas or Florican; Totanus calidris, the Red shanks or Snippet; and Totanus glarea, the Spotted Sandpiper or Snippet.

THE ECONOMIC BIRDS OF INDIA
GAME LAWS

Pheasants and Pigeons

With slight modifications to meet local supplies, the above enumeration is representative of the traffic throughout India. For particulars consult the further popular sections given below concerning the Edible Birds.

(c) Ortolans.—The true Ortolan (Emberiza hortulana) occurs only occasionally in India, but the substitutes for it are the bargel—Social or Short-toed Lark (Calandrella brachyactyla), the duri Ash-coloured Finch-lark (Pyrhrhalunda griseus) and other allied species abundantly met with on the plains of India. Buchanan-Hamilton (Hist. Ant. and Stat. Beng. (ed. Montgomery Martin), 1807-13, i., 226; ii., 148, 506; iii., 186) makes frequent mention of the ortolan.

(d) Pheasants, Partridges, Jungle-fowl, etc.—The Gallinæa: Taleef Shereef (Playfair, trans.), 1833, 145; Blanford, l.c. iv., 64-146; Hume and Marshall, Game-Birds, 183 et seq.; Journ. Bomb. Nat. Hist. Soc., xi., 228; xii., 573-7; xiii., 521; Ball, Jungle Life Ind., 538; Sanderson, Thirteen Years Among Wild Beasts, 147; Forsyth, Highlands Cent. Ind., 130-1; Finn, Ind. Pheasants, etc., in Ind. For., 1902, xxviii., 228, 277, etc.; 1903, xxix., 116, 205, etc., etc. (long and valuable articles).

Excluding the poultry from present consideration, there are something like 60 species of wild pheasants, partridges, etc., which are systematically shot and eaten. The majority inhabit the hills, and are, therefore, but rarely seen in the bazaars of the larger towns of the plains. In Simla, for example, there is a regular supply of the chir, kdtit, and mondl pheasants; of partridges the bow-litur or kainal, and last but by no means least, the chabar. The horned pheasant—jewar or argus—as it is sometimes called, is also occasionally seen. These and many others are included by the Sanskrit authors under the category of viشكira or birds which scatter their food. The Ain-i-Akbari (Gladwin, trans., i., 267; ii., 136; also Blochmann, transl., i., 63) mentions several forms and alludes to the practice of catching them by means of call-birds, a method pursued to the present day. One or two are favourite cage birds, especially the quail, and are reared for the purpose of fighting (Ainalie, Mat. Ind., 1826, i., 288). Others are much prized on account of their plumage (e.g. monal and argus). No information exists as to the extent of the traffic in these birds, but it may be affirmed that the huge annual slaughter has for many years called urgently for the protective game-laws which have only just come into operation. (The following publications, assorted provincially, will be found to contain useful local particulars:—PANJAB: Settl. Repts. Hazard, 1868; Banu, 1879; Ludhiana, 1878-84. Game-birds, pheasants, etc., are frequently mentioned in the Memoires of Balfour, written about 1519, and the luqeh, to which he makes special reference (320), appears to be the monal. CENTRAL INDIA: Forsyth, Lc. 1889, 54-7. KASHMIR: Lawrence, l.c. 118. UNITED PROVINCES: Gaz., iv., 243. BOMBAY: Gazetteers Kaira, Panch Mahale, Ahmedabad, Ratnagiri, Thana, Kanara, Belgum, Dhorewar, Satara. MYSOR: Rice, Gaz., i., 155.)

(e) Pigeons and Doves; Blyth, Ann. and Mag. Nat. Hist., 1847, xix., 104; Darwin, Animals and Pl. under Domes., 1868, i., 131-224; Rice, Squab Raising, in Farmer's Bull., U.S. Dept. Agri., 1903, No. 177; Blanford, l.c. iv., 1-52. It does not seem necessary to deal with this subject very fully. There are some 40 wild species known and valued, and in domestication practically all the breeds met with in Europe are to be found in India, and a few seem even to have originated in that country.

Pigeons are closely connected with certain traditions of the Muhammadan faith, hence the birds are often protected in certain localities, such as at Mecca. They have been reared for pleasure from the earliest times of the Moslem nobility of India. Baber (Memoire, 7) tells the story of the death of Omer-Sheik Mirza in 1494, through having been precipitated from his pigeon-house. In the Ain-i-Akbari (1590) full details are given of the methods adopted for rearing and training pigeons. Tumblers, carriers, pouters, etc., are mentioned, but it seems doubtful if the luqeh or luqqun of the Ain, identified by Blyth as having been the fantail, was so or not, though that name is commonly given to them.

Methods of Rearing and Training.

Tumblers.

THE ECONOMIC BIRDS OF INDIA

Poultry

BIRDS

at the present day. The kohah pigeon, the voice of which sounds like the call to prayer, and the baqahah, which utters a peculiar sound in the early morning, as also the yahu-yahu, may have been trumpeters and laughers. The lotan was doubtless a ground tumbler. One of the special and much-prized features of Indian pigeons is the remarkable way they return to the dovecote on a certain signal being given.

In some Hindu towns, such as Jaipur in Rajputana, pigeons exist in a semi-wild condition. A race of the blue rock has simply been allowed to breed undisturbed for countless ages. This bird seems to differ from the English stock in having the lower part of the back ashly, instead of pure white, hence its separation as *Columba intermedia*. Baber speaks of the Indian rock-pigeons as being smaller and more slender than the Central Asiatic bird, and as having a sharper cry.

Pigeons are much valued by many classes of people as food, and the traffic in them all over India must be exceedingly great. They are usually brought to market alive, and fed from day to day by the traders. In Calcutta they are stored in large flat baskets, the owner feeding them by squirting from his own mouth into the gullets of the birds, one by one, a small quantity of grain and water. [Cf. Settl. Rept. Sylhetum, 1883, 20; E. H. A., in *Times of India*, May 1890.]

(f) Poultry and Eggs.—This may be accepted as embracing the Domestic or Common Fowl, the Guinea-fowl, the Turkey, Ducks, Geese, Pigeons, etc. Since some of these birds are discussed in this article under their respective names, the present remarks may be restricted to the Fowl.

It is fairly generally accepted that all the Domestic Fowls of the world have been derived from *Gallus ferrugineus*, a bird met with in its wild condition throughout the lower Himalaya from Kashmir to Assam, and from the mountains of Burma to the Malay Peninsula, Sumatra, Siam and Cochin-China. It would seem probable that it was first domesticated in the Malay and introduced into India in that condition. It is mentioned in the *Institutes of Manu*, and appears to have reached Europe about 600 B.C. The wild bird, it has been observed, when reared in captivity or when crossed with the domestic fowl, is more fertile when procured from the east than from the west of the Bay of Bengal. A few special breeds may have originated in India, such as the Chittagong and the Sooty Fowl. Examples of the Frizzled Fowl (a bird with the feathers curled backwards) and of Jumpers are not uncommon, the latter more especially in Burma.

Considering the importance of the subject, remarkably little of a trustworthy nature has been published regarding the Indian domestic fowls. Ibn Batuta, Marco Polo, Varthema, Linschoten, Dampier and many other early travellers make special reference to the quality, size, and abundance of Indian fowls. Hove (Tours in Gujarat, etc., 1787, 80) says: “In this country fowls are prodigiously large, and are called by the Europeans Colomb fowls. They breed them now about Surat in abundance. . . . Some of them are so large that they are often mistaken by strangers for turkeys.” It is difficult to conceive why the early travellers in India so uniformly speak of the fowls seen by them as “large.” The ordinary fowl of India to-day is a very small and very inferior representative of the fowl of Europe.

Mention has been made of Chittagong fowls, and it may be added that it is customary to read of them as a peculiar and valuable race, characteristic of Eastern Bengal. In the Bengal Administration Report (1901-2), for example, the observation occurs that “the best poultry comes from Chittagong and the hill tracts, and are short-legged, large-bodied birds, much resembling English fowls.” The “jumper” of Burma is an exceptionally short-legged bird, derived doubtless direct from the Chittagong breed. Further to the east, the Cochin-China breed would appear to have originated. Game-cocks have from time immemorial been specially reared in many districts of India, and in some localities cock-fighting has, from the most ancient times, been a favourite pastime. Sonnerat (Voy. aux Ind. Or., 1782, v., 113) says he thinks the birds specially reared for cock-fighting are derived from the indigenous wild species,
and thus is led to believe that the domestic fowls of the world may have come from India. The special association of Chittagong, however, with the game-cocks of India has little more to justify it than the early association of the turkey with Calicut. Montgomery Martin, compiling from Buchanan-Hamilton, speaks of the people of Assam as keeping game-cocks (E. Ind., iii., 671). Lawrence tells us that in Kashmir capons are specially reared for the table, but in India as a whole little or no attention appears to be given to special methods of breeding, feeding, etc., of fowls for the table as distinct from those reared for the supply of eggs. Bernier (Travels, 1656-68 (Constable, Or. Misc.), 1891, i., 251) attributes this to “the people being tender-hearted toward animals of every description, men only excepted.” “The markets are amply supplied with fowls tolerably good and cheap. Among others there is a small hen, delicate and tender, which I call Ethiopian, the skin being quite black.” Inspired possibly by Marco Polo, Linschoten (who was by no means as accurate an observer as Bernier) affirms that the flesh of the so-called Ethiopian as also the bones are black. [Cf. also Thevenot, Travels in Levant, Indostan, etc., 1687, ii., 51.] Tegetmeier (Poultry Book, 265-8) gives full particulars of these so-called “Nigger-fowls” (the Sooty Fowls of some writers), and it need only be added that they are by no means common in India. John Leo (Africanus (Geog. Hist. Africa (Pory, transl.), 1600, 314) describes the incubators in use in Egypt during the 16th century.

In the more populous parts of India (Bengal especially) fowls, like many other articles of food, have risen in price considerably within the past 20 to 30 years. At the beginning of that period four large or eight small fowls could have been purchased for one rupee, while at present they cost 4 to 12 annas or even one rupee each. [Cf. Scott, Dom. Poul. known to the Jews. Mem. Wern. Soc., 1830, vi., 391-401; Wilson, Orig. Dom. Poul., 402-16; Low, Hist. Tenasserim, Journ. Roy. As. Soc., ii., 272; Anderson, Mandalay to Momien, 18; Hoey, Monog. Trade and Manuf. N. Ind., 152; Voelcker, Improv. Ind. Agr., 403; Lawrence, Valley of Kashmir, 365-6; Collett, A.B.C. Guide to Rearing Poultry, Ind.; Law Twedt, Poul. Keeping in Ind.; My Poul., by “The Indian Henwife”; Mackenzie, Popular Poul. Keeping; Wright, The Book of Poul.; Numerous writers in Indian public press such as in Bomb. Gazette, Aug. 1895; Madras Mail, Feb. 1896 (report on the Dudar Poul. Farm); Ind. Agrist., Feb. 1898; McCue and Bradshaw, Poul., in Agri. Gaz. N.-S. Wales, 1898, ix., 94-7, 1161-80; Planters’ Gaz., and Nos. 1899, 1903, article by “Camellia,” Feb. 1900; Ind. Agrist., May 1900 (report on Poul. Rearing in Beng. at the Model Farm of Pakur); Poul. in West Ind., in Imp. Dept. Agri., Pamph. No. 23, etc., etc.]

TRADE IN EGGS.—Mention has already been made of the production of Ducks’ eggs in Madras Presidency for the Burmese market. Though all large towns have regular supplies of eggs, nothing can be learned as to the sources on which they depend. It would thus seem as if every great centre produced its own fowls and eggs, within its immediate neighbourhood. In the official publication Prices and Wages in India, certain particulars are furnished regarding eggs in the Western Presidency. A rise in price has on the whole taken place, but in Bombay town this is not material, as eggs sell at 4 to 5 annas a dozen. Taking the years 1871-75 as being 100, they sold in 1901 at 107, in 1902 at 100, and in 1903 at 103; in Sind at 127; and in Central India and Rajputana at 118. The traffic in Egg Albumen is important. An article in The Indian Agriculturist (Feb. 1898) reviews an account that appeared in a Burma paper of the Chin-hiang China trade in that substance. Ducks abound in the neighbourhood, flocks of 4,000 to 5,000 being not uncommon. The eggs are broken and the white separated from the yolk. The white or albumen is used in dyeing, being largely exported for that purpose to Europe, and the yolk, used in the dressing of certain leather, is in much demand in Europe. The Diplomatic and Consular Report (1901, No. 2601, 10) gives the returns of the Chinese traffic in egg-yolk. It rose from 13,788 to 22,533 cwt.

[Cf. Ainale, Mat. Ind., 1826, 117, 238; O'Shaughnessy, Beng. Disp., 656-7; Royle, Prod. Islinglass, 5; Honigberger, Thirty-five Years in East, ii., 320; Waring, Pharm. Sept. 1899, vi., 149-56; Dec., 362; many newspaper articles on preservation of eggs, on the testing their freshness, etc., have appeared in the Indian press, mostly

137
reprinted from European, American and Australian publications. No writer has, so far as I can discover, given particulars of the Indian markets or of Indian experience.]

(g) **Quail, Snipe, Plovers, Florican, etc.**—When speaking of the plains of India the quail and snipe are by far the most important of the game birds. The former are often captured in great quantities and sent alive all over India, and the latter are both trapped and shot. As a protective measure, it may be added that some of the railways refuse to carry live snipe, since the birds do not eat after being captured, and are often handled most cruelly; for example, to prevent them fighting or escaping, they are blinded or otherwise disfigured. It is to be hoped, therefore, that very shortly, under the new Act, measures may be enforced even more stringent than the humane action of the railway companies. The florican is valued as much for its rarity as for the delicacy of its flesh. [Cf. Ainslie, l.c. i., 392; Hunter, *Imp. Gaz. Ind.*, vi., 1886; John Burke in *Field* (reprinted in *Times of Ind.*), Nov. 28, 1899; *Snipe-Shooting in Ind.*, Englishman, Feb. 10, 1902; E. H. A. in *Times of Ind.*, July and Aug. 1899.]

A fairly detailed account of this curiously interesting edible product will be found in the *Dictionary*. That article was compiled very largely from a report by Mr. Portman regarding the Andaman, and one by Mr. de Reepstorf on the Nicobar supplies. Blanford tells us that *C. francica*, the Little Grey-rumped Swift, affords the purest quality of edible nests. It is met with on the coasts of Tenasserim and Arakan, as also on the rocks of the Andaman and Nicobar Islands. The breeding season is in March. The nests produced by *C. fusiphaga* (= *C. ventosana*) are found in Ceylon, the Malabar Coast, the Nilgiri and Anaimalai hills, etc. Its breeding season is March to June. The former bird gives nests quite free from grass, moss or feathers, the latter is much adulterated with the substances named, which are simply cemented together by the inspissated saliva. Jacobus Bontius was perhaps the first European writer who described the edible swallow’s nest. He gives an excellent picture, and says the nests are sold in great quantity throughout India. He regarded them as made from the foam of the sea. Mandelslo (*Travels Ind.*, 1639, 134), speaking of the Malay, says that the swallow’s nests were found “on rocks by the seaside, and are of such esteem in China that they sell there for 3 or 4 crowns the lb.” It is probable that Volkamer (*Nurh. Hesper*, 1714, ii., 236) is also alluding to this substance when he speaks of the chickens that spin fibre out of their mouths. Milburn says edible nests are found in caves on the sea-coast of Sumatra, Java and many of the Eastern Islands. “The cleanest and best are almost as white as writing paper and as transparent as isinglass.” “They should be perfectly dry; if so crisp as to break, it is the better.” The merchants who trade in this substance are Chinamen resident in Rangoon. The nests are assorted into three classes and then exported to China. The finest qualities go to Pekin. The Japanese do not use these nests, but they are said to fabricate an artificial nest from seaweed which is sent to China. The trade seems to be declining, as shown by the steady diminution of the sum paid in Burma for the right to work the supplies (see *Manures*, p. 769; *Isinglass*, p. 693).

5. **Birds: Industrial.**—The materials that fall under this position are briefly—Bird-skins, Feathers, Guano and Quills. The first two may be collected together and the third will be found under *Manures* (see p. 769).

(a) **Bird-skins and Feathers.**—It is customary to discuss feathers
Skins and Feathers

under:—**Common Feathers** used for upholstery; **Down** used for quilts; **Ornamental Feathers and Quills**. In India the feathers of the domestic fowl are almost universally destroyed through the habit of removing them after immersion in hot water. Were an effort made to remedy this defect, India might supply a large quantity of upholstery feathers. The same remark is applicable to the supply of down. Ornamental feathers are usually referred to three classes:—

(a) those like the ostrich plumes whose barbules are long and loose, giving beauty of form; (b) those in which the plumes are decomposed, as in the egrets; and (c) those that manifest great beauty and brilliancy of colour (see below under *Plumage*). Balfour (*Cyclop. of India*) appears to be the only writer who has so far afforded particulars of the feather industry—fortunately an industry of historic but not of great future intrinsic value.

He tells us that "the Madras dealers in birds’ feathers used to carry on their trade on an extensive scale. One dealer had nearly 100 sets of hunters, each composed of four or five *shikaris* and one cook; most of these people are *korawas* (basket-makers) who live in and about Madras. Each set has its head man, who is responsible for the others. The sets are sent out once a year, each receiving from Rs. 20 to Rs. 100 together with a number of nets, a knife, etc. They traverse all India, collecting the feathers of kingfishers, etc." "They bring back from 1,000 to 6,000 skins which are exported to Europe, Burma, Penang, Singapore and Malacca." The blue jay feathers are much in demand in China.

(b) **Ostrich.**—Some few years ago an effort was made to establish ostrich farming in India (near Agra) but with little or no success. Mention has recently been made of Mysore as a favourable locality, a suggestion inspired by the great success of the Australian farms. [Cf. Madras Weekly Mail, Aug. 1899; Pioneer, Sept. 1903: for Food to be given to Ostriches, see Agave, p. 35.]

(c) **Plumage—Birds.**—The following, it may be added, are the chief birds killed in India on account of their plumage, the particulars given being abstracted very largely from Blanford. A certain amount of grouping has been attempted in order to save space; thus all the paroquets are brought together, all the bustards together, etc., the assortment being otherwise alphabetical according to the scientific names of the birds or groups of birds:

- **Ardea cinerea** (*Fa. Br. Ind., (Birds)*, iv. 382 et seq.), the Common or Blue Heron, the nari, anjan, sain, etc.; **Aetelis graya**, the Pond Heron or bagla, khonch-bagla, kokku, etc. A common and familiar bird of rice-fields and village tanks—often called the Paddy-bird; also **Bubaleus coromandus**, the Cattle Egret or mar-khia-bagla, gai-bagla, huni-koku, etc. This egret is a constant attendant on cattle and feeds on the insects that are attracted to them. Sclater groups these three herons together as birds that produce feathers which are sold in large quantities, but which do not fetch such high prices as the egrets proper.

- **Ceryle varia** (l.c. iii., 119), the Indian Pied Kingfisher, the koryala-kikila or karikata; **Haleon smyrnensis** (l.c. iii., 132), the White-breasted Kingfisher or kikila, khenda, machranga, etc.; **Pelargopsis gruial** (l.c. iii., 129), the Brown-headed Kingfisher, gural, bodami, etc. These and several other kingfishers, such as **Alcedo sipida**, chota-kikila, A. granalis, the Great Indian Kingfisher, and **Ceyx tridactyla**, the Three-toed Purple Kingfisher, are all extensively slaughtered for their skins. Hunter (*Stat. Acc. Beng.*) makes special mention of the traffic in the skins of kingfishers from Tippera and Chittagong to Burma and China. Mr. C. M. Inglis says that in Darbhanga there is a village of 16 houses, all concerned in the bird-skin trade. One man told him that on an average he snared at least 100 kingfishers during the season,
the skins fetching Rs. 15 to Rs. 20. This for the entire village would make a destruction of thousands a year. Decoys are used, namely, live birds with their eyes drawn up.

_**Coracias indica** (l.c. iii., 103), the Indian Roller, the Blue Jay of Europeans or nilkant, sobzak, tās, pālī pitta, kattu kadei. As already mentioned, this is perhaps the most extensively killed for its beautiful plumage of all the Indian birds, and as it is helpful to the cultivators, its destruction is to be greatly deplored.

_Eupodotis edwardsii_ (l.c. iv., 192 et seq.), the Great Indian Bustard, the sohum, hukna, hum, tokdar, tudgar, bat-meka, kanal-myle, etc. Met with throughout India except in Bihar, Chota Nagpur, Orissa, Bengal. It is usually found singly or in twos or threes, and keeps chiefly to the open dry country, especially wastes covered with low grass and scattered vegetation. It feeds on insects, especially grasshoppers, small reptiles, fruit, grain, shoots of grass, etc. In the _Ain-i-Akbari_ mention is made of the okar feathers of Kashmir. Baden-Powell gives the name onkar to the feathers used in making kabli, the plumes of the khod or helmet. These were probably the black feathers of a Bustard, or of the Snake-bird (see below). _Houbara Macroura_, the Houbara bustard or hōbara, tilur, talur, etc. A cold-weather visitor to North-Western India, Panjāb, Sind, Rajputana, Kach and Northern Gujarat. _Otis tetrix_, the Little Bustard or chota tilur, met with in the Panjāb. Lastly, _Syphonotes aurita_, the Lesser Florican or likh, chota charat, charas, barsati, ker mor, tan-mor, chinī-mor, nīla nimili, etc. Also _S. bengalensis_, the Bengal Florican. These birds are found at times throughout India from the Himalaya to Cape Comorin, but the former chiefly inhabits the Peninsula south of the Godavari in winter, and breeds in the Deccan, Western and Central Provinces, Central India, Rajputana, etc. The latter occurs in the country from the foot of the Himalaya and the Ganges to the plains of Assam. Blanford observes of the former that the numbers are being greatly reduced by the unromantic practice of shooting during the breeding season. And of the latter he remarks that it is one of the most delicious of game birds.

But it may be said that most of the above-mentioned birds are or have been killed on account of their plumage as well as for their flesh. Bustard feathers constantly appear in the Madras trade reports.

_Gallus ferrugineus_ (l.c. iv., 75), the Red Jungle-fowl or jangal-murgh (male), jangli-murghi (female); common throughout the Lower Himalaya from Assam to Kashmir. Also _G. sonnerattii_, the Grey Jungle-fowl or _komri, koli_, etc., of South, West and Central India.

The wild fowls, though killed mainly for food, afford skins that are as a rule preserved and sold. The wild fowl of South India is specially valued for making artificial fishing-flies; its golden or rufous spotted feathers are unsurpassed for certain purposes, and fetch higher prices than do most other feathers met with in the market.

_Herodias alba_ (l.c. iv., 389), the Large Egret, mallang-bagla, _tar-bagla, bara-bagla, pedda-tella-konga, mala-konga, vella-koku_, etc. Found throughout India and Burma; often seen solitary but in association with either of the next two species. In North India and Burma it breeds in July and August, and in the Karnātak in December to February. Also _H. garzetta_—the Little Egret or _kilicha, nella-nucha-konga_. Common throughout India and Burma. Lastly _H. intermedia_, the Smaller Egret, patokha bagla, patan-khā, etc. Met with throughout India and Northern Burma. The breeding season is the same as that of the large egret. These pure white, slim herons develop temporarily during the breeding season a dorsal train of feathers, which elongates and becomes "decomposed," as it is expressed, that is to say, the barbs are separate and distant from each other, thus forming the ornamental plume or aigrette for which these birds are much sought after and ruthlessly destroyed.

The present trade in Egret and Bustard feathers seems to be chiefly in the hands of Madras traders. Some time ago Commercellly in Bengal was famed for its egret feathers, and these were used for head-dresses, tippets, boas and muffts. Although this trade still exists in Darbhanga, Purannah and Malda, the birds are becoming very scarce. It would seem that at the present day the chief Indian supply is from Madras.

_Leptoptilus dubius_ (l.c. iv., 373), the Adjutant, or hargilā, _garur, chanthari dhauk, duṣta, pinigna-konga, don-zat, pīr-e-dang_, etc. A useful scavenger that
used formerly to frequent Calcutta and is still met with at the Salt Lakes and has been found in immense herds in Burma. The down of the young adjutant bird is (or rather was formerly) made into ladies' bonnets and victorines. The under-tail coverts are collected and sold in considerable quantity. They are known in trade as Marabout or Commercially feathers, and seem to be procured at present mainly from Tirchoor and Malabar, though formerly the traffic was chiefly from Commercially and Nadiya to Calcutta. It is described by Allan (A.D. 250); Baber (Memoirs, 1519-25, 321) and Ball (Jungle Life, 82) both refer to the nape-stone said to be found in the head of this bird.

Lophophorus refugens (l.c. iv., 96), the mondil, nil, lont (male), karari, ham (female), nil-mor, nilgur, datiya, etc. An extremely beautiful and large pheasant found throughout the Himalaya, from Chiriltal and Kashmir to Bhutan, at altitudes of from 9,000 to 15,000 feet, except in the winter, when it may be found at 5,000 feet. Skins of the cock birds are extensively traded in all over India, and a fairly large number are annually exported, the supply received at Calcutta coming mainly from Bhutan and Nepal. Sclater tells us that he has seen as many as 1,000 skins offered for sale at one time.

Palaearctis cyaneocephalus (l.c. iii., 251-9), the Western Blossom-headed Paroquet, the tua-tota, faraida, kir, etc. A fairly plentiful bird in the forests of the lower Himalaya and Peninsula of India. P. fasciatus, the Red-breasted Paroquet, the madina, kajla, gour-tota, etc. Himalaya up to 5,000 feet from Kumaon to Assam, Manipur, Burma, Cambodia, Cochin-China, etc. An inhabitant of well-wooded tracts, but visitant of the intervening fields. P. nebulalis, the Large Indian Paroquet or chandana, a bird met with plentifully in Northern and Central India, the lower Himalaya, the Northern Circars, Kangra and Mount Abu to Bengal. P. rosa, the Eastern Blossom-headed Paroquet, the kyay-fa-mo of Burma. Lastly, P. torquatus, the Rose-ringed Paroquet or tola, kybur tota, tiya tota, raju, chilluka, killi, kyay-gyot, etc. This is by far the most plentiful paroquet of India, and abounds near towns and houses and prefers open cultivated lands to forest tracts. It often does much damage to field and garden crops. It is very frequently kept as a pet, and is a very docile and loquacious bird. Baber (Memoirs, 319) gives a long account of the various birds of this kind that were taught to speak by the people of India in his day (early in the 16th century).

Most of the above species of paroquets are extensively killed on account of their skins, but since they are very abundant and often very destructive, little regret need be expressed at their being annually killed off to a certain extent. Paroquet skins are largely exported from Hill Tippera.

Pavo cristatus (l.c. iv., 68), the Common Peafowl, the mor, mahr, manja (male), manir (female), myl, nimmili, nolv, etc. Plentiful throughout all the drier tracts of India. It ascends the Himalaya to 2,000 feet in altitude. Abounds in Gujarat (a fact specially mentioned by Thevenot in 1687), Kach, and Rajputana, and being protected, since regarded by certain Hindus as sacred, it frequently does much damage to the fields. The males moul their long trains after the breeding season, about September, and the feathers are collected by the villagers and sold, but in many parts of the country large numbers are killed, and their feathers and complete tails sold to the dealers. In Indian Art at Delhi (1903, 198-9) particulars will be found of the artistic use of peacock feathers. They are largely employed in ornamental work, such as the manufacture of fans, morchals, chauria, braids, etc. Some few years ago a large trade was done in peacock-feather braids, which were used in trimming dresses and for other such purposes. The chief centres of manufacture are Agra, Aurangabad, Benares, Jhansi, Mysore, Nepal and Savantvadi. Peacock feathers seem to be largely imported from Bombay. [Cf. Baber, l.c. 318; Ainslie, Mat. Ind., 1826, i., 290.]

Ploutus melanogaster (l.c. iv., 344), the Indian Darter or Snake-bird, the banua, pan dubbi, goyar, etc. This bird exists throughout India and Burma, wherever fairly extensive lakes, marshes, etc., of fresh water or large rivers with slow currents occur. According to Jerdon the lengthened scapular feathers are looked on as a badge of royalty by the Khasias, and were once the badge of one of the Bengal regiments of Irregular Cavalry. The birds are killed on account of these feathers, which formerly were fairly extensively exported.

Tragopan melanocephalus (l.c. iv., 100), the Western or Simla Horned Pheasant, jowar, jaght, sing-mondal, jagurana (male), bodal (female), jagur, etc.
The Economic Birds of India

North-West Himalaya from Garhwal to Hazara. *T. satyra*, the Crimson Horned Pheasant, the *lunjì, ono, hop, tar-ryak*, etc. Eastern Himalaya from Garhwal to Bhutan. These two pheasants are sometimes called the Argus by European sportsmen, and their skins are generally sold under that name—the true Argus occurs in the Malay Peninsula.

Upupa epops (l.c. iii, 159), the European Hoopoe and *U. indica*, the Indian Hoopoe or *hudhud, sutár, kondeh pitta, chaval kurwei, ton-bee-sote*, etc. The former is met with in the Himalaya and on the plains of Northern and Central India, and the latter throughout India and Burma, except Sind and the Western Panjáb. Both birds are extensively slaughtered on account of their plumage. [ Cf. E. H. A. in Times of India, Sept. 29, 1899.]

Trade in Birds, Skins, etc.

(d) Feathers.—The above are the chief birds killed for their brilliant feathers, but all birds with bright-coloured plumage may be and occasionally are killed for that purpose, such as the honey-suckers, bitterns, jays, water-hens, bee-eaters, orioles, shrikes, bulbuls, grebes and hornbills. The trade in these and such-like is a very ancient one. Varthéma (Travels, 1510 (ed. Hakl. Soc.), 200), speaking of Tenasserim, alludes to the sword-hilts made of the helmet-hornbill. The modern trade in feathers of all kinds fluctuates greatly. In 1880–1 the exports were valued at Rs. 2,69,447; in 1884–5 at Rs. 6,33,017; in 1887–8 at Rs. 5,70,495; in 1895–6 at Rs. 5,55,185, since which date it appears to have declined materially; in 1900–1 it stood at Rs. 1,35,440; in 1901–2 at Rs. 1,79,618; in 1902–3 at Rs. 88,691; in 1903–4 at Rs. 5,093; in 1904–5 at Rs. 880; in 1905–6 at Rs. 4,416; in 1906–7 at Rs. 1,437. In former years the major portion of these exports went usually to the United Kingdom, which took in 1895–6, Rs. 4,18,006; in 1902–3, Rs. 60,000; and in 1906–7, nil. More recently to China (Hongkong), which took in 1895–6, Rs. 58,562; in 1902–3, Rs. 23,387; and in 1906–7, Rs. 1,350. Practically the balance on these valuations of the total for the years in question goes to the Straits. The imports of feathers are unimportant. As a natural consequence of recent legislation the portions of this traffic concerned in the foreign supply will be discontinued.

(e) Quills.—The traffic in bird-quills is unimportant. Peacock quills are used in embroidering leather, as for example in the small boxes made at Bilaspur and Anandpur in the Panjáb, etc. Porcupine quills are to a small extent employed in South India, mainly in veneering fancy boxes.

A shrub originally a native of America and now largely cultivated in India for the dye afforded by its seeds. It is very common in S. India, and believed to be there almost completely naturalised. Hove speaks of its cultivation in Bombay in 1787, and Buchanan-Hamilton (Stat. Acc., Dinaí, 1833, 155) mentions that "the Bixa, an American plant, is now rapidly spreading over Bengal." Occasionally planted for ornament, especially in Ceylon; the least touch of frost is fatal, but it will grow almost anywhere within the tropics where the rainfall is 50–60 inches. The plants make a good hedge or wind-break.

There are two forms, one having white flowers and greenish capsules, the other pink flowers and red capsules. The pink-flowered form is viewed as most desirable though it is not always the most easily grown, although one or other exists throughout tropical India. Fuller particulars of the distribution and cultivation will be found in Mr. Burkill's Review of Existing Knowledge.

ARNOTTO DYE

Boehmeria Nivea

China-grass

Dye.

Cheese-colouring.

Fibre.

Medicine.

Prices of Dyecake.

Porcet gives an admirable drawing showing the plant and a rococou factory. The pulp surrounding the seeds gives a beautiful flesh-coloured dye largely used for silks. In combination with the red powder of Mallotus philippinensis, a bright orange-red colour is obtained. The dye is exported to Europe from the West Indies to be used in colouring cheese, chocolate, etc. It may be extracted from the seeds direct, or the pulpy matter may be separated by boiling and made into cakes—the usual commercial form in Europe. The cakes are wrapped in the leaves of the banana and known as flag-annatto. The West Indians are said to rub the pulp off in their hands, and by adding lemon-juice and gum make crimson paint for their bodies. The mandrill employed with arnotto is usually crude pearl-ash: the alkali facilitates solution but affects the colour. The dye is fleeting and is chiefly used for silk, but to some extent also for cotton-cloths, e.g. in Cachar. The Maniipuris are said to avail themselves of the fruits of Gardneria pedunculata to deepen the colour of the silk after dyeing with arnotto and also to fix it. The latter suggestion needs verification, since the dye is not as a rule considered fast. The bark yields a good fibre used for cordage in the West Indies. In Medicine the seeds are regarded as astringent and febrifuge. The friction of two pieces of the wood is reported to produce fire very easily, and for this purpose is used by the West Indians.

The best Cayenne ("cake") arnotto fetches in France about 200 francs per 100 kilos, and in Germany about 80 marks per 100 kilos. Its use has been ousted from India to a great extent by the introduction of aniline dyes, and the demand is perhaps too small to encourage export. In the Toronto Exhibition leaflet (1902) it is stated that the value of the exports from Jamaica in 1900 amounted to £5,800. From the London market reports for 1903 (in Brit. and Col. Drug.; or Chem. and Drug.) it would appear that from 2½d. to 4d. per lb. is obtainable for best Madras seed, but that the demand is very limited. It may be mentioned that the average production per acre is about 0½ to 1½ maunds of seed yielding some 26 to 30 seers or rather under 1 cwt. of dye. [Of Taylor, Topog. Stat. Daaca, 1840, 143; De Candolle, Orig. Cult. Plants (Engli. ed.), 1884, 401; Lawson, Pharm. Journ. and Trans., 1885–6, 645; Watt, Select. Rec. Govt. Ind., 1888–9, i., 55; Pharmacog. Ind., i., 149; Kew. Bull., 1890, No. 48; Ferguson, All about Aloe and Ramie, 1890, 54; Moodeen Sheriff, Mat. Med. Mad., 1891, 38–9; Kanny Lall Dey, Indig. Drugs Ind., 1896, 47; Thorpe, Dict. Appl. Chem., 1898, i., 173; Cat. des Pl. Econ. Colon., "L'Hort. Colon.," Brussels, 1900, 44; Jackson, Pharmaceut. Journ., April 4, 1903; Bull. Union Agri. Caled., 1903, ix., No. 75, 6–7.]

It seems doubtful if the two forms indicated by the above-mentioned names can be botanically regarded as anything more than climatic or geographical races of one species. The practical value of their separate recognition may however be accepted as at once demonstrated by the circumstance that the one—the China plant—has been grown in the open air in England and regularly sown as a field crop in the south of
Europe, while the other—the Malaya plant—can only be raised under glass, so far as Europe is concerned. The distinction ought therefore to prove of considerable value to Indian prospective cultivators. In fact it seems possible that some share of past failures may be due to Indian experimentalists having forced the cultivation of the tropical plant in temperate areas. That being so, it may be useful to set forth the two forms separately, but the reader should consult The Agricultural Ledger (above mentioned) for the botanical synonyms of the plants in question:

\[\text{a Var. nivea proper; Watt, l.c. 8, t. 1. The China-grass or Rhea of commerce bears the following local and vernacular names:—chu-ma in China; cay-gai, pa-ma in Cochin-China; kankura (rarely kund or kurkund), in Bengal; reha (riha) or risa in Assam; pan in the Shan States, and gun, gwon in Burma (ma, see Cannabis, p. 251).}\]

It will be seen by a comparison with the Malayan names recorded as more especially applicable to the second variety below, that very possibly the only truly indigenous Indian names in the above enumeration are kankura and riha. Further, the latter name is perhaps only a modern translation from one plant to another of the word risa, the Naga name for a fibre-yielding plant which has recently come to be spoken of as the ban-riha or wild-riha of Assam (see Villebrunea, p. 164). In part support of this idea it may be added that the people who use the ban-riha fibre grow the true riha plant, but only as an article of export—they never use that fibre themselves, so that it seems fair to suppose that the plant which they use is their own riha or risa. In none of the classic books of India is there the slightest mention of kankura or riha. In fact there are no references to any fibre that could for a moment be supposed to be rhea. There is a curious passage, however, in the account of the Voyage to the East Indies, written by Linschoten (1598, i., 96), which describes a fibre under the name of “Hebare Bengalen,” that might be (and has been) supposed to be rhea, though it was more probably Calotropis gigantea, and perhaps the grass-cloth fibre of the early English writers (see pp. 207–8). Turning now to China, Marco Polo, speaking of Kweichan, mentions the bark fibre from which “they manufacture very fine summer clothing.” Many subsequent writers allude to the hiapu or sia-pu or the summer cloths of Kweichan, which being to-day made of China-grass, it is assumed were so made in Marco Polo’s time; and there is probably little doubt that they were. One of the earliest European travellers to describe the China-grass (of China) was Cunningham, who in the beginning of the 18th century sent Chinese plants to his English friends Sloan, Petiver and Plukkenet. Among these was the textile plant ma, which he called Urtica racemifera maxima Sinarum (Pluk. Amalth., 212, t. 49, f. 2), a plant which Linneaus identified (Sp. Pl., 1764, 1398) with his Urtica nivea.

\[\text{β Var. tenacissima (sp. Roxb.); Watt, l.c. 20, t. 2. This is the true rami or rame, which by some writers has been incorrectly called rhea while they have assigned China-grass as distinctive of the variety nivea. The first record of its introduction into India brought the Sumatran name calde (kalide) coloce or caluse to that country; throughout the Malay it is rami, rame, ramien or gonn; inan in Bonoa; gambe in Celebes; mountinaram in Java; kiparoy, kapieriet, haramay, kalakie, in Sunda; kloei in Sokojan, etc., etc. Prain (Sketch of Life of Francis Hamilton (once Buchanan), 1900, 24) gives a letter of Hamilton’s dated 1814, in which he refuses to believe that the caloce differs from B. nivea and further that he considered it groundless to expect the fibre to turn out of general use. Roxburgh (Trans. Soc. Arts, 1806, xxiv., 148) tells us that in 1804 the plant grown in the Botanic Gardens, Calcutta, from Malay seed had flowered and that he had sent a drawing of the same to the Court of Directors.}\]

**Races of Plant Grown.**—During repeated investigations, through the Indian rhea districts, a large percentage of the known plots of cultivation in Bengal, Assam and Kangra were systematically visited. With practically only one exception the stock was that indicated above as var. nivea, and the one exception that of a tea-planters’ vegetable garden in Assam, where a few recently imported roots of var. tenacissima were found. In several instances, however, plants which might be regarded as local developments, if not crosses between the two varieties, were
RHEA CULTIVATION IN INDIA

met with, thus possibly pointing to a cultivation of *tenacissima*, since abandoned, or to *tenacissima* being only a sport from *nivea*. Recently I have heard from Tirhut that a sport had spontaneously appeared there, in an experimental plantation, which was very hardy, although apparently an inferior fibre-yielder. There seems little doubt that careful study and selection would do much to improve the crop. But in no instance were plants grown in India seen to possess anything like the apparent luxuriance of a series of botanical specimens procured direct from Wenchow in China. Some of the most vigorous plants collected by me in India were found in North Lakhimpur, Assam, while the healthiest looking were those in the Ram Bagh plantation in Kangra—the survivors of the original six plants imported in 1863 by Mr. James Montgomery, India's pioneer rhea-planter. His widow, a very old lady, was alive at the time of my visit, and I had the extreme pleasure of being conducted by her over the plantation, and was much fascinated by the undying faith which she manifested in the ultimate success of her husband's life-work. One plot, she told me, had neither been transplanted nor manured for sixteen years, and yet the plants were fairly vigorous-looking. It was annually inundated and richly manured by the rise of the river. When I inquired if any of the European tea-planters in the district or Native zamindars had followed her example and laid out plots of land with rhea, Mrs. Montgomery replied that it was perhaps fortunate for her that they had long since abandoned all thought of rhea, because the produce of her little plantation was more than sufficient for the local demand.

RHEA CULTIVATION IN INDIA.

Future Prospects.—Indian Rhea cultivation and manufacture was dealt with very exhaustively in *The Agricultural Ledger* (1898, No. 15). That paper was the result of a special tour of inspection, conducted under orders of the Government of India, to each and every district where the plant was known to be cultivated or reputed to be found. With the details thus readily accessible, it may be the most useful course to make the present review amplify or correct the opinions already set forth, rather than to repeat in abstract the established facts. At the same time opportunity may be taken to answer the objections and difficulties that have been raised without becoming controversial. My previous writings have been affirmed to discourage endeavour, and as that was not my intention I would explain that my attitude has proceeded from mature conviction that a rhea industry is not likely to be established in India until certain misleading statements and misconceptions have been effectually removed. Of these I would mention the following:—

1. The affirmation repeatedly made, that rhea is a wild plant, found over large portions of India, and that it has only to be cut in order to be turned into gold. In my report of 1898 I have shown that this is not only an error but that rhea nowhere exists in India even as an escape from cultivation. That it is purely an exotic and is rapidly exterminated from land when neglected or abandoned. Still further, that the most valuable of the so-called wild-rheas (*ban-rhea*) of Assam is an entirely different plant, though one which affords a fibre for which there might be a market apart altogether from the possibility or not of organising an Indian rhea trade.

2. The statement that it can be grown anywhere in India and with a purely nominal amount of cultivation and care. Far from this being so, it is a plant that requires a particular class of soil, a large supply of manure annually, and definite climatic conditions. It must thus receive high cultivation and be protected from animals. If the price paid for the produce will not suffice to cover these expenditures then the industry will not pay.

3. The purport of my report may, therefore, be said to be that the experimental cultivation in India by Europeans has hitherto been in the most unlikely regions and that the price offered for the produce has rendered essential methods and
materials of cultivation prohibitive. This last statement might be compared with the final experience of Mr. Cyril E. Baxendale of Selangor. That gentleman seems to have been most unfortunate to say the least of it, for he tells us that his correspondence with "ramie spinners would fill a massive tome." He could not apparently dispose of some of his produce, and had to direct it to be burned in order to save demurrage charges at Liverpool. As a not unnatural consequence he adds, "We now leave the ramie to the cows. They like it." [Cf. Capital, Aug. 11, 1904; Agri. Bull, Straits and Fed. Malay States, 1903, 359, 362-6; and compare with Ind. Gard. and Plant., Dec. 15, 1898.]

4. I have endeavoured to point out that the most satisfactory regular cultivation and the most promising experiments seen by me, have been those within approximately the self-same latitudes as the successful production in China. In other words, the southerly extremities of Rangpur and Bogra in Eastern Bengal would be approximately in the latitude of Canton and Formosa, and the most northerly Indian area (Kangra) in that of Nanking. Thus the Indian area of successful production so far as ascertained by me corresponds fairly closely with that of China, and I have urged that in dealing with the Chinese form of the plant, at all events, it would be well in the future to concentrate attention on the region indicated. And I may add that within the more southerly limits of that area I found the plant by no means so vigorous as on the most northerly, so that a northern rather than a southern extension would seem most full of promise. Outside the area, more especially within tropical tracts, it would appear likely, however, that good results might be obtained with the Ramie or Malayan plant.

**Conditions of Cultivation.**—During my tour of inspection through the Indian rhea districts I had frequent occasion to comment on the singular uniformity that prevailed in the name given for the plant, the character of the stock grown, the location of the plots of land under the crop, the class of cultivators concerned, the method of cultivation pursued, the system of separation of fibre employed, and the purpose to which the fibre was put. These and many other points seemed significant and highly exceptional in Indian agriculture as a whole, where much diversity of opinion is usually manifested. In Bengal and Assam the plant had to be grown in order to secure fibre wherewith to make or repair fishing appliances, and there the matter began and ended. Usually the Indian agriculturist shows interest in the produce of his fields; rhea is not an agricultural crop, it is a plant grown by or for the fishermen! In only one Sub-division of the Rangpur district (Kurigaon), and even there in connection with but one or two villages, was it found as a field crop in the hands of the regular cultivators (rajbunis). Everywhere else it was exclusively a garden plant found on the homesteads of the fishing classes. On an average the plots would not exceed 20 square feet in size, and were as a rule beds of pure manure sometimes 2 feet in thickness, raised above the level of the surrounding land, and closely fenced in to protect the plants from cattle which otherwise would completely devour the crop. In China it is practically grown on poudrette. A writer in The South Indian Observer (March 1902), who professes to have a practical knowledge of rhea-growing both in India and China, says that no part of India is in any sense a favourable field for the introduction of the rhea-planting industry. [Cf. with the reprint in Ind. Plant. and Gard., June 1902, and compare also with Plant. Gaz., Dec. 1898.]

_A Garden, not Field Crop._—In the whole province of Bengal it would be difficult to find a better soil or a more enlightened class of cultivators than in Rangpur, and yet few, if any, have taken to rhea, in spite of the fact that the fibre fetches locally from £50 to £180 a ton and even more fabulous prices. They have witnessed the plant being grown by the fishermen for at least a century. Buchanan-Hamilton's
description of its cultivation in 1807 might be given as an account of the rhea-production of to-day, and yet the cultivators gave almost invariably one answer to the inquiry made by me why they did not take to rhea. "Why should we?" they asked. "We have other crops that pay quite as well and give infinitely less trouble." To that I had no very definite answer to offer. It would have been useless to have made the assurance that if they were prepared to risk a little, a large export might be developed and machinery invented that would perhaps render rhea-fibre production both profitable and easy. The Indian cultivator is neither willing nor able to undertake risks, still less to purchase machinery. Tobacco and ginger in Bengal and tea in Assam are consequently likely to continue to occupy the land best suited for rhea, until European capital and enterprise come to the aid of local resources. Dr. Buchanan-Hamilton drew the attention of the Indian cultivators to rhea as a valuable fibre and expressed the hope that jute (which he also found in the same districts with rhea), a fibre then quite unknown in Europe, would not attract attention until san-hemp had been given a fair trial. What has been the result of the hundred years that have come and gone? Both rhea and san-hemp are in the identical positions to-day that they were when Buchanan-Hamilton wrote; in fact if anything they have gone backward, while jute has expanded into one of the most important crops of present-day Bengal agriculture. It cannot, therefore, be said that in the region of rhea cultivation the farmers are opposed to such new crops as trade may demand, so long as they are profitable. The undoubted answer to the present state of affairs must be that jute has paid handsomely and rhea has hitherto offered no inducement to extended production.

Indian System of Cultivation.

It may perhaps be as well to bring into prominence the admission that it is impossible to furnish a definite statement of the cost of production and possible margin of profit in rhea cultivation. Though many writers have loudly condemned unfavourable opinions about the future of rhea and have given their personal assurance of ultimate success, no one has been either able or willing to furnish actual data that could be accepted as representative. It may perhaps be the more convenient course, therefore, if I arrange province by province such material as exists regarding the methods of cultivation and experience gained generally.

Bengal: Eastern and Northern.—Soil and Rotation.—At Joyganj, in the district of Dinajpur, the late Rajah Syama Sankar Roy, Bahadur, experimented with rhea. He laid out several plots of high land that contained a rich loamy soil and aggregated 600 acres. He placed the plantation thus formed under the charge of a European manager. The plants grew remarkably well and gave three (sometimes four) cuttings a year. The experiment had to be discontinued, however, since the price offered for the produce was not equal to actual cost of production. The land was simply abandoned, and fourteen years later (the date of my visit) not a plant of rhea was to be found, though much of the land had never subsequently been cultivated. In Rangpur district rhea is fairly extensively grown, but with one or two exceptions not as a field crop. It flourishes exclusively within the tobacco-growing portions of the district, and most successfully where the finer qualities of tobacco are produced. It demands the best soil; the land must be

147
above height of prolonged inundation, but possessed of free subsoil moisture (which in Rangpur is about 3 feet below the surface); the fields have, moreover, to be manured and carefully tended. In Rangpur wherever soil of a rich sandy loam occurs, there *kankura* cultivation may be expected, and wherever heavy clay soils appear there it disappears. In other words, wherever a situation and soil suitable for tobacco is met with, there rhea may be found, and when grown on fields it is rotated with tobacco and ginger. Of Bogra the same remarks may be made, viz. that tobacco and rhea occur on sandy loam, rotating with chillies and sweet potatoes. but that the absence of all these is universal with the appearance of red-clay soils.

It is hardly necessary to repeat similar observations regarding the other districts of Northern and North-Eastern Bengal. The plant is not grown in every district, nor in all parts of the same districts where it is met with. In Dinajpur, for example, it is confined to the northern tracts; in Rangpur, Bogra, Jalpaiguri and Kuch Behar, similar isolations exist. In other words, there are conditions that seem to have arbitrarily restricted production in the past and which are admitted freely by the cultivators as favourable or unfavourable to the crop to-day. One instance may be given at once. Rhea will not grow as a field crop nor even as a profitable garden plant to the south of Bogra in the rice and jute clay lands. But much more obscure though doubtless of equal value are the botanical facts I have endeavoured to deal with in my report. The comparative absence of leguminous plants, both as wild species or as field and garden crops, is a most significant feature of the rhea country. So again importance must, I believe, be attributed to the appearance of certain peculiar garden crops, not met with outside the area in question. Of these I would specially mention—*Matra verticillata, Chrysanthemum coronarium, Brassica campestris* (a plant closely allied to Chinese cabbage) and *Ramex vesicarius*, which, with the green tops and flowering shoots of rhea itself, are all extensively eaten as vegetables and take the place very largely of the peas and beans of other parts of India. So again *Corchorus capsularis* is very possibly a native of China and that plant is common in Eastern and Northern Bengal and Assam, while *C. olitorius* is the jute of the other districts of Bengal and of India generally. These are striking coincidences if that be the view taken of them. In my opinion they have a far higher value, and justify the conclusion that there are climatic and other physical conditions intimately associated with the restriction of the area of what might be called the Indian commercial (or rather, successful) production of rhea to the tract of country indicated—a country that might be said more closely to resemble the rhea area of China than of any part of India.

**Methods of Cultivation.**—In Bengal rhea is propagated by root cuttings, though the system of burying stem-cuttings horizontally is sometimes pursued, more especially to fill up vacancies and to increase the number of plants in the field. The cuttings are usually 6 to 9 inches in length and planted under 3 to 4 inches of soil. They are placed from 1 to 3 feet apart each way. There are said to be two seasons for transplanting, the first in April to May (before the commencement of the rains), and the second in September to October (at the close of the rains). The majority of cultivators favour the former season. The fields are weeded and hoed after each cutting and heavily manured every year during the cold season. Unless so treated, and liberally, the plants should be removed into new plots of land after two, three, or at most four years, according to the fertility of the soil.

**Number of Cuttings.**—The shoots are cut down when the bottom portion of the stem begins to turn a brown colour. At this stage the leaves, low down on the stem, also begin to fall off. Two to four or even five cuttings are obtained a year, the shoots being 4 to 5 feet in height. The majority of cultivators mention three cuttings as a good average crop. Two cuttings they regard as indicative of neglectful cultivation, and five or six, they hold, can only be obtained from very small plots, shaded, heavily manured and freely watered. As a rule the entire plot is cut down at one and the same time, but occasionally the more intelligent cultivators select the stems when ripe, and thus practically cut only small quantities at a time, but throughout the year.
RHEA FIBRE OF INDIA

From September-transplanted plots the following were given as the seasons for cutting: 1st cutting in May (the worst); 2nd in June (the best); 3rd in July; and 4th in August. But many cultivators prefer to reject the May cutting and to use it for green-manuring the plot, thus having only three cuttings. If transplantation takes place in April to May, there are usually only the three cuttings already indicated. A cutting made later than August is regarded as affording a very inferior fibre. Many cultivators, nevertheless, cut down the plants once or twice during the cold season, but with a view to cause a vigorous simultaneous shooting for the June cutting.

Outturn.—The information procured by me on this subject was so unsatisfactory that I hesitate to publish it. So far as I can learn, the average yield of the highly cultivated homestead lands, worked out to the acre, would not exceed 600 lb. (say 5 to 7 maunds) per annum of roughly cleaned and dry fibre. As compared with this it may be stated that the average yield of jute might be put at 15 to 20 maunds. It has been urged by some writers that since it gives 2, 3 or even 4 cuttings a year, the yield of rhea is bound to be higher than the one cutting afforded by jute. But jute occupies the land for, say, only a few months, that is to say it is not a perennial but an annual crop; it can be raised on much cheaper and more abundant land than rhea; it demands little or no cultivation, and usually no manure; and lastly the fibre is easily separated. With these advantages, let alone the fact that it produces more stems to the acre and that these grow to a length equal to the combined length of all the cuttings obtained from rhea, it is not to be wondered at that jute is both more popular and more profitable than rhea at the prices at present offered by Europe.

Probable Direction of Expansion.—The most hopeful prospect of a future Indian expansion may be said to lie within its present area in North Bengal. The overflow might then be looked for to pass east and north-east into the valley of Assam rather than to go to the southern and south-western or south-eastern districts of Bengal. In fact, it would almost appear as if there had been a migration north-east since the date of Buchanan-Hamilton’s explorations in 1807. Its suitability to the Rangpur and Jalpaiguri districts and to the Duars, would point, however, to a possible expansion westward towards Tirhut. In other words, it would almost seem as if the Indian rhea of cultivation might become distributed within the belt of districts which, starting in the extreme east-north-east in Lakhimpur and passing through Sibsagar, Nowgong, Kamrup, Goalpara, Kuch Behar, Rangpur, Jalpaiguri and the northern extremity of Dinajpur, would pass still west to Purneh, Bhagalpur, Durbhangha, Muzaffarpur, Champaran, and possibly also to Saran. The sub-montane character of this tract of country, skirting as it does the foot of the Bhutan, Sikkim and Nepal Himalaya, may be at once admitted as very possibly possessing many physical and meteorological characters in common. It may be said to lie between 25° 30’ and 27° north latitude. How far a western expansion may be possible the future alone can reveal, but it may be added that recent experiments in Tirhut and those proposed in Purneh seem encouraging. No climatic difficulty would appear at all events to exist in the way of an eastern distribution. Rangpur lies right in the centre of the region indicated, but, as already stated, the crop was found to attain its greatest perfection in the north and the north-eastern divisions of that district—the portions that may be said to face eastward towards the Brahmaputra valley.

By way of concluding these brief observations on the Bengal rhea industry, it may be added that Sir D. M. Hamilton, of Messrs. Mackinnon Mackenzie & Co., is believed to have prosecuted with fair success the experimental cultivation of Behmeria nivea for some few years in the immediate neighbourhood of Calcutta. It may, therefore, be said that the Indian people are looking to him to prove or disprove the com-
CHINA-GRASS AND RAMIE

Assam

mercial possibilities of this fibre. Capital and personal enthusiasm are the essential elements of success, and it seems, therefore, likely to be established whether Lower Bengal is or is not the most hopeful centre. And as having a direct bearing on this issue it may be added that a writer in The Englishman (Dec. 6, 1900), who signed himself "D. M. H.," made the pertinent observation, "Until we know the cost of growing the article it is not much use discussing the cleaning and manufacture." That is the crux of the whole controversy; will it pay?

Assam.—It is perhaps hardly necessary to repeat all the conditions and circumstances of rhea cultivation in this province, since in most essentials these are identical with what have just been stated regarding Bengal. One or two important differences may, however, be set forth. Assam, having been a poorly populated country prior to the advent of tea, much of the fertile sandy loams that in Northern Bengal have for centuries been under crops were available for European enterprise and rapidly became tea-gardens, instead of rice, wheat, tobacco, ginger and rhea farms. Any expansion of rhea plantation in this province would, accordingly, have to contend with tea, for available waste land, and with European planters instead of Native landholders. Another feature, and one of even greater importance, may here be stated, namely that the valleys of the Brahmaputra and Surma carry culturable flat and undulating lands far to the north of the districts discussed in connection with Bengal. According to my observations this northern trend is distinctly advantageous. Moreover, Assam possesses in a remarkable degree the features of vegetation already discussed in connection with Northern and North-Eastern Bengal. As I take it, therefore, Assam is pre-eminently the rhea province of India, though doubtless to this category must be added the northern tracts of Burma, which are practically an extension eastward of the rhea area, until it becomes conterminous with that of China, Cochin-China and the Malay Peninsula. In fact it might be said that the districts of Northern and North-Eastern Bengal, discussed above, are collectively the most western section of the great Rhea, China-grass and Ramie area of the world.

Two other peculiarities of Assam may now be mentioned—one highly favourable, the other unfavourable. There is a climatic feature of the rhea area that in Assam becomes greatly developed, namely the winter rains and humidity. The cold season instead of checking growth carries it forward, so that the growing season extends almost right up to the hot season. In other parts of India the dryness of the atmosphere during the winter months is such that growth is checked at the close of the rains. The untoward aspect is that the immense natural fertility of the soil has not merely the necessities of life, but the comforts that he and his family desire. That being so, nothing in the world will induce the ordinary Assamese cultivator to do more work than he pleases. It is hopeless, accordingly, to look to the people of the country to engage in a new and arduous piece of work, however remunerative it might be. If rhea is to be established in Assam it will have to be by European capital and enterprise and through imported labour. Will this pay? It might as a by-product with tea, but we have nothing to show that it would by itself.
Rhea Fibre of India

Seasons.—The pioneer investigator of rhea in India was apparently Col. S. F. Hannay. In 1850 that indefatigable agriculturist published a report of his experimental plantation, and described the Native methods and results in language that left little to discover for those who followed. He obtained 6 mounds of clean fibre, but was of opinion that a higher yield with more accurate methods might be obtained. Mr. Monahan (while Director of Land Records and Agriculture) wrote a bulletin on rhea cultivation in this province. As that paper is easily procurable, and has been largely drawn upon in my detailed report, I do not consider it desirable to reproduce it further. Briefly, it may be said that just as in Bengal so in Assam, the finest sandy loams are required for the cultivation of this plant—a circumstance that of necessity enhances the cost of production. It is usually planted out in April and May, or in October and November. After two years the soil becomes exhausted and the rhea stems weak and thin; the roots are then taken up, divided, and replanted in a plot of land specially prepared for their reception. With frequent manuring the plant may, however, be continuously grown on the same land for many years. Rhea planted about the end of the rainy season, say October to November, will yield a first cutting about the end of March or beginning of April, and will continue to give cuttings every month or six weeks in the rainy season and every two or three months in the cold weather. It would thus seem that in Assam four or five cuttings a year may be depended on, say in May, June, July, August and November, or even as late as December: One cultivator whom I questioned personally said that he could make his plot give cuttings every 15 or 20 days; yield, in his opinion, was purely a question of manure and moisture. He held that the quality of the fibre depended upon the rapidity of growth; the older the stems the coarser the fibre, and hence high manuring paid, and when moisture was deficient irrigation would also be profitable. A sudden interruption to growth, he thought, ruined the fibre. I believe upon the whole he was nearly right, and his remarks have a special bearing on the rhea produced outside the area I have indicated, more especially in the warm dry tracts of Northern India, which have a short term of annual humidity followed by many months of extreme heat and an absolutely dry atmosphere and soil.

Yield.—This has been variously stated. According to Mr. Monahan, anything between 76 lb. and 605 lb. of cleaned fibre may be obtained per acre according to the care and attention bestowed on the crop. An estimate, based on the results obtained at the Nowgong Jail, came, however, to 911 lb. Mr. (now Sir James) Buckingham, who has given the subject of rhea cultivation in Assam considerable attention, thinks that 640 lb. (8 mounds) would be a safe average. According to another experiment in Nowgong, reported on by Mr. L. J. Kershaw, the outturn was: July cutting, 48 lb.; September, 169 lb.; and October, 116 lb.; three cuttings a year and a total of 333 lb. per acre. But from an actual experiment, performed by purchasing a plot of growing rhea and reaping the crop, Mr. Kershaw showed the outturn to be 900 lb. per acre, although the owner stated that his last year's experience was 600 lb. in three cuttings.

Doubtless the labour question, as already observed, is the first and foremost consideration in Assam, while in Bengal the chief difficulty may possibly be to secure suitable land for the crop.

Burma.—So little is known regarding the rhea cultivation of this province that no good would be served by reviewing in detail the information that actually exists. Mr. Copeland, Deputy Conservator of Forests, reported of Nanlan that small plots were to be found attached to several houses in all the villages on the plateau. His account of the method of cultivation, process of separating, and uses of the fibre, etc., is precisely that already narrated in connection with Bengal and Assam, except that Mr. Copeland is of opinion that the Shanse would very possibly extend their cultivation if a remunerative price were offered for the fibre. From Maymyo was received a sample of what was spoken of as "wild-rhea," and known to the Natives as hpetye. This proved, like the Assam wild-rhea, to be an entirely different plant and not rhea at all. The Burmese so-called wild-rhea was the stinging-nettle—Girardinia heterophylla, (see p. 161), which throughout the mountains of India.

is now and again employed by the hill tribes as a source of fibre, and is best known to commerce by the name of Nilgiri Nettle. Amongst the Shans the true rhea is, however, fairly extensively grown, and under the name of gun. The fibre is separated by scraping off the cuticle, then breaking out the core of wood. It is twisted into thread and woven into small bags, or employed in sewing leather sandals, etc., on account of its great strength. A modern European use of rhea is the manufacture of shoemakers' thread. The Shan bags are similar to the Naga bags made of wild rha or Villebrunea integrifolia (see p. 164).

Panjab.—Far away to the north-west, in the mountainous district of Kangra in the Panjab, the first European investigator (following on the path of Col. Hannay on the north-eastern frontier) was Mr. J. Montgomery, to whom reference has already been made. In pursuance of India's sporadic policy of research Montgomery was allowed to import direct from China, at a great cost and after much loss of time, six China-grass plants. A reference to Col. Hannay, in Upper Assam, would have procured not only a large supply of the self-same plant (at a comparatively nominal cost), but would have secured at the same time full details of the methods of cultivation, as also the experience gained by him. There is no local rhea cultivation in these provinces similar to that described in Bengal, Assam and Burma. I have already admitted, however, that I consider Kangra well suited for rhea cultivation, though it is by no means so favourably placed as Upper Assam or Northern Burma. It hardly seems necessary, therefore, to review Montgomery's results further than has been already briefly indicated. His plantation was an exceedingly small one, on rich, loamy soil, annually enriched by river silt. The plants grew vigorously, were remarkably healthy, and the estimate of yield framed on the results obtained from a selected number of stems (1,000) was originally 750 lb. to the acre, but five years later a fresh estimate raised the outturn to 972 lb. It has since been admitted on all hands that estimates based on a selected number of stems, or even on small plots of garden land, are utterly untrustworthy.

United Provinces.—In these provinces numerous experiments have been performed, and moreover the trials of fibre-extracting machines, conducted under the auspices of the Government of India, were held at Saharanpur. According to Col. Hyde's report, the results obtained might be thus expressed: two cuttings a year were all that could be expected, though if liberally manured and watered, three might be obtained. The green stems yielded from 1½ acres came to 3½ tons, but 480 lb. of useless stems had to be rejected, reducing the produce to 7,360 lb. of stems or 3·28 tons, which yielded by Mr. Greig's machine 207 lb. of fibre. Adding the second and a possible third cutting, the annual total yield would have been considerably under 300 lb. filasse or clean fibre per acre. Sir George King, while Superintendent of the Botanical Gardens, Saharanpur, discussed in 1869 the results obtained at Dehra Dun. He very properly observed that being "on the ground all the year round, both rabi and kharif land rents must be debited against the crop, and also water rent, where irrigation is necessary. Besides this, allowance must be made for more manure than the Native cultivator usually puts on his land." But if well manured and watered, Sir George thought three cuttings might be obtained.
The late Mr. Gollan (then Superintendent of the Botanical Gardens) was of opinion that at Saharanpur three or even four cuttings might be secured, the second or monsoon crop being the best and yielding about one ton of green wands, stripped of leaves, per acre. He was very correct indeed when he observed that “rhea will grow, or to be precise, exist in nearly all classes of cultivable soils with a minimum of attention, but in order to make it produce long straight wands of good fibre-yielding quality, it requires a warm, humid, equable climate, a rich friable loamy soil, which if further enriched with liberal dressings of fertilising manures, such as cow and horse dung, bazâr refuse, etc., so much the better.” Mr. Gollan would appear to have given the total yield at, say, 2 tons green stems, yielding at 4 per cent. under 200 lb. of fibre per acre a year. But he hastened to add: “I do not look upon rhea as a crop that can be grown with profit in the United Provinces or anywhere in Upper India, at the price being offered for the ribbons.” “I, therefore, take this opportunity of warning the Upper Indian planter, to make sure of his ground, by experiments on a small scale, before he largely sinks his capital in rhea cultivation.”

South India.—It may suffice to give but one illustration of the results and experience of South India, since there is no Native industry and it is believed that all European experiments have been practically abandoned. The Glenrock Company, Ltd., laid out a plantation of 400 acres at Pandalur in South-East Wynnaad, and 100 acres at Kullar, some 5 miles from Mettapollium. These were worked for five years from 1884 to 1889, and ultimately abandoned because “the fibre obtained at the price ruling, did not pay for the cost of production.” In one year 8 tons of green stems were cut from a measured acre, or 128,000 stems, but that was an experimental case. Mr. Minchin shows that the range of quantity of water in the green stems is very great—namely, from 75 to 90 per cent. of the total weight, and that it depends on the humidity of the locality or of the season of production. At his plantations the ribbons were stripped both by the Death and Ellwood machines and by the Fremy system, but during the rains “great difficulty was experienced in drying the ribbons.” Three good cuttings were normally obtained in the Wynnaad and with irrigation as much as six, but there is always very little rain for four or five months of the year. Commenting on this feature Mr. Minchin (late Manager of the Glenrock) observes: “It may be that a more equitable distribution of rain might give a fourth cutting.” In another part of his report he says: “I consider that Dr. Forbes Watson’s estimate of 750 lb. of ribbons per acre is the utmost that can be obtained per annum from rhea, and that quantity only under very high cultivation. These 750 lb. of ribbons should give after degumming about 500 lb. of clean flasex.” “Unless the market is prepared to give up to £70 per ton for rhea ribbons I do not think there is any inducement to undertake the cultivation.” Let it be clearly observed Mr. Minchin means ribbons, and the market quotation for these seems to be anything from £15 to £30, or a little less than half the price necessary to make rhea cultivation profitable in South India.

Mr. Minchin’s experience and opinions are likely to be admitted as the only ones with which the public have as yet been favoured, that are entitled to be accepted as something more than speculations and estimates. It will be seen that the Glenrock had to close their plantations,

and lose their capital, because a yield of 750 lb. of ribbons or 500 lb. of filasse (the so-called cleaned fibre of Bengal and Assam) would not pay working expenses. It will be for the practical planter to consider whether indications of a trustworthy nature have been adduced for Bengal and Assam in support of a higher and a more profitable yield than obtained in the Wynnaad (with its abundant cheap labour), and whether that difference will make the profit.

Conclusion.

By way of bringing these observations to a close, it may be remarked in passing that the disappointing Indian results can be contrasted with Mr. Frank Birdwood's opinions (Journ. Soc. Arts, 1904, 401). "What remains to be proved," he says, "is, can it be grown in India, and be prepared for the market at a profit? Many questions have to be considered; chiefly cultivation. It is impossible to lay down hard and fast hypothetical rules; the planters in India are busying themselves in the matter and their experience is worth all the textbooks ever written." Naturally, but perhaps Indian planters may ask themselves how many failures and heavy losses such as those of Mr. Montgomery in the Panjáb, of the Rajah S. S. Roy in Joyganj, Bengal, and of the Glenrock Company in South India, to say nothing of Mr. Baxendale of Selangor, may be necessary to establish the conviction that India at least, more especially outside the area indicated by me, is not the most promising of rhea-growing countries. In Tirhut, recent endeavours seem to have given some promise of a possible future success, and Mr. Bernard Coovtrey has recently furnished full particulars of the results obtained (see the passage below, p. 157). In Assam the plant grows freely, but with exception of the Jokai experiment, cultivation has not hitherto been seriously entertained by planters. The Jokai plantation had been abandoned some time previous to the date of my personal inspection of the rhea cultivation of India, and the Company's Manager could only show me a few miserable shoots not eighteen inches high, as all that survived. I could discover no trace of Col. Hannay's experimental plot, thus once again proving that when abandoned the plant cannot hold its own against indigenous vegetation, and has, therefore, not become acclimatised even in Assam. Perhaps the most hopeful country of all, Upper Burma, remains to be commercially exploited. But the real issue, I venture to suggest, is not "Can India grow rhea?" but "Can the purchaser afford to pay a price that will leave a margin of profit to the Indian producer?" And this will meet its solution in the further question, "Can and do other countries (China more especially) produce it profitably at a lower price than India is able to do?" Hence if there is a manufacturer's side that requires expert knowledge for its full comprehension, there is also an agricultural aspect that demands careful consideration. Both issues must go hand in hand, and perhaps the most hopeful solution would be found in the owners of patent machinery and of spinning and weaving factories undertaking, for a time at least, the production of the plant and the fibre they require. This would save the disappointment of finding no market for the fibre when produced.

SEPARATION AND MANUFACTURE OF THE FIBRE.

As already observed, Dr. Buchanan-Hamilton has the honour of having first published an account of rhea fibre in Bengal. Of the

Ribbons never prepared.

Separation of Fibre.

Stems scraped.

Drying the Stems.

As witnessed by me in Bengal and Assam the fibre is obtained purely and simply by hand scraping. Ribbons are never prepared by the Natives, since the bark is removed before the fibre is stripped from the twigs. The following passage from my original report gives an account applicable, I believe, to the whole of Assam and Bengal at the present day: — "The stems are required to go through a process of drying, hence rainy weather or even cloudy days during the drying stage are supposed to injure the fibre. The shoots are at once stripped of their leaves, and the leaves are very generally returned to the field as manure. The shoots are then carried to the dwellings of the cultivators, and by means of a bamboo knife or scraper are deprived of the bark and the green succulent outer-tissue around the fibre. It is regarded as essential that all the plants should be scraped or decorticated within 24 hours after being cut. The stalks are then laid out on the ground in some dry situation and exposed to the sun during day and removed within doors at night to avoid the dews, and this method of drying is continued for some 4 to 10 days. The stems are thus com-

separation of the fibre prevalent during his time, he says, "The fresh shoots are cut, and steeped in water to procure the fibres of the bark." Now, if that was the system pursued in 1807, it has since changed completely. I have only come across one or two persons who have spoken of the use of water in the separation of the fibre. Col. H. H. Stansfield, speaking of Bhagalpur, described a process of slow boiling, simmering and beating in water. To the boiler was added crude carbonate of soda (sajji maddi), the stems being boiled in this for 1½ to 2 hours. The shoots were then taken out and beaten on a board in contact with running water. They were next returned to the boiler and simmered for another hour, then beaten again in running water till the bark and gum were entirely removed. The ribbons were then drawn through a rough carding machine to remove all adhering woody tissues. It is said that a maund of shoots could be thus easily worked per hour, and yield 2½ per cent. of fibre ready for spinning. Mr. Montgomery tells us that he had tried retting on the green and dried stems as well as on the green and dried peel, in running water and in stagnant, both cold and hot. The results were uniformly unsatisfactory. These then (with Hannay’s process of steaming, shortly to be described) are the only passages with which I am familiar where a process of retting or of boiling are spoken of as having been actually tried or used in India. It has, however, been recently announced that the Algerian method of retting in sea-water has proved an unqualified success. If that be so, a great difficulty—the removal of the gum—has been once more satisfactorily overcome. Mr. D. Hooper (Curator Industrial Museum, Calcutta) performed recently an experiment with artificially prepared sea-water and reported his results. His observations have been reproduced in many Indian newspapers [cf. Capital; Indian Planting and Gardening, etc.], and unfavourably criticised in the Anglo-Indian Review. The Madras Mail, commenting on this reawakening of interest, observes that "hope lives eternal in the human breast, and there is no inherent reason why in this particular case hope should tell but a flattering tale."

Remunerative Market.—Many writers including myself have for years past urged, however, that it is not a machine nor a process that is wanted, but a remunerative market. The Chinese method is perhaps as nearly perfect as attainable with the people and the conditions concerned. It is unapproached by any European invention or Indian indigenous process [cf. Letter in South Ind. Observ., March 1902]. Moreover the Chinese production is on a large scale which leaves apparently a sufficient margin to meet present European demands.
Cleaning the Fibre. 

Fibre Softened by Boiling in Rice-water.

Preparation of Fibre.

Decorticating before Stripping.

Decorticating Machine.

Ribbons.—It is customary to find (in reports published in Europe) the statement that rhea ribbons are exported from India. I cannot say definitely that that is not so, but I should think it highly probable that the supply must have been derived exclusively from European experimental plantations (the Glenrock, for example) or that it was prepared to order. The Bengal cultivator invariably scrapes off the bark before separating the fibre from the stem, and thus offers for sale what may be a crudely cleaned fibre (or China-grass) but is certainly not the much condemned "Indian rhea ribbons" that have given an evil name to, and greatly lowered the value of, the Indian fibre. The Bengal cultivator, strictly speaking, decorticates first, then strips the fibre, and it seems to me his process is a more rational one than that followed by each and every one of the inventors of the so-called decorticating machines hitherto placed on the market. These either strip off the bark with its adhering fibre or smash up the contained stem (scutching) and liberate the bark and fibre in that way. No doubt by a subsequent action some of them get rid very largely of the adhering bark, but they fall far short of the operation of complete removal of the bark and of the green pulpy external tissue which is immediately effected by the cultivator on the stems being cut. Whether his subsequent process of drying the exposed fibre before separating it from the stem is advantageous or not I have had no opportunity of testing, but long acquaintance with the Indian cultivator has prejudiced me in favour of the view that he rarely does much within his own sphere of life that is useless, and he certainly never imposes on himself very considerable additional labour to no purpose.

According to the description given by Col. Hannay in 1850, the Chinese strip the bark and fibre into ribbons as the first operation. The ribbons are then steeped in water for a couple of hours, and thereafter scraped to remove the bark and gum. He then adds that this is quite different from the method pursued by the Dooms in Assam, and observes, "A cheaper method of preparation, and one which is best suited for separation on a large scale, is to subject the strips of fibre, after being taken from the stalks, to the steaming process in boxes, tubes or cylinders. The steaming will soon carry off the sap and its bad qualities, and the bundles well dried will then, I think, be quite in a marketable state." Here we have what may be regarded as the principle, if not also the actual manipulation of the process patented many years afterwards as the Fremy system. Speaking of the Wynad experiments, Mr. Minchin says, "Small portable boilers on wheels were used, which followed the coolies who were cutting the stems along roads through the cultivation. The steam was turned into closed wooden boxes into which the stems were placed. The skinning by hand was a slow process, but the ribbon was saved."

Machinery and Processes.—So much has been written for and against the various machines and processes that have been invented and patented for stripping the bark into ribbons, for degumming the fibre, or for producing filasse direct from the stems, either by chemical or mechanical contrivances, etc., etc., that it seems undesirable to venture further, in this very brief sketch of the existing Indian rhea industry, on so very controversial a subject, and one which has hardly assumed practical importance in India. It may, however, be said that by one set of writers it has been upheld that the proper way is to treat

Ribbons or Dry Stems.
Finally Cleaned Fibre.

the green stems and produce direct what might be called a green filasse; by others, that since the fibre from such a process has still to undergo an elaborate chemical treatment before being fit for the spinner, there is nothing gained by turning out filasse on the spot. All that is required is the production of dry ribbons or even dry stems. By still another set of writers it has been upheld that the percentage of fibre a plant varies so very greatly that it would be dangerous to organise a future trade on such a basis. The prices offered for ribbons of bark would have to be very low, in order to safeguard against an unprofitable yield of fibre—thus ruinous to the grower of good stock. It has accordingly been contended that success can alone be obtained if the clean fibre, in a state very nearly, if not altogether, fit for the spinner, be produced by the grower, though perhaps at central factories adjacent to the areas of cultivation.

In the Kew Bulletin (add. ser., ii., 1898), the reader will find full particulars regarding the various methods of cleaning the fibre, and of all the machinery up to then in use.

Mr. Bernard Coventry’s highly interesting paper in The Agricultural Journal of India (1907, ii., pt. 1., 1–14) reached my hands after the above observations had been passed to the press. It has thus been only possible for me to make room for a brief notice. He would seem to lay more stress on the machinery used than on the climatic and soil conditions of the countries of production or the growth of plant grown. In that he may possibly in the future find himself mistaken. In any case the yield of 2½ per cent. of clean fibre is practically that mentioned by not a few of the past Indian investigators, from Hannay, Stansfield, etc., downwards. But Mr. Coventry narrates the circumstances under which rhea fibre cultivation had been undertaken in Tirhut. These, it would seem, were precisely those recommended by me some years ago (Agri. Ledg., 1898, No. 15, 466-7).

The area covered by these contracts aggregated over 3,000 acres. As the planting and cultivation progressed it was found, however, that many localities which had been selected were unsuited to the growth of rhea, so that ultimately the area actually put down did not exceed 2,000 acres.” (Coventry, Lc. 4). In a further passage Coventry mentions incidentally the area in Daling Sarai as having been 500 acres. Speaking of the subject of yield, he says, “The stems in well-established plants should be as tall as possible, from 4 to 6 feet, but never less than 3 feet. Four good cuttings should be secured per annum if it is to pay, and the total weight of these four cuttings of green stems should not be less than 30,000 lb. per acre, or say 15 tons. The yield of dry fibre from these stems should not be less than 2½ per cent., making 750 lb. per acre per annum. This amount will vary with the efficiency of the decorticating machine. The possible amount of fibre to be obtained from the stems is believed to be 5 per cent., but owing to the large amount which is broken and cut away in the rough process of decorticating, only 2½ per cent. can be relied on for an average yield with existing machinery, and this is given by the Faure machine.” It is thus not quite clear whether these are the results actually obtained at the Research Institute, Fusa, or only indicate Coventry’s personal opinions and expectations. It is all the more disappointing, therefore, that this uncertainty has to be concluded by the opinion that, “if the spinners are truly desirous of developing this important industry they must encourage the growers and offer a price more commensurate with the intrinsic value of the product.” What is doubtless wanted is a remunerative demand. [Cf. Agri. Ledg., 1898, No. 15, 466; Kew Bull., 1907, 4-8.]

Indian Industrial Uses.—I came across no Natives of India who were aware that the fibre could be spun into such fine yarn that it might be woven into fabrics. In the case of Bhagalpur it is stated that it had been used some twenty years ago in admixture with silk. Whether it is still so employed I have been unable to discover, but throughout Bengal and Assam it is spun into coarse thread, three strands of which are again spun together to make fishing- lines and the cord of which the kai jalas or fishing-nets are made. While travelling in Dinajpur and Rangpur I heard of one or two markets or annual fairs at which the fibre, the cord, or the nets of rhea were said to be regularly offered for sale, such as the Bora Daroga meta and fair at Kaunia.
FINANCIAL ASPECTS OF RHEA.

Yield in Other Countries.—The foregoing remarks have been thrown together with a view to represent all that is actually known regarding the cultivation and manufacture of rhea in India. I have quoted figures of yield and prices obtained for bark and fibre, but I have not attempted to give actual estimates of the cost of production nor of the practical results obtained, because so far as I am aware these can hardly be said to exist in connection with India. It would seem, however (to judge by the yield of bark and of fibre reported from other parts of the world, where rhea cultivation has been conducted on business lines), that we have to suppose that the plant is infinitely less productive in India; in other words, that India is not well suited for rhea production; or that the plant has degenerated to a stock very much inferior to that which exists in China, Japan, the Malaya, and America; or that our system of cultivation is altogether defective and deficient; or that the Indian results have been much under-stated; or, lastly, that the returns from other parts of the world have been greatly over-stated. I cannot, therefore, attempt more than to allude briefly to some of the figures that have been published outside the limits of India. In a report issued by Mr. L. Wray, jun., the results of the Perak Government cultivation are given for five experiments. These varied in yield from 1,280 lb. to 2,508 lb. of ribbons per acre, or a mean of 1,656 lb., which gave 1,173 lb. of clean fibre. With so splendid a result (very nearly double the usual figures recorded for India) one would have expected the experiment to have been announced as a financial success, but Mr. Wray tells us that with ribbons at £7 a ton in London, a net loss of $18.30 per acre was sustained. Of Wenchow in China it has been found that one cutting of 80,000 stems yielded 312½ lb. of fibre per acre. It is thus possible that, adding the other cuttings, the total return would have been 900 to 1,000 lb. of China-grass.

Mr. E. Mathieu of Singapore has published a highly satisfactory account of rhea cultivation in the form of a review of the results obtained by the Director of the Botanic Gardens of Java. Mr. Mathieu supports his views by reference to parallel results obtained in America and Algeria. He believes that after three or four years' growth a Malayan plantation should yield in four cuttings 20 tons of stems per acre, and that these ought to give 3-7½ per cent. of clean dry fibre or 1,680 lb. per acre, worth in London £24 a ton, which would yield a net profit over working expenses of $102.30 per acre. If this estimate be accepted, the Malay plantations would yield fully double the average outturn mentioned in connection with India. But even such a splendid production falls far short of others that have to be recorded. According to certain returns published in connection with the Keru valley, California, four cuttings are said to have been obtained a year, making a total of 50,400 lb. of green stems, or a little more than double Mr. Mathieu's estimate for Malayan production and perhaps five times the mean of all the figures given above in connection with Indian experience. Mr. Charles Richard Dodge (Useful Fibre Plants of the World, 89) gives 25 tons of green stems with leaves as a fair average for California, and Hilgard mentions a yield at the Californian Experimental Station (Bull., Nos. 90, 91) of 1,935 lb. of fibre per acre. From the experimental cultivation of a small plot of B. nivea at Kew, it was calculated
that the yield would be 29,000 lb. (say 13 tons) of green stems after the leaves had been removed. At Algiers (according to the late Director of the Botanical Gardens—Mr. Hardy) the yield was 48,000 lb. of green stems with their leaves, or 27,600 lb. of stems: this amount on drying is reduced to 4,900 lb. and affords 1,400 lb. of fibrous thongs. But two such crops may be obtained a year, so that the total of ribbons would be 2,800 lb. At Padua, according to M. Gonset de Mas, 28,300 lb. per acre were obtained in the second year, and 32,360 lb. per acre of stems without leaves in the third year of the plantation. The last quotation worked out at 1,280 lb. of raw fibre. Lastly, M. Favier gives 1,285 lb. of fibre per acre as the approximate average annual yield.

**European Industrial Uses.**—I do not attempt to express a definite opinion on this aspect of the rhea question, though essentially necessary to any full comprehension of the financial issues of production in which India is at present concerned. The fibre would appear to be used for sacking, sailcloth, belting, table cloths, sheeting, shirting, dress cloths, laces, nets, thread, string, cordage, ropes, fishing lines and paper. Wiesner (*Denkschr. Akad. Wiss. Wien. Math.-Nat.*, 1902, lxiii., 7, 22, 28) makes many references to the Chinese use of this fibre in the manufacture of paper. On the authority of Karabacek (*Das Arabische Papier, 28-9*) he states, for example, that it was used in ancient times in China for the production of the best document papers. But the applications of rhea are more varied and diversified than those of almost any other known fibre. Still, its progress in popular favour has been remarkably slow. It is employed at present very largely for giving strength to other textiles, and has hardly assumed an independent or recognised position of its own. It might be said that its disadvantages are its abnormal strength and lasting properties under all vicissitudes; its stiffness and glossiness; its want of rustle; its peculiar lustre (which has not caught popular fancy); and its imperfections in dyeing (especially black shades)—these are the sort of objections often urged against rhea. But it seems possible that they would all disappear if two further adverse circumstances could be overcome, viz., first the necessity for special and expensive machinery, and second the very high cost of production. The difficulty that long obstructed rhea, namely the discovery of a good decorticating and degumming machine or process may, however, be said to have disappeared, and the chief objection now advanced by the growers is that the price offered is not remunerative, and by the manufacturers that more cannot be paid until a special position has been secured for the fibre in the markets of the world.

Practically every fibre obtained from the Natural Order Urticaceae or the Nettles might be mentioned as a possible Rhea Substitute. These are, however, referred by botanists to two sub-tribes, viz. the Stingling and the Stingless Nettles. Of the former may be mentioned Girardinia, Laportea and Urtica, and of the latter Behmeria, Debregasia, Maoutia, Sarcoc dies and Villebruna. These and a few other allied genera are well known to afford strong and beautiful fibres. There is, however, an objection to the former group that applies in nearly equal force to all the species, namely that the poison of the stingling hairs renders it difficult to collect the plants; and indeed in some instances the poison is absorbed and retained by the fibre during the process of preparation. The stingling nettles are consequently an intractable group of plants, no single member of which has assumed or seems likely to assume commercial importance in the modern commerce of any part of the world, even although the fibres they afford are strong and exceedingly beautiful. The other group—the stingless nettles—in addition to the China-grass or Rhea contains several plants that are much appreciated in the countries where met with plentifully, and mainly as sources of useful fibre. Several of these are also capable of extended utilisation, should the necessities of commerce call for new and diversified fibres. Each possesses special features of its own, and the chief difficulty that stands in their way is that which has retarded rhea itself, namely that the necessity for their recognition has scarcely arisen. By far the most promising fibre of this series is Villebruna integripolia.

In the remarks that follow I shall deal as briefly as may be possible with each of the more hopeful rhea substitutes, and, as customary, in the alphabetical sequence of their scientific names:—

Debregasia hypoleuca, Wedd.—This large shrub is met with plentifully on the margins of fields, by road sides and watercourses, and near houses, in the western temperate Himalaya, at altitudes of 3,000 to 6,000 feet. It is best known by the following vernacular names:—pūruni, tashidri (tushiyara), śíāru, tashidri-siār, siārū, sandārī, sansādū, amner, thanū, pinc̄ho, prin, etc.

It is freely pollarded in October, and forms long, straight, willow-like shoots which yield a fair percentage of bark-fibre; the shoots are also made into crude baskets for local use. The fibre is very generally extracted by the hill people and employed for ropes and cordage. Various methods of separating and cleaning the fibre have been reported. Baden-Powell observes that the shoots are not steeped in water but are dried, and when brittle are beaten and the fibre collected. The fibre is reported to be exceptionally strong and of special value for fishing-nets, because of its resisting the action of water. As cordage and rope it is employed for all agricultural and domestic purposes by the hill people, but I have never heard of its being spun and woven nor have I come across any account of a systematic production or even of a scientific investigation of the fibre.

The closely allied species D. relina, Baud., perhaps hardly deserves to be treated as distinct. It is a tall shrub of the sub-tropical Himalaya (especially Eastern) and of the mountains of Western and Southern India and Burma—common in evergreen forests. The following are its better-known names:—Tashidri, kamhyem, kopsi, kurgul and putehaw. It takes the place very largely, in the mountains of Western and Southern India, of the previous species on the Himalaya. It is also used by the Himalayan people, more especially on the eastern extremity, but is less plentiful to the west than the former. In the Madras Manual of Administration it is spoken of as one of the chief fibres of that Presidency. It is fairly extensively used in the Nilgiri hills, and a consignment was sent to Europe by the Glenrock Company which was valued at £70.
N I L G I R I  N E T T L E

BOEHM BRIA
GIRARDIA HETEROPHYLLA

Mr. Cameron refers to it as one of the commonest and most conspicuous plants of the Wynad and Nilgiri hills. Its fibre he tells us is used for bow-strings, and "would appear to require to be better known to be much appreciated." In Ceylon it is used for cordage and string especially suitable for fishing-lines.

Girardinia heterophylla, Done.—In commerce this is known as Nilgiri Nettle. There are three fairly well recognised varieties, viz. (a) heterophylla proper, the condition met with on the temperate and sub-tropical Himalaya from Marri eastward to Nepal, Sikkim, Bhutan, Assam and Burma; (β) palmata, the special form on the Nilgiri hills and Ceylon; and (γ) zeyllinica, the variety met with on the mountains of Rajputana, Central India, the Central Provinces, and the Deccan, south to Travancore. It is commonly stated that palmata yields a fibre superior to either of the others. It would be more correct to say that palmata had been systematically studied and reported on in 1862 by the late Mr. Mclvor, Superintendent of the Horticultural Gardens, Ootacamund, while the other forms, though known to be fairly extensively used by the hill tribes, had not been separately investigated. Under these circumstances it seems likely to serve the purpose of the present work if all three be treated conjointly. The following are the vernacular names best known:—bichia, alū, ava, bhābar, keri, sanoli, horū-surat, pha-pai, tukak, serpa, herpa, ulo, kazu, shish-una, kubra, jurkandālū, kundālū, moti khajati (or môt-l-kajoti), aqia, agarra, avah, ana, schorigenain, hpetye, betya, beksha, etc. [Cl. Agri. Ledg., 1898, 78-9.]

Production.—In the North-West Himalaya Girardinia takes the place of DEBREGEA NIA in the higher and more interior or northern tracts; it occurs between 4,000 and 7,000 feet in altitude, and thus practically above the altitude of Debregenia. It is a tall, stout, much-branched plant that grows to a height of 6 to 10 feet and usually in the form of dense clumps which, owing to the very poisonous nature of the stinging hairs, are left severely alone both by men and animals. The plant is, however, fairly extensively utilised by the hill tribes, especially on the Himalaya, as a source of strong and durable fibre. The long straight shoots are cut down in the cold season (August to October), stripped of their leaves and buds at once, so as to remove as far as possible the stinging bristles; they are then washed for three or four days in water, and the fibrous bark thereafter drawn off as with hemp. Capt. Rainey, speaking of the present plant, not Debregenia, says the shoots after being cut are exposed to the open air for one night; then stripped of their leaves and sun-dried; next placed in vessels and boiled with wood-ashes for twenty-four hours. The fibre is thus found to separate easily and is removed, washed and sprinkled with the flour of the grain kedra, and left to dry, when it is ready to be spun. Campbell observes that in Nepal this fibre is used in making an exceptionally strong cloth called bangra (Agri. and Rural Econ. Nepal), and Gamble and others use for that cloth (as met with in Sikkim) the name gunny or gunnun; in Burma theca is called gun. These names are doubtless derived from bhanga (which signifies to break) and ganja—two words that, at the present time, are restricted to the intoxicating property of hemp. The term gunny in modern commerce is applied to a sack made of jute.

It has already been mentioned that Mclvor cultivated the form palmata on the Nilgiri hills. The soil best suited he describes as alluvial deposits such as are found in ravines. He sowed the plant in rows 15 inches apart and cut down the young shoots for fibre twice a year, namely in July and January. In doing so he left 6 inches of stem as the stool for future shoots. After each cutting the earth between the rows was dug to a depth of 8 inches and manure applied. From the crop of July an average produce of 450 to 500 lb. of clean fibre may be expected. Of this 120 lb. will be superior quality; in other words the produce of the very young and tender shoots, which should be assorted by themselves at the time of cutting. The January crop will yield on an average 600 to 700 lb. per acre. This fibre is, however, inferior owing to the shoots being mature. Were fine fibre only desired, Mclvor was of opinion it would

be necessary to reap the shoots at an earlier time, and perhaps more frequently than stated.

The inner bark abounds in fibre, that of the young shoots being the finest and strongest and peculiarly silky and at the same time woolly. The shoots when cut were allowed in McIvor’s experiment to remain as they fell for two or three days, by which time they had largely lost their stinging property but were pliable enough to allow the bark being peeled off and separated from the leaves. The bark was then tied in small bundles and dried in the sun. When quite dry the ribbons were beaten with a wooden mallet, which caused the outer bark to fall off and leave the fibre comparatively clean. The fibrous part was then wrapped up in small bundles and boiled for about an hour in water with wood-ashes. The fibre was thus removed and washed as rapidly as possible in clear running water, after which it was bleached as with flax or hemp.

Nothing further is known of the above experiment, but it may be inferred that the result was not considered a financial success since the endeavour to grow the plant and sell the fibre appears never to have been repeated in any part of India.

Burma.

By way of concluding it may be said that, in connection with the inquiry into rhea fibre in Burma, information was received of what was called Wild-rhea—a plant fairly extensively used as a source of fibre by the Shans. On a botanical specimen being furnished this was found to be Girardinia heterophylla, called by the Shans ban-riha. Mr. Caer, Deputy Conservator of Forests, Mandalay, wrote that the fibre was not considered so good as gun (rhea) and was not used much by the Burmans. The Palungs, however, were said to mix it with gun. It is somewhat curious that the Jabako and Angami Nagas also employ Girardinia fibre mixed with their ban-riha (Villebrunum) or with cotton, and in Europe the opinion formerly prevailed that the special feature of Nilgiri Nettle fibre was the ease with which it could be mixed with wool, a property not possessed by rhea, and due to the woolly nature of Girardinia.

Properties.—Recently, however, as a consequence of inquiries made at the Industrial Museum, Calcutta, a sample of the fibre was sent to the Imperial Institute for report. Dunstan furnished a reply which has been issued by the Reporter on Economic Products as a Commercial Circular (1905, No. 1). The following abstract may be here given:

It is evident that these results confirm those of Cross and Bevan, but indicate that the present sample is less susceptible to the prolonged action of alkali (as shown by the b-hydrolysis) and contains a larger percentage of cellulose. The fibre of Girardinia heterophylla is remarkable for its ability to withstand the action of alkali, its richness in cellulose, and the length of its ultimate fibre. There can be no doubt that the product is of excellent quality, and it seems highly probable that, if it could be prepared on a commercial scale, it might take a high position among textile fibres.

Mr. B. J. Rose, of the Indian Trade Enquiry Office, 73, Basinghall Street, London, E.C., obtained a commercial valuation of the fibre which was as follows:

"The small sample of the prepared fibre of the Nilgiri Nettle (Girardinia heterophylla) received from the Reporter on Economic Products was submitted to a fibre broker, who reports as follows:—We have examined the sample of vegetable fibre, and beg to report on same: microscopical examination reveals similar structure to flax, appearing, however, to be ineffectively retted; soft and more open than flax, also of a more downy nature. Length and fineness similar to flax and slightly more silky. In our opinion this fibre is more likely to be employed under similar conditions to the flax fibre than as a wool substitute. We value the fibre at £20 per ton." [See also p. 151.]

Laportea crenulata, Gaud.; the Fever or Devil Nettle. An evergreen shrub met with in the tropical Himalaya from Sikkim eastward to Assam, Burma, Ceylon, Perak, Java, etc. Is known by the following:

Surat, chorpatta, moringi, sir-nat, medumma, phetyakee, etc.

This curious plant may be described as the most poisonous of all the nettles of India, although compared with the preceding it is harmless looking. Its stinging hairs cause excessive burning pains, which last for days, augmented on the part being washed; at the same time it produces violent sneezing and copious running at the nose and contraction of the jaw with severe swelling of the part affected. J. D. Hooker (Him. Journ., 1852, ii., 188); Masters (Prod. Angami
PUA HEMP

Bœhmeria urtica dioica

Hills); Beddome (Pl. Sylv., ii., 306), and many other writers allude to the poisonous property of this plant.

Properties.—The bark is known to yield a strong and fairly useful fibre, the ultimate cells of which measure 8-16 mm., but its great loss on hydrolysis, together with its poisonous property, stamp it as unlikely ever to become of commercial importance. The Indian plant is closely allied to B. canadensis, the fibre of which at one time was of importance in Europe and which recently has been proposed for cultivation in France as a substitute for rhea.

Macoutia Puya, Wedd.; Agri. Ledg., 1898, No. 15, 120-6, and pl. Is known as pua-hemp, and Nepal Hemp, and by some writers as Wild-rhea, poy, pua, puya, yenki, kyinki or kienki, puttanti, sat-sa or sat-sha or sap-sha, etc. A shrub from 2 to 6 or even 8 feet in height, fairly plentiful in the damp forests at the foot of the Himalaya from Garhwal eastwards through Nepal and Sikkim to the Khasia hills and the mountains of Burma, at altitudes of from 1,000 to 4,000 feet.

This is purely a wild plant and is nowhere cultivated. It does not grow in the forests but frequents glades and open places, overrunning abandoned fields. It sheds its leaves in winter, comes into fresh foliage about May, and flowers and fruits in August and September; the shoots intended for fibre must be cut before the fruit matures.

Properties.—Mr. G. A. Gummie described (in 1890) the preparation of the fibre at Mungpoo in Darjeeling, his description coinciding in almost every particular with Dr. Campbell's account written in 1847: "The bark is peeled off the stems in long strips; boiled in water, thickened with common woodashes until it is pulpy; then as much as possible of the adhering bark is separated from the fibre by alternately beating with a wooden mallet and washing in cold water. After this the water is rinsed out, and each bundle of fibre is thickly covered with a paste of micaceous clay, and dried. When thoroughly dry, the clay and the remaining bark are easily shaken off, leaving the fibre in a state fit for use. If fibre is required free from dust, it is repeatedly rinsed until the water runs clear, and then re-dried. The white or bluish-white clay found here and there, near streams, is preferred as it gives the fibre a good colour. If its appearance is of no consequence, yellow clay is said to be as effective. I do not know whether the action of the clay is altogether mechanical or not. A few samples which were prepared by treatment with lime and chalk were coarse in appearance and rough to the touch; those treated by clay, on the other hand, were soft and silky." It need only be added that Gummie says "pua is chiefly used for fishing nets and lines. I am told that formerly the Lepehads made cloth from it, but the contraction and expansion readily caused in it by atmospheric changes made it uncomfortable and undesirable for wearing apparel."

Sarcoclamys pulcherrima, Gaud.—A large shrub in Assam, the Khasia hills, Sylhet, Chittagong and Burma, and distributed to Sumatra. It bears the following names:—golab jam, dogal or daggal, sonaful, tsatya, shap-shap-pan.

This bark gives a good rope fibre, and the leaves and twigs in conjunction with the bark of Althizia are used in Assam in the production of a madder-brown dye.

Urtica dioica, Linn., also U. parviflora, Roxb.—One or both of these plants are met with plentifully near human dwellings on the Himalaya (up to 12,000 feet) from Kashmir eastward to Assam and Burma; also on the mountains of Central, Western and Southern India, at altitudes of from 3,000 to 5,000 feet. They are given the same names as Girardinia.

Properties.—The young tops and the hypertrophied shoots (caused through the parasitic action of an aecidial fungus) are largely eaten on the Himalaya. Nettle fibre was the textile of certain purposes in primitive Europe (Hehn), and still is in use. The word Net is derived from the same root as Nettle. A knowledge of their fibres prevails in India, but it can hardly be said they are manufactured. Gubbins doubtless was alluding to Urtica parviflora when he said that the
plant is cut in October and sun-dried; when brittle it is beaten and the fibre separated. "Seeing it stated that there was considerable labour required in cleaning the fibre, I made particular inquiries on this head; as far as I could learn, there is no greater trouble in cleaning the fibre of the *Vitex,* when merely dried, than is experienced with the hemp of the hills which is not retted in water." The fibre is said to be employed for making ropes. [O. H. Hanauk, *Micro. Tech. Prod.* (Winton and Barber, transl.), 1907, 88-9.]

**Villebrunnea integrifolia, Gaud. *Agri. Ledg.*, 1898, No. 15, 108-19, and pl.; *Risa Fibre.* This small tree or bush is met with on the Eastern Himalaya to Assam, the Khasia hills, Sylhet, Manipur, Chittagong, and right across to the other side of India; on the Deccan Peninsula from the Konkan southwards; and lastly in the Andaman Islands. It is the *bon* (wild) *riha* of Assam, also *riva, risa or ree, jutta, bon-kotkora, lükoi or lükokkhun, lipic or lipiah, kaphiki.*

**History.**—It affords both the red and the white fibre made known by Hannay in 1850 under the name of *mesakhi.* In fact, Dalton confirmed years ago that Hannay's *mesakhi* was the same as his *bon riha.* Royle suspected Dalton to be correct and I have little or no hesitation in saying that he was so, though it is curious that none of my correspondents in Assam or on the eastern frontier anywhere have sent me either the plant or the fibre under the name *mesakhi,* nor was that name mentioned to me during any of my numerous explorations on the Assam frontier. Although fairly plentiful in the Deccan it does not seem to have a vernacular name, nor apparently is it known to afford a useful fibre by the people of Western India. During a brief tour in Coorg and the Wynaad some short time ago I personally endeavoured to learn something about this plant. It was found plentiful in the lower damp valleys near the cardamom plantations, but no one seemed aware of its being of any value. *Debrefeasia velutina* was pointed out as the only known wild fibre plant. Subsequently one writer, in response to my account of *Villebrunnea* (*Agri. Ledg.*, i.c.), affirmed that wild-rhea was plentiful in Salsette and the fibre regularly exported up the Persian Gulf, but on being asked for a sample, sent a plant which was neither rhea nor any of the rhea-substitutes, thus once more demonstrating to what extent the bugbear *ban-* (wild) *rhea* has obstructed the natural development of India's fibre resources.

A botanical specimen of the present plant was sent from Assam to the Herbarium, Royal Botanic Gardens, Calcutta, by Jenkins early in the 'fifties. On the label of that specimen is recorded the following—"This is the *ban-rhea* from which the China-grass cloth fibres are prepared." I mention this circumstance as of historic value since it proves that the so-called wild-rhea of the early Assam investigators and the *bon* (*ban*) *rhea* pointed out to me on numerous occasions, during explorations in Assam and across the north-eastern frontier into the country of the Mikirs, Nagas, Singphos, Jabakas, Manipuris and other tribes, is the self-same plant of which so much had been said fully half a century ago. In the country indicated the plant is indigenous, but so far as I could discover, is nowhere systematically cultivated though doubtless encouraged to grow and even planted along embankments, roadsides and other suitable situations with a view to affording a ready supply of fibre. In its purely wild habitat it frequents damp glades near streams, though with its roots well above water-level. Because of its being an indigenous plant and called *ban-* (wild) *rhea* there arose the very mistaken notion that it was the source of the cultivated rhea, and still more perniciously the idea that rhea fibre could be procured in India from a wild source for little more than the cost of collection, and further that all that was necessary to secure a never-failing supply was to plant out waste lands with the wild rhea. I have already fully disposed of these absurd notions and need hardly repeat that the wild-rhea of Burma is *Girardinia.*
WILD RHEA OF ASSAM

the wild-rhea of Sikkim 

Maoutia, and the wild-rhea of Assam the present species—three plants that are as remote from rhea proper and from each other as they could well be. They are all nettles it is true, but there the resemblance begins and ends. They are different botanically, chemically, industrially and agriculturally. To continue to think of them as wild forms of rhea is the blindfold acceptance of a name at the probable expense of a future trade. To place this wonderful fibre—wild-rhea of Assam—on the markets of Europe as equal in price, merit and industrial application with the wild-rhea of Burma, would in all probability be to condemn it to complete neglect. It has merits and properties of its own as different from rhea itself and from all other wild-rheas as from flax. It would, therefore, be of great advantage were some entirely distinct name accepted and recognised in Europe as the commercial name of this fibre, such, for example, as that which I have ventured to assign to it above, namely its Naga name Risa.

Conditions of Cultivation.—According to the opinion hitherto published, it may be propagated by root-cuttings, by slips, or by seed, and its cultivation conducted on the same lines as with the willow in Europe. It is said to be grown largely by the hill tribes on the north-west of Yunnan, and by the Singhphos and Dhoannese of the Assam north-east frontier to a small extent only (Hannay). The tree when left un molested attains a girth of about 2 feet and a height of from 30 to 40 feet. It is abundant within the valleys bordering on the Khasia and Garo hills. It is only found in mixed evergreen forests, and is greedy. It thrives principally in shady damp places on the sides of streams, but does not grow at all on the plains or in places exposed to the sun. The tree flowers in March, and the seeds ripen in April (Lloyd). I collected the plant repeatedly on the plains of Assam proper, for example on the embankment of the Rajghur in Sibsagar, and at Nahor Rani in Tezpur. It is very plentiful at Tingali, at the foot of the Jabaka Naga hills, growing on loose soil with plenty of water. It could be grown on the sloping lands of most of the depressions or hulla great within tea estates—lands which at present are not only waste, but often a source of positive danger to the tea plant.

Collection and Separation of Fibre.—The trees are pollarded during the months of November to February, and the young shoots become available in June and through the rains. The fibre is extracted from the branches in exactly the same manner as from Behmeria nivea, only the fibre is longer. One man preparing risa can get as much fibre in the same time as three men preparing the cultivated rhea fibre (Lloyd). The young shoots begin to appear in May, and these alone are used for fibre. The Naga way of preparing the fibres is quite different from the Assamese. The cuttings are best made from May to October, during the rainy season. The shoots are carried to the villages, where the outside green skin or bark and a little slimy matter are scraped off. Then the ribbons of partly cleaned fibre are stripped from the shoots. The inside of these ribbons is next scraped with a knife so placed in the band as to allow the edge to rest against the forefinger. The strips are drawn through repeatedly in order to remove the slimy and gummy substances from the inner face. After being cleaned in this way, the ribbons are left to dry in the shade. When fully dried they are next steeped in water and wood-ashes for about twenty-four hours, and then boiled in rice water for four hours. The fibre will be then found to be quite free from gum, and may be separated into fine threads. This is, however, a tedious process and is mostly carried on by the old people of the villages. The Assamese, on the other hand, take off the ribbons when the shoots are in a half-dry state and do not first scrape off the outer bark and gum. They also leave the inner face coated with the slimy substance. They purify it in a coarse way by washing in lime and then twist it into twine, or simply divide up the ribbons and without any preparation twist these into twine. This is employed in making the nets used to catch deer (Severin).

Yield and Utilisation.—Col. L. A. M. Lumden, C.B. (of Lumden's Horse) was good enough to supply the thongs of bark that were furnished for examination and report. These were stripped from wild plants that had not been cultivated nor pollarded to produce special fibre-yielding shoots. The consignment was, therefore, very mixed and an allowance has to be made for this circumstance. The following facts are instructive. The green branches stripped came to 36 maunds 32 seers; the green ribbons of bark obtained from these weighed 3 maunds 30 seers; and the dry ribbons, without any preparation other

than drying in the shade, came to 1 maund 30 seers (Lumsden). The fibre is used in the manufacture of a coarse cloth, but chiefly for fishing-nets (Hannay). In the Garo hills the fibre is only prepared in small quantities and for home consumption. The people use it in making nets, and in certain cases for mixing with silk in making cloth (Lloyd). In the Jambaka Naga country it is valued because of its great strength. It is coarsely woven into the bags that are carried over the shoulder. These are often beautifully ornamented, being embroidered with dyed thread of the same fibre (Phillips). The Nagas believe that the harder the thread is spun the stronger it becomes (Severin).

Properties of the Fibre.—In 1853 Capt. Thomson reported that for canvas or lines the fibre required only to be known to be generally used for these purposes. Royle published the results of a comparative study of the fibre supplied by Hannay as follows:—Petersburg clean hemp, broken with a weight of 160 lb.; Jubbalpur hemp, with 190 lb.; China-grass, with 250 lb.; rhea with 320 lb.; and wild-rhea with 340 lb. These were the results obtained half a century ago, but still no progress has been made with this fibre. In March 1897 I collected personally a supply of bark in the Sibsagar district, and submitted the same for examination to Mr. Melrose Arnot, at that time Chemist of the Bally Paper Mills. He reported that the fibres separated from the bark were beautifully white and of a fine silky lustre and measured 25 to 30 mm. long and 0·013 mm. in diameter. They were cylindrical or nearly so, and tapered at both ends; they had a small central canal and thick striated walls; a pecto-cellulose very similar to flax, but much finer while being equally long. Arnot then added, “As compared with the fibre of B. nivea this is exceedingly fine, indeed it is one of the finest fibres I have ever measured, and although not anything like so fine in the individual fibre, the filaments are long and strong, and I have no doubt that in every respect the material would prove more easily workable on textile machinery, and it would undoubtedly produce very much finer textures than B. nivea.”

“The colouring matter contained in the bark appears to be well worth serious study.”

These results were only just what might have been anticipated: no one can scrape the bark off a young shoot and procure a sample of the fibre without realising that it must be very valuable. But in order to have an independent opinion I desired Col. Lumsden to procure me the supply of ribbons alluded to above, and these were forwarded to the late Sir F. A. Abel, Director of the Imperial Institute, London, with the suggestion that Prof. W. R. Dunstan might be invited to examine and report on the fibre.

On April 28, 1898, I forwarded the fibre along with a letter in which the following occurs:— “During my explorations in Assam I gave special consideration to the ban-rhea. I found, as I had suggested in the Dictionary, that while related no doubt to B. nivea it was a perfectly distinct plant, namely Villebrunea integripolia. It can be grown on all waste lands; it has little or no gum, will give a high return where Rhea fails; is a very fine fibre, and perhaps as strong, if not stronger, than China-grass. On these considerations I contemplate making an effort to bring this fibre to the attention of commerce, and I shall be very grateful if you can see your way to secure the co-operation of the Officers of the Research Department. I desire to have the fibre examined both chemically and industrially. For the latter purpose I shall be glad to send a larger consignment on hearing from you.
ribbons have been simply stripped off the stems. They have not
been cleaned in any way, and the loss no doubt will be found serious.
The plant produces shoots 20 feet long; the bark strips off easily, but
no doubt machinery could be readily designed to produce a cleaned
and partly bleached raw fibre. Perhaps the most important point in
connection with this fibre is that it could be produced at a third the
price of Rhea.'"

In October of the same year I had the pleasure to receive Dunstan's
report, and the following passage sets forth his results and conclusions —
"Unfortunately the untreated bark-fibre was sent for examination, con-
sisting of the bark peeled from the plant—containing the bark-fibres in
strips from 3 to 5 feet in length. The only course to adopt was to imitate
as nearly as possible the retting process adopted on an industrial scale,
which the almost complete absence of gum rendered possible. Two
samples of fibre were received. A small quantity of each was placed in
dishes covered with water and allowed to stand for about three weeks,
after which time one of the samples was sufficiently soft for the fibre to
be removed. This was carefully combed and picked, and by this means
about 10 grams of a nearly clean brown fibre in long silky threads were
procured." The fibre thus treated was then submitted to the usual
chemical examination, and commenting on the same, Dunstan adds —
"It is interesting to compare these numbers with those obtained in the
examination of the fibre of _Boehmeria nivea_ made by Messrs. Cross
and Bevan. Watt has pointed out that these two fibres are certainly
distinct; the _Ban-Rhea_ may be the more important of the two, owing to
its growing wild on waste land, to its containing little or no gum, and also
because it furnishes a silky fibre at least as strong as China-grass." "A
comparison of the results of the examination of these two fibres clearly
brings out the superiority of the _Ban-Rhea_, especially in regard to its
smaller loss by hydrolysis and its higher nitration number. At the same
time it must be remembered that the process adopted in treating this fibre
in the laboratory only very roughly approximates to that which would be
used on a large scale. Portions of the original samples have been submitted
to a fibre expert, who reports that they can be readily treated by a special
and simple process which has recently been devised. Further information
as to this process can be supplied if this aspect of the matter is thought to
be of importance."

I need only add to the above that I purposely sent the "untreated
bark fibre" from the belief that perhaps Dunstan might like to
have the opportunity of seeing everything contained in the bark and
thus learning its good as well as its bad points. The fact that it lent
itself to simple retting is a point of infinite value which might not
have been discovered so soon, nor told us with such force, but for
the happy accident of my having imposed on Dunstan the necessity
of having to separate the fibre for himself. Comment seems almost
superfluous. The report demonstrates the superiority of _risa_ fibre
over ordinary _rhea_ in regard to strength, texture and composition. The
results cannot but be considered as most important, and should com-
mand this new fibre to the favourable attention of all persons interested
in _rhea_, _rami_ and the allied _rhea_-fibres. As a catch crop to the tea in-
dustry _risa_ has perhaps no rival, certainly no equal. The fact that this
fibre may be cleaned by simply retting the ribbons of bark (after the

Expensive Methods Unnecessary.

Peasant Industry.

BOMBAX MALABARICUM, DC.; Fl. Br. Ind., i., 349; Gamble, Man. Ind. Timbs., 90; Pharmacog. Ind., i., 215; Cooke, Fl. Pres. Bomb., i., 120; Duthie, Fl. Upper Gang. Plain, i., 98; MALVACEAE. The Red Silk-cotton Tree, semul, pagun, roko-simul, simbal, bouro, semor, sáur, sávara, mundla, bürga-chettu, pulá, burla, sádmali, letpan, etc., etc. A large deciduous tree common throughout the hotter forests of India, Burma and Ceylon.

Expensive Methods Unnecessary.

Fashion of jute) is perhaps of even more interest than its exceptionally high merit as a textile. Expensive decorticating and degumming machinery and methods are thereby rendered unnecessary. It is thus possible that the fibre could be turned out at a price that would not only undersell rhea, but for certain purposes compete with flax, if not with jute itself. At all events the cultivation and separation of a cleanly cleansed fibre of great merit might easily enough be accomplished by even the poorest agriculturist. While rhea must of necessity command capital and enterprise, risa can be developed by the peasant. Indian and English newspapers and periodicals have meantime been flooded with the usual quinquennial dose of the will-o’-the-wisp controversy on the favourable or unfavourable aspects of rhea cultivation in India. Hardly a word has been said in commendation of this interesting fibre, which thus seems destined once more to lapse into oblivion.

Silk-cotton Tree.

Gum.

The tree yields a dark-brown Gum which is sold in the bazars under the name mokha-ras. Another vernacular name for the gum is supári-ka-phul, "produce of the betel-palm," the name supári being said to be given to the blunt thorns of Bombax by children who mistake them instead of the fruits of Arcea Calcehu (the true supári). The gum only exudes from portions of the bark which have been injured by decay or insects, for incisions in the healthy bark do not cause it to flow. It is collected from March to June, and is used as a katira or hog-gum. Mooden Sheriff (Mat. Med. Mad., 1891, 61) says there are three market qualities of sémul gum, of which the first fetches Rs. 12 per maund, and the third Rs. 8. The gum is used in medicine. It is very astringent and is used by both Hindus and Muhammadans in diarrhoea, dysentery and menorrhagis.

Fibre Floss.

The inner bark of the tree yields a good Fibre suitable for cordage, and the seeds afford the so-called red silk-cotton or semul-cotton, a fibre too short and too soft to be spun, but useful in stuffing pillows, etc. It has also been talked of as a paper-fibre. The smoothness of the floss is believed to prevent its felting, and hence in the textile industries it could only be employed to mix with other fibres in order to impart a silky gloss. Its only importation, however, is in upholstery. But it should be observed that Buchanan-Hamilton and other writers have considered it as apt to deteriorate and become lumpy, distinct defects in upholstery. There are four plants which may be said to be the silk-cotton plants of India, viz:—(1) Eriocladon affractusum, DC.; (2) Bombax malabaricum, DC.; (3) Cochlospermum Gossypium, DC.; (4) Calotropis gigantea, R. Br. [For further information see Calotropis, pp. 207-8.]

Silk-cottons.

The flower-buds of Bombax constitute an article of Food, being eaten as a pot-herb. Some years ago it was reported that the estimated amount annually consumed in the Central Provinces was 5,000 maunds (Nicholl, Exc. Rept., 1878-9). The root of the young tree (semul-múla) is said to be a Medicine and used as an alternative; it is made into a confection with sugar and gí and administered as an aphrodisiac or as a restorative in phthisis. The young fruits (máruti-moggu) are stimulant, diuretic, tonic, and expectorant. The wholesale price is quoted for Madras as about Rs. 3 per maund. The Timber is not very durable, except under water. It is used for planking, packing-cases, toys, fishing-floats, coffins, the lining of wells, etc. It is also sometimes made into canoes and water-troughs. The tree is called the yama-drums or tree of the infernal regions or of the god of death, because it makes a great show of flowers and produces no fruit fit to eat. The cotton is made into tinder, and the wood

168
BONES AND BONE-MANURES

For some time the export of bones and bone-manures from India was much deplored by writers on Indian economy. The majority of the scientific investigators whose publications have been enumerated above have, however, pointed out, first, that the Indian soils as a whole are not deficient in phosphates of lime; second, that bones contain, in view of their cost, too small a proportion of nitrogen to justify their use; third, that cereals are not so much benefited by bone-manures as by nitrogenous manures; and fourth, that it is the roots which are not grown as field-crops in India that are most immediately and successfully treated with bone. For these and many other reasons it has been contended that to the Indian cultivator, as matters stand at present, it is perhaps more profitable to sell the bones found on his fields than to utilise them as manure. Mollison, however, observes that “The rayat could, if he took the trouble, collect in some districts quantities of bones, the cost of which would be cartage and his own labour. He could grind the bones into powder . . . and by simple process of fermentation make the bones more soluble and, therefore, more quickly acting than in their natural condition.” If these operations were conducted in the rayat’s spare time and the value of his labour more or less discounted, I have no doubt that the bone-manure would be found as cheap as any other manure procurable. “Bone-manure has been found specially useful with sugar-cane, and to some extent is used with both tea and coffee.”

Palmyra.
THE PALMYRA OR BRAB PALM

*tålì, tanbin,* etc., etc. The name "brab," commonly used in Bombay, is derived from the Portuguese *brrava,* "wild palm."

It is now known that the Talipot Palm of the older writers was not *Borassus* but *Corypha anacandra.* *B. flabellifer* is an erect graceful palm, dioecious, with terminal crown of fan-shaped leaves. It is believed not to be native to India, but is now cultivated and run wild throughout the plains of India, Burma and Ceylon. Symonds speaks of the "Palmyra forest" of Timmervelly. It is probably a native of Africa, although its present African congener, *B. ethiopum,* is slightly different. Sadebeck (Die Kulturges. der Deut. Kolon., 313) says that *B. flabellifer,* var. *ethiopum,* Mart., does not yield the Piassaba-fibre. Wiesner (Die Rohst. des Pfanzcnz., ii., 454-5) details a careful microscopic examination of the differences between the fibres of *Corypha* and *Borassus.* A distinguishing feature of the two palms is the swelling in the upper stem of the African form. A common supposition is that the African plant became extinct owing to the tearing off of the young leaves for fibre, and the same fate was once said to threaten the palm in Ceylon. It grows readily if protected from cattle, etc., and is a valuable tree for checking sand-drift. But E. J. Butter (Agri. Journ. India, 1905, i., pt. iv., 304-10) describes a fungal disease that threatens to prove very destructive.

Properties and Uses.—Every part of the Palmyra is turned to account in some way or other, and a Tamil poem enumerates 800 uses of it. There are, for example, five fibres:—A loose fibre which surrounds the base of the leaf-stalk; a fibre which may be separated from the leaf-stalk; a fibre called *tår* which may be prepared from the interior of the stem; a fibre or core derived from the pericarp; and the fibrous material of the leaves. The leaf-fibre is utilised in the manufacture of basket-ware of Madras, produced at Pulikat in Chingleput, Kimedi in Ganjam, and Bezwada in Godavari, etc. Fine strips of the leaves specially prepared and dyed are plaited into braids and worked up into fancy boxes in nests, cigar-cases and the like. At Diamond Harbour near Calcutta, hats have for many years been made of this material and sold to the Europeans, who visit Calcutta. A recent inquiry into the braiding materials of India revealed the fact that after *Borassus*, *Corypha*, *Musa* *Phanerix,* and *Clunygrype,* were the most hopeful. [ Cf. R. E. F., Ann. Rept. and Prog., 1897-8, 22.] A few years ago investigations were instituted in India with a view to determining the extent to which the corde-like fibres might be employed in brush-making, as substitutes for the American piassaba fibre and the Ceylon **kittul** (*Corypha urens*). So far indications have not been obtained of a very great demand for these special Indian fibres. The stem or *tår* fibre is prepared in some special way by the fishermen so that it becomes pliable and can be plaited into fish-traps. It is neither spun nor twisted, a single thread or fibro-vascular bundle being used; the method of preparation adopted by the fishermen has not as yet been made public. [See also Brushes and Brush-Making, p. 197, also Corypha urens, p. 286.] The export trade in tal coir (or "Palm Fibre") as it is often called (to the European centres largely in Tuticorin (Ann. Rept. Ind. Mus., Calc., 1899-1900, 15). The leaves themselves are found serviceable for fans and in thatching. They were formerly prepared as a writing parchment, being so used by the Dutch Government. In Bengal and elsewhere long strips of the leaf are employed by school-children as washable "slates."

In Medicine the juice of this plant is used as a stimulant and anti-phlegmatic. The root is considered cooling and restorative, as also the gelatious contents of the unripe seeds. The ash of the spathe is given for enlarged spleen, and the silky substance on the young petioles of the leaves is utilised as a styptic. The *Timber* splits easily but will support a very severe cross-strain, and when old is useful for rafters. It is also hollowed out into water-pipes, channels and gutters, and is made into canoes. It is to some small extent exported and used in making walking-sticks, rulers, umbrella-handles, etc. The juice is used in the preparation of cements.

By far the most important aspect of the Palmyra palm is as a source of Food. On tapping the flower-stalk a juice (raś) is obtained, which is either consumed while fresh as a beverage or allowed to ferment, which it will do after sunrise, thus forming an intoxicating liquor (tārī or toddy). If the toddle be distilled the result is palm wine (arak), and by destructive distillation a good quality of vinegar is produced (see p. 1111). The *raś* is also boiled down into a kind of sugar called gur or jaggery (see p. 928). Small round cakes used formerly and to some extent still pass as currency in Timmervelly district. [ Cf. Yule and Burnell, Hobson-Jobson, 1903,
TODDY (TARI) PALM

111. 446.] The tapping for ras does not injure the wood, as in the case of the date-palm, since it is only necessary to bruise the flower-stalk and to crush the young flower or fruit within, and with this object slices of the spathes are made for several days in succession. An earthen pot, into which the sap runs, is tied to the end of the stump, and if the juice is to be drunk fresh the pot is coated with lime inside in order to prevent fermentation. The Palmrya continues to yield sap at the rate of three or four quarts a day for four or five months. It begins to yield when about fifteen to twenty years old and goes on for about fifty years, but once in three years the operation must be discontinued or the tree would die. The female tree yields about half as much sap again as the male. The juice is richer in sugar than that of most other palms; it is said that three quarts of juice will make one pound of jaggery, which (from canes or palms) is the sugar chiefly used by the poor people of India. The sweetness of Burmese bread seems to depend on the use of toddy-juice to raise it.

The extent to which the spirituous liquor is employed may be judged from the fact that at one time the Bombay Government became so alarmed at the excessive consumption of arak in Surat that they ordered large numbers of this useful palm to be destroyed. In this connection it is interesting to observe that Fryer, who visited Surat in 1673, mentions that on drawing near the roadstead they saw groves of Brab-trees, from which the Parsis made a "wine akin to Toddy." This wine the sailors drank, and the result was perpetual disturbances of the peace. The plentifulness of the toddy resulted in the district being overrun by "soldiers and seamen of the Moors." The tree flowers in March; the young fruits are formed in April and May and matured in July and August. Within the shell of the young fruit there is a jelly-like fluid which is eventually transformed and deposited as a hard albumen. The jelly and soft albuminous layers are often eaten fresh in April-May, or cut into small pieces and flavoured with sugar and rose-water. The seed within the albumen is also eaten, being sold in Bengal under the name talsana. In July and August the ripe fruits are gathered and the succulent mesocarp is scraped off to be made into small flat cakes called pátâk. The nuts within are found to be solid and almost unbreakable, but after being buried for two or three months they germinate, and the young seedlings are eaten as a vegetable or are pickled. In The Agricultural Ledger will be found an account of the way in which these shoots (dantalás) are regularly grown as a vegetable crop. The nuts are planted as close together as possible, being laid on the surface of a prepared seed-bed in June-July. The crop is dug about four months later. About 50 fruits are planted to the square yard, and these may produce 100 or more dantalás. In a cheap year the gross value of a crop per acre at ordinary market rates would be about Rs. 1,800, rising in a dearer season to Rs. 3,000. The vegetable, which is roasted before being sold, is eaten chiefly by Kolis and low-class people. The nut itself is usually broken open and the embryo cooked or eaten dry or after it has been converted into a flour—not unlike tapioca. [Cf. Paulus Augineta (Adams, transl. and Comment.), iii., 439; Baber, Memoirs (Leyden and Erskine, transl.), 327; Ass.-Akkari, 1590, 70; P. della Valle, Trav. Ind. (ed. Hakl. Soc.), ii., 291; Fryer, Voy. BORAX or SODIUM BI-BORATE; Ball, Man. Econ. Geol. Ind., 1881, pt. iii., 498–9; Agr. Ledg., 1902, No. 5, 132–4; Min. Industr., 1900, 57–9; Holland, Rec. Geol. Surv. Ind., 1905, xxxii., 99–101. This salt is known in India under an extensive series of vernacular names such as sohágá, tinkál, annabédi, kuddhí khár, tankankhár, venkaram, velligaram, D.E.P., i., 504–11. Borax.
BORAX

Borax

Sohaga
or Tinkal

billigárú, lakhíja, varut, tan-kana, tinkar or tankar, etc. In some parts of the Panjáb frontier and Tibet it is táslé or sal (shal) (one variety being chú tsalélé or water-borax, the other tásle mentog or flower-borax).

History.—The substance was apparently known to the ancient Sanskrit authors and is unmistakably mentioned by Sueruta. From the Sanskrit are derived doubtless its Persian and most of its Indian vernacular names, as also its old English synonym timéal. Perhaps the earliest mention (by a European writer) of this substance, in connection with India, is the reference by García de Orta (in 1563) in which he says it is known to the Gujaratis by its Arabic name of tincor. It is mentioned by Abul Fazl in the Ain-i-Akbari (Blochmann, transl., 1590, i., 26), and is called tangar. Hove (Tours in Gujarat, etc., 129), who visited India in 1787, describes the salt as refined in Káthiáwar. Ainslie (Mat., Ind., 1826) gives a good account of it as a drug and says that the process by which tinkal was refined into borax was kept a secret by the Dutch. Royle (Prod. Res. Ind., 419) gives a brief notice of the substance, but by far the most complete statement hitherto published may be said to be that given by Baden-Powell in his Panjáb Products (1868, 90–4). This reviewed the reports of Cunningham, Hay, Edgeworth, Mardacieu and others.

Supply.

Sources.—Borax proper is a native borate of sodium found, along with common salt, on the shores of certain lakes in Tibet and possibly beyond in Persia and China, and is deposited with sulphur by hot springs in the Puga valley of Ladák, Kashmir. The Indian area may thus be said to commence in Puga valley of Ladák and to pass east to the lakes of Rudokh. To the south of Lhasa, at the Yamdokcho, borax is also obtained. Holes are dug in the ground in many parts of the deserts of Tartary, and within these tinkal is said to collect.

Trade Routes.

The Western supply (from Puga) enters India by Kullu and is refined at Sultánpur, before being consigned vid Mandi and Bhaji to Simla, or vid Rámpur in Bashahr to Jagádhri and thence to the plains. Smaller quantities from this same source also find their way through Chamba to Nurpur or to Kashmir and Lahore. Tibetan borax enters India across the frontier of the United Provinces. Atkinson furnishes an interesting account of this traffic. The borax, he says, is collected in June to September and sold at certain markets. It is brought by Bhotia traders and purchased by the merchants at Rámagnar, where it is refined.

Uses.

Mordant.
Medicine.
Antiseptic.
Domestic.
Insecticide.
Glazing Material.

Economic and Industrial Uses.—Borax is employed extensively as a MORDANT in dyeing and calico-printing. MEDICINALLY it is viewed as a tonic, useful in loss of appetite and painful dyspepsia, and also as an exceedingly valuable detergent in affections of the skin. The antiseptic and disinfecting property of borax, although fully known, might, as it seems, be much more extensively taken advantage of than appears to be the case. For household purposes its uses are practically limitless. As a substitute for soap and soda crystals, it may be regarded as cleaning without destroying colour, and a little added to the starch gives a pleasing gloss to collars, table-linen, etc. As a preservative for meat it is invaluable, and it is probable that as an insecticide (especially in the tea-garden) it would be found unrivalled. Its most important use may be said, however, to be for glazing pottery and as a simple and convenient enamel for metallic surfaces, such as the dials of watches and clocks or domestic enamelled metal wares. It acts as a flux in the formation of a glass which has a low melting-point and thus affords a material that may be employed even in the ornamentation of the surface of glass or glass vessels, since it can be fused and fixed at a temperature lower than what would re-melt the glass on which it has been painted. But ornamentations produced by borax are generally held to be unstable because of the fact that borax is rendered anhydrous by fusion. In time they gradually absorb moisture and become hydrated and efflorescent, when the glaze splits and crumbles to pieces. Sir William O'Shaughnessy was instructed by the Government of India in 1839 to investigate the question of the production in India of glazed pottery sufficient for use at Indian hospitals. His report will be found in the Appendix to the Bengal Dispensatory, and on pages 710 and 711 he also gives a most instructive description of the lime-borate that he employed.
USES AND TRADE

Borax may be said to be invaluable in welding, and is employed by blacksmiths, brassfounders and electroplaters. It is largely consumed in the manufacture of glass beads, imitation precious stones, certain qualities and descriptions of cements (see Glass Beads, p. 563). It is, in fact, fairly extensively utilised by the Indian jewellers in the manufacture of artificial gems, and with shellac it forms a most valuable varnish. In soldering oxidisable metals its action is to clean the surface by fusing away the oxides into a borax bead. Similarly it is employed by the Indian jewellers to cleanse gold and silver ornaments. Plum-bago pots are found to last very much better if after being annealed in the oven they are painted with a solution of borax. Lastly borax is employed as an ingredient in certain toilet soaps and cosmetics, and one of its most curious and interesting uses is that of its employment in the production of a self-trimming wick in candles. For this purpose the wick is saturated with borax, then made into a candle. When ignited an incandescent bead is formed that greatly improves the light-giving property of the flame, while at the same time the wick, being weighted by the bead, turns over to one side and thus protrudes sideways out of the flame. In that position the wick readily oxidises and is consumed, thus dispensing with the necessity of snuffers. [Cf. Paulus Egineta (Adams, transl. and Comment.), iii., 418, 476; Garcia de Orta, Coll., xviii.; also Comment. by Ball in Proc. Roy. Ir. Acad., i., 404; Birdwood and Foster, E.I.C. First Letter Book, 1600, 48; Mandelslo, Travels Ind., 1639, 84; Tavernier, Travels (ed. Ball), 1670, ii., 19; Milburn, Or. Comm., 1813, ii., 207; Watts, Dict. Chem., 1883, i., 440-50; Madras Mail, June 14, 1889; Produce World, Aug. 28, 1896; Journ. Soc. Arts, 1897, xlv., 1173-4; U.S. Yearbook Dept. Agri., 1900, 555; Rept. Cent. Indig. Drugs Comm., 1901, i., 117; Watt, Ind. Art. at Delhi, 1903, 22, 29, 86; etc., etc.]

Trade.—For some years past the foreign demand for Indian borax has been steadily declining, in consequence of the Italian manufacture from boracic acid and sodium carbonate, as also in consequence of the discovery in California and Nevada of limitless supplies. So recently as 1886-7 the foreign exports of borax were 24,273 cwt., valued at Rs. 5,80,637. During the five years ending 1906-7 they have increased from 5,002 cwt., valued at Rs. 1,13,003 in 1902-3, to 5,613 cwt. and Rs. 1,15,300 in 1906-7. The internal consumption has not, however, declined materially. In 1897-8 the imports across the land frontier to India were 15,273 cwt.; in 1898-9, 16,564 cwt.; in 1899-1900, 20,315 cwt.; in 1901-2, 31,085 cwt., valued at Rs. 3,61,446; so again in 1902-3 they were 29,874 cwt., valued at Rs. 3,52,231; in 1904-5, 19,025 cwt., Rs. 2,24,589; and in 1906-7, 21,506 cwt., Rs. 2,60,864. It will thus be seen that borax is an article of considerable importance in the industries of India, and it is satisfactory to know that the local supplies have proved sufficient to check materially imports from Europe and America. There are, however, signs of a slight renewal of the imports from Great Britain. In 1895-6 these were only 13 cwt.; they rose steadily to 597 cwt., valued at Rs. 9,050 in 1901-2; were 463 cwt. and Rs. 6,792 in 1902-3; 848 cwt. and Rs. 10,840 in 1903-4; 1,500 cwt. and Rs. 18,139 in 1904-5; 1,700 cwt. and Rs. 20,839 in 1905-6; and 2,798 cwt. and Rs. 37,039 in 1906-7.

It is probable that several species yield the true Frankincense or Olibanum of commerce, and of these perhaps the most important is B. Carterii. These balsamiferous trees inhabit the Somali coast of Africa to Cape Guardafui and also the south coast of Arabia. The African or Arabian frankincense has long
THE INDIAN OLIBANUM TREE

BRASSICA
Mustard

Various Qualities.
been regularly imported into India, and bears the following names:—kundur, luban, thua, vishay, eseeh, parangi-sham-birani, kunurakam-pishin, etc., etc. Muhammadan writers distinguish several kinds of the imported olibanum, viz. kundur zakar, male frankincense, which is the best quality and consists of deep yellow tears; kundur uma, female frankincense, kundur madharaj, the exudation artificially made into tears; kishár kundur or kashja, the dhup of the Bombay market, consisting of the bark of the tree with the exudation; and duká kundar, the dust of the olibanum and substance reserved for the Indian and Chinese market, whilst the finer qualities (such as the kundur zakar) are assorted and exported from Bombay to Europe. Frankincense is thus an article imported and subsequently re-exported, and is not strictly speaking an Indian product, though it is largely traded in by Indian merchants. It may be useful to furnish, therefore, a few details of the trade of which Bombay is the centre and draws 90 per cent. of the imports and has, moreover, a monopoly in the re-exports. During the five years 1898-9 to 1902-3 the imports expanded from 20,487 cwt., valued at Rs. 2,12,423, to 28,582 cwt., valued at Rs. 3,79,279, and have since (1906-7) increased to 32,552 cwt., valued at Rs. 4,12,082. Similarly the re-exports amounted in 1898-9 to 20,218 cwt., valued at Rs. 3,63,168, in 1902-3 to Rs. 5,27,827, and in 1906-7 to Rs. 6,40,540, and were sent chiefly to the United Kingdom, Austria-Hungary, China (Hongkong), and recently to Germany and Russia. [Cf. Paulus Egineta (Adams, transl.), iii, 217; García de Orta, Coll., lv, also Comment. by Ball in Proc. Roy. Ir. Acad., i. (3rd ser.), 677; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), 1598, ii, 99-100; Birdwood and Foster, E.I.C. First Letter Book, 337, 340, 406, 410; Celsius, Hierobot, 1745, i, 23; ii, 22, 29; Milburn, Or. Comm., 1815, i, 139; White and Humphrey, Pharmacoop., 1901, 496; etc., etc.]

Indian Olibanum Tree.

B. serrata, Roxb., ex. Colebr. (I.C. t. 377).—This is sometimes called Indian Olibanum Tree, and (more especially the gum) is known as sadhe, silet, kundur, luban, guggul, guggula, dhup, chhittu, bastaj, etc. There are two varieties:—(a) serrata proper, a moderate-sized gregarious tree of the intermediate northern and southern dry zones; and (b) oblata, a native of N.W. India. It is often met with in tracks of country where few other trees exist, and on that account is valuable.

Gum.

The Gum (resin) (salaí-gugul) occurs as a transparent golden-yellow semi-fluid substance which slowly hardens. It exudes only on injury to the tree and in the Panjáb is collected twice a year, in March from an incision made in the previous October, and in June from an incision made in March. It is computed that each tree yields annually about 2 lb. It is, however, probable that nearly all that has been written about its medicinal properties refers to the imported olibanum, from which it must be carefully distinguished. The Sanskrit word kunduru is probably wrongly applied to it, and conversely, although it would appear to be the gum quoted of Soerki authors gumu of Sorki authors gumin of Indian bdellium (Commiphora Mukul). It is a gum, slightly aromatic, has a balsamic-resinous odour, is consumed almost entirely in Central and Northern India and hardly if at all exported. As a result of various inquiries some samples were sent to Dunstan, who reported that Indian olibanum "closely resembles Frankincense in its chemical properties. There is little demand for such a product in England, but it might find a market on the Continent as an ingredient for incense." It is employed in rheumatism and nervous diseases and is an ingredient in certain ointments. In Gujarát it is burnt as incense in religious ceremonies. The Timber, which is rough and moderately hard, is recommended for tea-boxes. It is used for fuel and for making charcoal, as well as to some extent in the manufacture of doors, shutters, bowls, dishes, etc. Fernandez (Man. Ind. Syl. 99 (quoted by Gamble)) observes that the tree enjoys a considerable immunity from being browsed or lopped for fodder owing to its resinous leaves, and moreover has a great capability for withstanding forest-fires. It is thus valuable in the clothing of dry hills. [Cf. Taleef Shereef (Playfair, transl.), 1833, 146; Mooden Sheriff, Mat. Med. Mad., 1891, 96-9; Bisceo, List Hyderabad Trees, 1895, 3; Kanny Lall Dey, Indig. Drugs Ind., 1896, 50; etc., etc.]

D.E.P., i, 520-34. Mustard and Rapes.

BRASSICA, Linn.; Fl. Br. Ind., i, 155-7; Prain, Agri. Ledq., 1898, No. 1; Cruciferæ.

This genus contains some of the most useful of esculent plants, such as the Broccoli, Brussels Sprouts, Cabbage, Cauliflower, Colewort, Colza,
Kale, Kol Rabi, Mustard, Rape, Savoy Cabbage, Turnip, etc. There are probably nearly 100 species, a good many of which are cultivated, with under these perhaps as many more races or special forms recognised by the farmers and gardeners of the world. They are all natives of the north temperate zones, but pass into the tropics as cold-season crops. There would appear to have been three great centres of production—a European, an Oriental and a Chinese. The present review of Indian information is intended to set forth the leading commercial facts regarding the more important plants, viz. the Mustards and Rapes, and can, therefore, only incidentally indicate the other species.

In the Dictionary (1884) it was urged that from an agricultural point of view the Asiatic forms may be referred to three important sections: (a) Sarson, (b) Toria, and (c) Rai. The information given in that work was essentially a compilation, and in no sense a report of personal investigations. Since that date, Lt.-Col. D. Prain while Curator of the Herbarium, Royal Botanic Gardens, Calcutta, was able to devote much attention to the study of the Bengal cultivated forms. He had sent to him seeds of the mustards, etc., grown in practically every district of that province. These he specially cultivated at Sibpur, and was thus enabled to study the plants critically, from germination to harvest. As a result he published a very comprehensive report of his investigations, illustrated by twelve plates and two maps. [Cf. Agri. Ledg., 1898, No. 1.] By a comparison with Duthie and Fuller’s account of the species met with in the Upper Provinces (Field and Garden Crops) and other such publications, it would seem that what Prain has said of Bengal is, in the main, applicable to the whole of India. But following up Prain’s studies, Dr. W. Kinzel, of the Agricultural Station at Daline, has furnished the results of microscopic and chemical studies of authenticated seeds supplied to him by Prain. [Cf. Die Landwirtschaft. Versuche-Stationen, lii., 160–93, transl. and republished in Agri. Ledg., 1901, No. 7.] It has thus been rendered possible, through the combined labours of Prain and Kinzel, to identify the Indian rapes and mustards with a degree of assurance not hitherto admissible.

Until such personal investigations had been made it was not to be wondered at that numerous ambiguities, due to faith having been too implicitly placed on vernacular names, should have disfigured the literature of the subject. Prain expressly tells us that the rai of one district may be the tori of another, or the sarson of a third. “Although often, perhaps indeed usually, rigidly enough applied within a given district, Native names are worse than useless when they are depended on to yield information regarding another group of districts.” This is doubtless true, but is perhaps due more to the ignorance or carelessness of the cultivators of the plants. The writer is fortunate that, like Prain, may be able to analyse Native opinion in the light of authentic specimens. It is most satisfactory, therefore, that the literature of this hitherto very obscure subject has been placed on a rational basis. “Practically,” says Prain, “there are but three mustards cultivated in Bihar and Bengal. These three constitute the familiar Rai, Sarson, and Tori crops. Each one of the three varies within its own limits to a greater or less extent: none of them shows the slightest tendency to pass from one to another. So far, at least, as the Lower Provinces are concerned, the existence of anything in the nature of a form intermediate between Rai and Sarson, Rai and Tori, or even between the more closely allied Sarson and Tori, is wholly imaginary.” Many of the errors that have been made by botanists would seem to have arisen from greater faith having been put on the study of dried herbarium specimens than on practical knowledge and experience of the living plants. So also the association of the Indian with the European forms has led to confusion. Prain accordingly concludes his most admirable paper as follows: “As regards the relationship that our three staple mustard-oil crops bear to the corresponding crops in Europe, it may be tentatively held:

1. That Rai (Brassica juncea) is a crop not grown in Europe, at any rate on a commercial scale, but that it takes the place here of B. nigra and B. alba, which in turn are not grown in India;

2. That Sarson (B. campestris, var. Sarson) is a crop not grown largely, if at all, in Europe, but that in India it takes the place both of B. campestris, var. oleifera, and B. rapa, var. oleifera, which in turn are hardly ever met with here: finally,

THESE TWO SPECIES, IF MET WITH AT ALL IN INDIA, OCCUR IN GARDENS ONLY WITHIN THE TEMPERATE AREAS OR IN UPPER INDIA DURING THE WINTER MONTHS. THEY ARE NOWHERE FIELD CROPS, BUT DO THEY CONTRIBUTE IN ANY WAY TO THE INDIAN SUPPLIES OF MUSTARD OR OIL.

I. INDIAN FORMS OF SARSON AND RAPE.

B. CAMPESTRIS, LINN.; PRAIN, L.C. 22-44, 46.

From the standpoint of commerce it is a matter of supreme indifference whether campestris, NAPUS, AND RAPE can be treated as separate species or sub-species of one and the same species. The European cultivated races of the assemblage may be grouped as follows: oleifera, the Colza; NAPUS-BRASSICA, the Swedish Turnip and Rutabaga; NAPUS the Rape, and RAPE the True Turnip. The turnip or shalgham is extensively cultivated in India as a cold-season crop. The Brahmanas and Banias are said to have a prejudice against it. In no part of India are either the Swedish or True Turnips grown as field crops intended to feed cattle. PRAIN had sent to him from Chittagong, seed of a mustard that proved on cultivation to be almost identical with the European Colza. FROM SIKKIM AND BHUTAN he procured seed of a plant that turned out to be B. NAPUS var. ESCULENTA, DC., THE SWEET NAVET.

The following are the chief varieties and races:

PRAIN (L.C. 77) says the plant thus briefly indicated "occurs in every province of Bengal except Chittagong, where it is replaced by a different mustard. It is easily distinguished from RAI by its stem-clasping leaves, and from TORI by the greater amount of "bloom" on its foliage, by its taller stature, its more rigid habit, and its thicker, plumper pods. When reaped the seeds are distinguished by their usually white colour; when brown the seeds are distinguished readily from those of RAI by the larger size and the smooth seed-coat; from those of TORI by their being of a lighter brown, and by not having a paler spot at the base of the seed."

"There are two races—one with erect pods, the NATUA SARSON or SARSON proper, and one with pendent pods, the ULTI or TÉRO SARSON. Each race has two distinct subraces—one with 2-valved, the other with 3-4-valved pods."

"The forms with hanging pods are not common except in North Bengal and East Tirhut (Purnea), the subrace with 2-valved pods being almost confined to this area. But the 4-valved kind extends sparingly through Western Tirhut, and crossing the Ganges spreads southwards through South-West Bihar and Western Chota Nagpur."

"The forms with erect pods practically occur everywhere: the 2-valved subrace, however, is little known in Bihar, though it is grown both in Shahabad to the south-west and Monghyr to the south-east. It extends over the whole of Chota Nagpur and over Orissa and West, Central, and East Bengal. The 4-valved subrace occupies West Tirhut and West Bihar, extending thence sparingly through South-East Bihar and along the dry parts of West Bengal, as far south as Midnapore. It also occupies North Bengal and the northern part of East Bengal (Mymensingh), to the exclusion of the 2-valved subrace. Roughly
CULTIVATION OF SARSON

speaking, therefore, the 2-valved erect subrace is characteristic of Chota Nagpur, Orissa, West, Central and East Bengal; the 4-valved erect subrace is characteristic of the western half of Bihar, and again of North Bengal, while the pendent subrace occupy the region between the areas to the north of the Ganges occupied by the erect 4-valved subrace."

"The name Sarson prevails in Chota Nagpur in Bihar, and in extreme North Bengal. In Bengal proper this is the mustard known as Sweti Sarisha, or simply Sweti. In Orissa it is Ganga toria."

Dr. Kinzel says, "It is so easy to recognise this species as such, that perhaps with a little more experience it may become possible to distinguish microscopically the seeds of the various races of sarson. In brown-seeded sarson the structure of the testa is very uniform, and is almost equally so in the white-seeded and yellow-seeded kinds. The mucous epidermal layer has been found to be undetached in every one of the races." In The Agricultural Ledger (1901, No. 7, 111, pl. i., ff. 1-3) are shown the form and structure of the seed-tests of various qualities of sarson. This, it will be seen, is composed, like that of all the species of Brassica, of a soft parenchyma below, a layer of glutinous cells, a layer of colouring matter, a layer of palisade tissue (the cells of which are narrow, elongated and acute, the shape and size varying with each form of mustard), and lastly an epidermal layer. To appreciate the value of the relative developments of these structures in the various species and races, it is necessary to inspect Dr. Kinzel's plates. Concluding his account of sarson, he observes that "the quality of mustard-oil varies from 0·564 to 0·875 per cent., and shows remarkable uniformity in some of the races. In nine sorts examined the mustard-oil averaged 0·798 per cent. The quantity present was lowest in the race with the longest seeds (Lalka Tor, the large-brown race)." Wiesner (Die Rohe, des Pflanzen., 1903, ii., 726) reviews Kinzel's paper and thus indirectly accepts some of Prain's main conclusions regarding this and the other special Indian forms of Rape and Mustard. The Taleef Shereef (Playfair, trans., 1833, 92, 94) mentions sarson under the names sedarth and eir kup.

Cultivation and Area.—N. G. Mukerji (Handbook Ind. Agri., 271), endorsing previous published opinions, says that tori (latnii, sarisha, shorshe) and also sarson (shweti shorshe) are usually sown with wheat or barley, or in gardens with carrots, amaranth, etc., while rai is grown by itself. They are sown in September, i.e. six weeks to two months before the regular rabi sowings. He then observes that when grown as mixed crops 1½ lb. of seed to the acre are required, the yield being 1½ to 2 maunds. When sown as pure crops 4 to 6 lb. of seed are necessary and the produce 4 to 6 maunds. With rai the seed should be 3 lb. and the crop 3 to 4 maunds.

The greatest possible difficulty exists in furnishing definite particulars regarding the area of production and methods of cultivation of sarson in India as a whole. Duthie and Fuller's account of the United Provinces of Agra and Oudh may very possibly be admissible as indicative of the main features of interest, when taken in conjunction with such particulars as may be derived from Prain's account of the mustards, etc., of Bengal. From the Field and Garden Crops we learn that sarson is a cold-season crop, grown usually mixed with wheat or barley. It is sown either broadcast or in parallel lines running across the fields. It is cut shortly after the harvest of the associated crop. But it is difficult either to fix the actual area under it, or to ascertain the yield. The districts of the middle and lower Doáb are specially well suited to it, and in these hardly a wheat or barley field can be seen in which some portion is not devoted to sarson. The extent of that cultivation may be inferred from the fact that in 1901-2 while only 125,585 acres were returned as pure "sarson, rape or mustard," 8,267,844 acres were shown as mixed crops of these oil-seeds along with wheat, barley, etc. If, however, we accept the yield in the mixed crop to have been approximately in the same ratio

177 12
as that of the pure crops, the net area (worked back from the published production) would have been 1½ million acres (calculated as pure crops) yielding 467,450 tons of "Rape and Mustard." That calculation represents a yield of, say, 5 cwt. an acre. *Sarson* is, however, an extremely precarious crop, being very liable to pests and blights as also to climatic vicissitudes. For example, it is peculiarly subject to the ravages of an aphid that sucks the sap of the young shoots to such an extent that they fail to produce seed. It is, however, exceedingly profitable, and whenever possible the cultivators put at least some portion of their lands under it.

**Indian Rape or Tori, Lutni or Maghi; Sinapis dichotoma, Roxb., Fl. Ind., iii., 117; S. campestris, subsp. Napus, Fl. Br. Ind., i., 156 (in part); Brassica campestris, subsp. Napus, var. dichotoma also Toria, Duthie & Fuller, Field and Garden Crops, pt. ii., 29; B. campestris subsp. campestris, var. dichotoma also Toria, Watt, l.c.; B. campestris, Linn., subsp. Napus, var. dichotoma, Prain, l.c. 36-40, 46, 76-7.

Prain (l.c. 76) says that after rai this is the most important of Indian grades of mustard. It is a cold-season crop on the plains of India and a spring crop on the Himalaya. It was sent for cultivation and study from all the districts of Bengal except Saran and Shahabad. "It is easily distinguished from Rai by its stem-clasping leaves and its small size; when reaped the seed is recognised as being larger, though of the same colour, and by having a paler spot at the base of the seed; the seed-coat, too, is only slightly rough. From *Sarson* or Indian Colza it is easily distinguished by its smaller size and by its leaves, though stem-clasping, as in *Sarson*, being less lobed and having much less bloom. The seeds are of much the same size in *Tori* and in ordinary *Sarson*, but as a rule the seeds of *Sarson* in Bengal are white. When *Sarson* seeds are brown they are of an amber colour, and have no paler spot. The seed-coat, too, is smooth. The seeds of *Sarson* are sometimes considerably larger than those of *Tori*. When this is the case, the two are easily distinguished."

"There are two kinds of *Tori*—a taller, rather later, and a shorter, very early kind. Both kinds, however, ripen well ahead of any *Rai* or any *Sarson*. The earlier kind of *Tori* does not appear to occur in North-West Tirhut; the later kind is unknown in East Bengal or in Chittagong; elsewhere both sorts prevail throughout the Lower Provinces."

"This mustard is known as *Tori* in Bihar and the northern districts of North Bengal, *Lutni* in Chota Nagpur and the drier parts of West Bengal, *Sarisha* in Orissa, West Bengal, Central Bengal and the south-western districts of North Bengal, *Maghi* in the south-eastern districts of North Bengal and throughout East Bengal. The Bengal name *Sarisha* recurs in Chittagong."

---

**Microscopic Examination.**

Kinzel (l.c. 108) informs us that "as compared with European Rape and Colza, the amount of mustard-oil the seeds contain appears very variable. As compared with other species, the testa of the seeds has remarkably narrow, very distinctly circular markings. The only species with circular markings almost as small is *B. rugosa*, Prain, which is at once diagnosed by its detachable epidermal layer. All the samples dealt with here have in transverse sections an undetached epidermal layer with narrow lumen. "The transverse sections of the samples examined were, moreover, very uniform. As compared with the other species, the cells of the palisade-tissue have a very thin wall, and consequently a clearly defined wide lumen, exactly as in *B. Napus*, Linn., the European Rape. In transverse section they appear very blunt at the apex. The layer with colouring matter is very loose; the viscid cells are often in two layers; the thin-walled parenchyma is disposed in three to four layers," Kinzel gives the range of mustard-oil as from 0·239 to 0·543 per cent.

**Cultivation and Area.**—It has not been found possible to isolate some of the facts regarding this plant from those of *sarson*. The foregoing observations have, therefore, to be read in connection with the special particulars that have been elucidated regarding *tori*—the present plant. Duthie and Fuller urge that so far as the United Pro-
PRODUCTION IN INDIA

In terms of production, the present plant is mainly grown as a pure crop, while sarson and rai are almost entirely produced as mixed crops. It follows therefore that the area in these provinces shown as "pure" can be taken as tori (luni, lahi) or rape. According to the Agricultural Statistics of India (1901–2 to 1905–6), compiled by the Director-General of Statistics, there were in the United Provinces during 1901–2, 120,436 acres and 36,841 tons of pure rape; in 1902–3, 140,296 acres yielding 31,320 tons; in 1903–4, 131,926 acres yielding 29,043 tons; in 1904–5, 140,100 acres yielding 18,800 tons; in 1905–6, 154,700 acres yielding 30,000 tons; and in 1906–7, 153,400 acres yielding 30,000 tons. But the area of mixed crops, that is to say of mustard and rape, grown along with other crops was much greater, namely, in 1901–2, 1,461,000 acres and 430,617 tons of seed; in 1903–4, 2,429,000 acres and 542,000 tons of seed; in 1904–5, 2,509,000 acres and 336,000 tons of seed; in 1905–6, 2,026,000 acres and 398,000 tons of seed; and in 1906–7, 2,210,000 acres and 424,000 tons of seed. Rape is "produced in greatest abundance in the districts which border on the Himalayan Terai, and is cultivated all over the hills up to altitudes of 11,000 feet" (Atkinson). It is very little grown in the districts of the Ganges-Jumna Doab, where it generally occurs as a subordinate crop in vegetable gardens. Concluding their account of this product these authors say, "The export of rape is one of the leading features in the commerce of these Provinces, and centres at Cawnpore.

"Rape Seed" is an important article of export trade from the Panjáb and it is grown in Kashmir and Afghanistan. Unfortunately no Panjab writer has as yet studied the mustards botanically, and it is not, therefore, possible to discover to what extent the reports that have appeared should be accepted as rape or be assigned to colza or even to mustard. These crops are largely grown in Ferozepore, Hissar, Jhelum, Rawalpindi, Dera Ismail Khan, Lahore, Gujrat, Dera Ghazi Khan, Jhang and Karnal Districts, in the order of importance named. Fully three-fourths of the crop is raised on unirrigated land, a fact that must commend it greatly to the cultivators. The traffic centres very largely in Ferozepore and the exports go mainly to Karachi. The year 1900–1 was one that might be described as having been abnormally favourable to rape-seed cultivation in the Panjáb. The area under the crop became more than double the average of the preceding years, and was returned at 1,699,700 acres. The yield was also remarkably fine, so that it was described as 25 per cent. above normal, and the total yield became 260,167 tons. Since 1900–1 both area and yield have somewhat declined, though in 1905–6 the area was again recorded as 1,699,700 acres, but the yield only 194,900 tons.

Nothing of any value can be learned regarding the rape, sarson and mustard cultivation in the Central Provinces, Berar, Rajputana, Central India, Sind and Bombay. Mollison (Textbook Ind. Agric.) does not refer to these crops. "Gujarat Rape" of the Bombay and Karachi trade returns would appear to be mainly a special and superior quality of the present plant. But the total area under the crop in the province of Gujarat is not great, being usually about 500 acres, so that the expression "Gujarat Rape" denotes a quality of seed not necessarily procured from the province indicated (see p. 183). However, the total area returned for Sind and Bombay (including their Native States) as devoted to rape
and mustard is well under 200,000 acres, or less than the acreage of these crops in the Ferozepore district alone. So far, therefore, as can be learned, the sub-mountain tracts of the United Provinces and the greater portion of the Panjáb may be taken as the Indian region of rape production.

Bengal province is mainly concerned in the sarson and rai trade. But it may be pointed out that in official statistics the acreage of pure mustard crops in the United Provinces is that which is alone accepted. Hence, as already indicated, the sarson and rai, which are always mixed crops, are excluded from consideration, whereas in Bengal and the Panjáb they are included. In consequence of this arbitrary treatment the "Rape and Mustard" cultivation of the United Provinces is shown as very much smaller than that of the Panjáb, while as a matter of fact it is quite as large and possibly larger. If, therefore, a correction be made of, say, 1,500,000 acres, added to the total area of India under Rape, Colza and Indian Mustard, the result would be 5 to 5 1/2 million acres instead of a little over 4 million acres as presently accepted. If this conclusion be upheld by future inquiry, Bengal would still head the list of Indian provinces with about 2 million acres, and would be followed by the United Provinces with very probably 1 1/2 to 2 1/2 million acres, and by the Panjáb with 1 1/2 million acres, while all the other provinces and Native States put together would conclude the enumeration with less than half a million acres between them.

Brassica Substitute—Eruca sativa, Lam.; Fl. Br. Ind., i., 158; Brassica Eruca, Linn.; B. erucoides, Roxb., Fl. Ind., iii., 117; Duthie and Fuller, Field and Garden Crops, ii., 26, pl. 36; Dioscorides, Codex Anicius Juli, 512 A.D., pt. i., pl. 118; Paulus Α'γινητα (Adams, transl.), iii., 118, gives the key to classic and Arabic literature. This is known in Europe as the Rocket and in India as the tara-mira, tara-moni, duan, dua, jambho, jamba, usan, shwan, chara, etc. According to Prain, the name sheti sarisha given by Roxburgh to this plant is nowadays restricted to sarson.

The tara-mira is a native of S. Europe and N. Africa, and is extensively cultivated as a cold-season crop in Upper India, ascending to altitudes of 10,000 feet. It is fully dealt with by Duthie and Fuller, but is only incidentally mentioned by Prain, a circumstance that may be accepted as denoting its comparative absence from Bengal. However, all the standard authors on Upper and Western India (such as Stocks, Stewart, Baden-Powell, Atkinson, etc.) describe the plant and the methods pursued in its cultivation. It is most commonly grown mixed with grain or barley, taking with these crops the place which rape fills in wheat-fields. It is also met with very largely in association with cotton. It is sometimes grown alone, but only on exceptionally dry fields. It may be sown at any time between the beginning of September and the end of November, and it ripens about the same time as the rabi crops. The yield is said to be from 4 to 12 maunds an acre. Usan is very largely used as green fodder, especially when grown with gram or peas, and the oilcake is much appreciated for feeding cattle. The plant is grown as a substitute for sarson or rape, and the oil is used mainly for burning, but to some extent for food.

The trade in this seed seems mainly within India and as a substitute for sarson, while for foreign countries apparently as a grade of rape. It appears under the name of jamba very frequently in the export manifests from Karachi, the supply being apparently drawn from Sind, Rajputana and the Panjáb.

II. INDIAN MUSTARD.

B. juncea, H., f., & T.; Sinapis juncea, Linn.; S. ramosa, S. patens, Rozb., Fl. Ind., iii., 119, 124; Duthie and Fuller, Field and Garden Crops, ii., 33; Prain, l.c. 16–22, 47, 76; Indian Mustard, rai, asl-rai, etc.
PRODUCTION OF INDIAN MUSTARD

Brassica (L.c. 76) concludes his admirable account of this species with the following brief statement of the main facts brought to light by recent investigations. Rai or Indian-mustard is the most important of the three species of "Brassica" grown in Bengal. It is met with in all the provinces except Chota Nagpur, where it is practically unknown, though it seems to be cultivated to a slight extent in Singhbhum. It is easily recognised by having none of its leaves stem-clasping; and, after reaping, its seeds, which are brown, can be readily distinguished from those of Tori or Indian Rape by their smaller size, their being distinctly rugose, and being reddish-brown all over. From Sarson, which has white seeds or, less often in Bengal, brown seeds, it is equally easily distinguished; Sarson seeds are always considerably, very much larger, and even when brown have the seed coats smooth.

"There are three subraces, a tall, late kind, and two shorter earlier kinds, one of these latter roughish with bristly hairs, the other smooth with darker coloured stems. The taller subrace is quite absent from Chota Nagpur, and from Tippera and Chittagong. The shorter subraces are quite absent from Orissa, and are absent from North Bengal, except Dinajpur, and from East Bengal except Tippera."

The name Rai, occasionally Lahi or Li, once also Mai, occurs everywhere except in Orissa, where this mustard is termed Chota Sarisha (chota = "small," with reference to its seeds). In various districts other names are locally applied, either alone or as alternative names for Rai. Kinsel (L.c. 113) in describing the seeds of Indian mustard furnished to him by Brasn, says that the testa examined under the microscope in surface preparations after treatment with sulphuric acid and caustic soda shows very peculiar circular markings very readily distinguished from those of any European Brassica except B. Besseriana (Sarepta Mustard), which, however, differs in having a separable mucous epidermis. It may be noticed in passing that, as a rule, it is not necessary to make transverse sections in order to demonstrate this separability, because among a large number of surface preparations some fragments that lie transversely are always to be met with when looked for. The colour of the testa of Rai is on the whole clearer than that of European Rape and Colza. The lumina of the cells of the palisade tissue, as indeed the whole testa, show in section characteristic features that in practice impress themselves on the memory, though they could hardly be reproduced except by photography. "The quantity of mustard-oil present in Rai varies from 0.572 to 1.059 per cent., and gives an average in six kinds examined of 0.814 per cent."

Cultivation and Area.—This mustard is cultivated here and there throughout India, and is met with (or closely allied forms are) westward to Egypt and Europe, and eastward to China. It enters directly into competition with Russian mustard (B. Besseriana) a plant extensively cultivated in South and South-East Russia (the Sarepta Mustard). Though the cultivation in India is fairly extensive, it is extremely difficult to procure satisfactory information regarding the extent of production in the various provinces. As already fully exemplified, the returns of Rape and Mustard are given conjointly along with those of colza (sarson), but it would seem certain that Bengal and Assam are the most important provinces and South India the least important. In Upper India (the United Provinces, Panjāb, Rajputana and Sind) the rape crop becomes more important than the mustard. Duthie and Fuller, speaking of the United Provinces, say that this species varies very much in height, some of the kinds attaining 5 feet or more. It also varies in the shape of the pod, which, usually cylindrical, sometimes becomes stout, laterally compressed and less torulose than in typical kinds. They further observe that this mustard is rarely grown alone (except in Benares), but is subordinate to wheat, barley and peas. It is not nearly so extensively cultivated as rape and is usually restricted to the borders of fields. It yields less oil than rape (one-fourth instead of one-third) to the weight

181
**MUSTARD AND RAPE**

of seed; moreover the oil is less esteemed as an article of food. The seed is very generally used in India as a spice to give flavour to vegetables, and sometimes also as a medicine. Mustard-flour is not consumed by the people of India, and the traffic for that purpose is therefore entirely foreign. It would seem, however, that both the Indian and the Russian seed are largely used as one of the ingredients in some of the modern preparations of mustard-flour sold in Europe. The plant is very often (like rape) cut green in January and given to cattle, and in some localities the young leaves are eaten as a vegetable. (For further particulars see the paragraph below on Oil and Oilcake).

**B. oleracea, Linn.** The Cabbage, Cauliflower, etc., etc. It will serve the purpose of this work to indicate very briefly the chief cultivated plants of this species met with in India. In all the forms the leaves are glaucous or green and destitute of hairs: the leaves of the inflorescence only are stem-clasping. The chief forms are:—var. *acephala*, which includes the Kale, Borecole, Cow-cabbage, etc.; var. *bulbosa*, best known through the Savoy Cabbage and Brussels Sprout; var. *Pastoria*, the Cauliflower and Broccoli; var. *capitata*, all forms and colours of Cabbage proper; var. *cambrica*, the Siam Cabbage or kohl-rabi; lastly, var. *chinensis*, the "Leaf-beet" or China Cabbage. [Cf. Kew Bull., 1888, 137-8; 1893, 344.]

The cabbage (kobi), cauliflower (phul-kobi), and the turnip-rooted cabbage (knot-khol or kohl-rabi) have recently become established vegetables and are grown by the market gardeners in the suburbs of all large towns. Except with the Native gentlemen, however, they are not grown in the average village garden, and are not as yet eaten by the mass of the population. A large coarse form of cabbage is extensively cultivated and has become perfectly acclimatised; the early cabbages met with in the markets are the young heads of that plant. The knot-khol is relatively more extensively grown in India than in Europe, and seems to succeed admirably in the cold season, if liberally watered for the first fortnight of its growth. There are two kinds commonly seen, a purple and a green, and both are much appreciated; they come into season before almost any other European vegetable. The Chinese cabbage is a rainy-season vegetable, but notwithstanding its being procurable when few other vegetables are to be had, it is not popular in India. [Cf. Engler and Prantl., Pflanzenfam., iii. (2), 178-7.]

**B. rugosa, Prain., l.c. 11-6, 47; Sinapis rugosa, Roxb., Fl. Ind., iii., 122; B. chinensis, Duthie & Fuller (non Linn.), Field and Garden Crops, pt. ii., 34. The Cabbage-leaved Mustard, pasai or pahari-rais.**

Although this plant is closely allied to *B. juncea* it is quite distinct. None of the leaves are exactly lystately lobed, and the radical ones are persistent. It is a cold-weather crop of the Western, Central and Eastern Himalaya especially in Nepal and Kumaon. It possesses a very short stock till it sets to flower. The permanent radical leaves form a loose cabbage-like head often mistaken for China Cabbage. Prain believes this plant came to India from China like *B. juncea*, but in its present form. He, however, recognises as a wild condition of the same stock the Manipur plant discovered and named by me provisionally as *B. dentata*.

Kinzell (l.c. 115-7) remarks, "As this is the only Indian species (so far at least, as the material at the writer's disposal has gone) which possesses a cellular separable mucous epidermis, the identification of these fragments of tissue in Indian oil-seed with *B. rugosa* is, at all events, a fairly probable one given to the further similarity of their structure in surface preparations." The full description and also the plates given by Kinzel should be consulted by those who may have occasion to identify this or other Indian mustards by the appearance of the seeds. The sample of *B. rugosa* examined by him came from Kalimpong, and was found to contain 0.826 of mustard-oil.

**B. rugosa, var. cuneifolia, Prain, l.c. 14; Sinapis cuneifolia Roxb., Fl. Ind., iii., 121.**

This plant is extensively cultivated in Northern Bengal and Assam as sage or pot-herb. In my article on *Benehmeria nivea* (Agr. Ledg., 1898, No. 182
518) I have referred to it as one of the rather remarkable vegetables prevalent within, and hardly met with outside, the rhea-fibre area of India. It occurs, for example, in Dinajpur, Bogra, Rangpur, Kuch Bihar, and throughout the valley of Assam. In nearly every pleasant garden a row or two of this plant may be seen. It has a rosette of ground-leaves generally of a dark bluish-green colour and with very broad yellow mid-ribs and leaf-stalks. When young it looks like a cabbage, but in time it shoots up a much-branched inflorescence to a height of four to six feet. This becomes clothed with numerous sessile leaves. All the parts are eaten, more especially the young flowering shoots with their delicate leaves. It is one of the most significant of vegetables, and there are probably several easily recognised forms. It is known, throughout the area, as *lai-hak* or mustard-vegetable. This, with the previous species, would appear to be the only cabbage-like vegetable that existed in India prior to the introduction of the cabbage and cauliflower.

**THE OILS AND OILCAKES OF MUSTARD AND RAPE.**

In the foregoing observations mention has been made of the Oils obtained from the various species of *Brassica* and *Eruca*. It seems desirable to bring into a separate paragraph a few of the more striking characteristics of these oils and their oilcakes. All the species afford a bland or fixed oil in addition to a volatile or essential oil (Gildemeister and Hoffmann, *Volatile Oils* (Engl. transl.), 1900, 182, 409–17). The essential oil is practically not known to the people of India, so that when mustard, rape or sarson oils are mentioned (by popular writers) it should invariably be accepted that they are alluding to the fixed or fatty oils. The peculiar properties of the essential oil are those on which the merit of a mustard seed mainly depends. It is on this account, therefore, that the researches of Kinzel are of such special interest to India. The passages already quoted from his report give an estimate of the percentage of mustard-oil (a term used in Europe to denote the essential oil only) present in the samples examined by him. Previous reports on the presence of this oil, in the various qualities of Indian rape and mustard, have been unsatisfactory because not definite; they have accordingly retarded foreign exports. Schimmel & Co. give the following as the percentage of mustard-oil in the samples examined by them:—Russian seed, 0.4 to 0.5; Dutch, 0.7 to 0.8; Italian, 0.6 to 0.7; East Indian, 0.6 to 0.7; German, 0.7. Kinzel gives the average yield of tori seed as 0.549, rai seed 0.814, and sarson 0.708 per cent. (Agri. Ledg., 1901, 104.) The pungency of the Indian is thus not so very different from the corresponding European seeds.

The *karwa-tel* (= bitter oil) is the fatty oil obtained from Indian mustard and rape seed, and inferior qualities from *sarson*. It is the chief oil used in Indian cookery, and is accordingly very important to the people. Rape (and sometimes also *sarson*) is in India largely used to anoint the body. The practice seems to be fairly ancient, since it is alluded to by Terry (Voy. East Ind. (ed. Havers), 1665, 377) as follows:—

"The better sort anoint themselves very much with sweet oyls, which makes their company very savory." Rape and *sarson* (colza) are names which unfortunately have come to be used almost synonymously by Indian commercial men, and are so treated in official statistics. Nevertheless the fatty oils derived from them are even more distinct from each other than are those from the corresponding European plants. In the *Kew Report* (1877, 34; Kew Bull., 1894, 96–7) we read that the Indian seed known as "Gujarat Rape," largely crushed at Dantzic, is found to yield 3½ per cent. more oil than the European seed, and leaves a cake
richer in fatty matter and albuminoids. That information was derived from a paper by Dr. Wittmack of Berlin. But the presence of a percentage of the essential oil of mustard in rape-cake has been said to render such injurious to cattle. Roxburgh regarded Indian mustard-oil (fatty oil) as inferior to rape-oil. Duthie and Fuller hold the same opinion. Speaking of mustard-oil, they say it is less esteemed as an article of food than that of rape. Most other writers affirm, however, that although the yield from mustard is less, the quality of the oil is superior to that of either rape or sarson. Thus it seems probable that the qualities of rape and mustard vary considerably. Sarson is, as a rule, spoken of as an oil that rapidly turns rancid and even for burning purposes has to be purified before it can be used. The mustard-oil of the bazars of India has a pungent odour and bitter taste, due to the presence of a certain amount of the essential oil. This is occasioned through the habit of watering the cake before pressing it a second time in order to abstract the residuary oil. It is often largely adulterated with poppy-seed and other oils. Dunstan in his paper on Indian Edible Oils (Agri. Ledg., 1899, No. 12) unfortunately affords no information on the comparative values of the Indian mustards and rapes. He furnishes, however, most useful particulars as to their specific gravity, acid value, saponification, viscosity, etc., etc., and classes them as semi-drying oils. Leather in a paper on Food-Grains and Fodders of India (Agri. Ledg., 1903, No. 7) gives further details of the chemical compositions of these oils. Lastly the Pharmacographia Indica furnishes all necessary information on the medicinal merits of four qualities. These appear to be Indian mustard, rape, sarson and jamba (Erucia sativa).

The adulteration of linseed with certain qualities of mustard or rape seed has been reported to prove very injurious to cattle fed on such cakes. This subject has been dealt with very fully in the Dictionary, and the article in that work on Oils and Oilcakes should therefore be consulted. [Cf. Leather, Agri. Ledg., 1897, No. 8, 158; also see Linum, p. 731, and Manures, p. 770.]

**PRODUCTION OF AND TRADE IN MUSTARD AND RAPE.**

**Acresage.**—It has been shown that owing to many of the crops indicated above being grown in conjunction with other plants, it is difficult if not impossible, in our present state of knowledge, to give any very satisfactory statement of the area that they annually occupy. The suggestion has been hazarded that the total (expressed as pure crops) cannot be far short of 5 or 6 million acres. But according to the Agricultural Statistics published by the Government of India, both the area and the yield vary considerably, especially in the Panjab, Rajputana and Sind, in response to the amount and seasonableness of the rains. For example, the Panjab acreage of these crops, returned in the official statistics of area and yield, was in 1899-1900, 397,500; in the following year, 1,638,400; in the next year, 665,800; and again in 1903-4, 1,038,900, since when it has remained fairly stationary.

**Yield.**—Turning now to the estimated production, it would seem that during the ten years ending 1901 there were two periods of abnormal yield, namely 1897-8 and 1900-1. If these be disregarded, the traffic fluctuated from a little over half a million to close on one million tons of seed, during the decade mentioned, and production has shown on the whole a tendency to expand. This view is in strict accord with the constantly
repeated statements of popular writers that the trade in these oil-seeds has been steadily increasing, and is now one of the staples of Indian commerce.

**Rape and Mustard Seed: Rail-borne and Coastwise Traffic.**—The returns of Rape and Mustard carried by rail and river show the exporting provinces to be the United Provinces, Bengal, the Panjáb, Assam and Bombay, in the order named. But as illustrative of the fluctuating nature of the trade, it may be mentioned that in 1897–8 Bengal exported a little under 2 million cwt., the United Provinces close on 1½ million, Assam about ¼ million, and the Panjáb ¼ a million cwt. of these seeds. The following year the figures were—United Provinces 2¼ million, the Panjáb 1½ million, Bengal 1¼ million, and Assam a little over ¼ million cwt. But by 1906–7 a complete change had taken place—the United Provinces exported 2½ million cwt., the Panjáb 1 million, Bengal ¾ of a million, and Assam under ¼ million cwt. Calcutta usually heads the list of importing towns, but Bombay and Karachi take the lead in years of high production in the Panjáb. The importance of Karachi as a distributing centre seems to have been falling off, and that of Sind correspondingly expanding. But here again the trade seems to fluctuate so tolerably that no reliance can be placed on comparisons of short periods.

**Exports.**—The foreign exports of Rape from India in 1891–2 were 30,793 tons, valued at Rs. 1,70,89,524; in 1893–4, 365,954 tons or Rs. 4,73,45,133; in 1895–6, 112,489 tons or Rs. 1,40,09,294; but they fell in 1900–1 to 86,368 tons or Rs. 1,23,57,451; recovered in 1901–2, to 346,244 tons or Rs. 4,45,56,044; and fell again in 1902–3 to 196,345 tons or Rs. 2,47,11,358. Since then the values of the exports have been—1903–4, Rs. 2,53,41,010; 1904–5, Rs. 2,73,37,732; 1906–7, Rs. 2,46,70,617. The exports, the chief receiving countries are Belgium, France, Germany and the United Kingdom.

The Mustard traffic is much smaller than that in Rape. In 1891–2 the exports were 2,640 tons, valued at Rs. 3,86,818; in 1894–5, 7,809 tons or Rs. 11,27,605; in 1900–1 they fell to 1,721 tons or Rs. 3,25,589; in 1901–2 they were 3,232 tons or Rs. 5,61,895; and in 1902–3 stood 2,613 tons valued at Rs. 4,93,342. Since then the annual values have been—1903–4, Rs. 4,22,123; 1904–5, Rs. 6,19,004; 1905–6, Rs. 8,94,553; 1906–7, Rs. 5,65,000. Of these exports by far the most important receiving countries in recent years are France, followed by Belgium, Germany, Ceylon, Mauritius and the United Kingdom, the names being given in sequence of importance.

**Mustard and Rape Oil.**—The traffic in Mustard and Rape Oil shows much steadier expansion than that of the seed. In 1899–1900 the exports stood at 259,661 gallons, valued at Rs. 3,52,962; in 1900–1 at 38,270 gallons, valued at Rs. 4,70,161; in 1901–2 at 286,169 gallons, valued at Rs. 4,74,023; in 1902–3 at 314,792 gallons, valued at Rs. 4,79,649; in 1903–4 at 346,174 gallons, valued at Rs. 4,84,835; in 1904–5 at 432,752 gallons, valued at Rs. 5,58,762; in 1906–7 at 273,684 gallons, valued at Rs. 4,90,893. The bulk is exported from Calcutta.
THE PAPER-MULBERRY

Out of the last year's total (1906-7), 257,282 gallons went from Bengal; 14,244 gallons from Sind; and 2,158 gallons from Bombay. The receiving countries were Mauritius, 113,068 gallons; Natal, 93,787 gallons; United Kingdom, 19,892 gallons; Australia, 22,581 gallons; Straits Settlements, 10,159 gallons; and British Guiana, 3,574 gallons.

BROUSSONETIA PAPYRIFERA, Vent.; Fl. Br. Ind., v. 490; Gamble, Man. Ind. Timbs., 633; Brandis, Ind. Trees, 613; Engler and Prantl, Pflanzenfam., 1889, iii., pt. i., 76; URTICACEAE. The Paper-mulberry or Tapa-cloth, *malayum*, *thale*, *kodzo*, *kaji*, etc. A small tree or bush, native of China and said to be wild on the hills of Upper Burma and Martaban. Frequently cultivated in India, largely so in the Southern Shan States (Cradock), and distributed to Siam, Japan, etc., Western China, Ichang and Yunnan, etc. According to Wiesner (quoted in Stein's *Ancient Khotan*) it is the paper material of Eastern Turkestan; it was introduced into Southern Europe and parts of Germany about 1750. Brandis remarks that it is a marvellous instance of a plant that may be sown both in temperate and tropical countries.

From the bark of this tree is obtained a fibre which perhaps deserves to be carefully investigated. From it is made the falsely named Chinese "leather-paper," the Japanese *kodzo*-paper, the curious paper-maché school-slates of the Burmese (*parabaik*), the *tapa*-cloth of the South-Sea Islands and the mulberry paper cloth of the Karans. It is an excellent paper-fibre, though according to some authorities the stock is a little difficult to prepare of good colour. The silkworm can be fed upon the leaves, and the annual pruning of twigs to obtain a fresh flush for the silkworm might be made to give a profitable return as a paper-fibre. The plant produces suckers in profusion, coppices well and grows fast. It has been most successfully cultivated at Dehra Dun, but the district is too far from the paper-factories to allow of profitable production. It will not survive on jungle-land or on dry soils, nor can it stand severe cold; but it might pay on waste land near the coasts of Bengal, Burma, Malabar, etc., whence transport would be cheap. The usual Japanese method of propagating is by slips. Kämpfer, followed by Rein, says that every autumn after the leaves have fallen the young shoots near the ground are cut off, and in this way, after three or four years, bushes with from four to seven one-year-shoots are obtained. It is estimated that 2 cwt. of raw *Broussonetia* bark will yield about 31 cwt. of white bast—about 45 per cent. Craddock describes the manufacture pursued in the southern Shan States. It closely resembles the description quoted in the *Dictionary* from Royle (Fibrous Pl. Ind., 1855, 341-2). Rein (Indus Japan, 1889, 165, 393-5, 401, 403) gives an interesting account of the plan and furnishes an illustration printed on *kodzo*-paper. (See Daphne, pp. 486-7 Paper and Paper Materials, pp. 862-4.)

Brooms are made all over India from a wide assortment of materials presently to be enumerated, the selection being as a rule

186
BRUSHES AND BROOMS

BRUSHES

MATERIALS

governed by the supply available and the necessities of the people. Stein (Ancient Khotan, 1907, 333) figures and describes what is very possibly the most ancient specimen in existence. This was found at Dandán-Uliq (a city abandoned in the 8th century). The lower portions of some grass were seen to have been plaited into a continuous strip, then rolled round and secured firmly by a string, thus forming a broom, which in every detail agrees with the corresponding article of modern India.

Indian-made brushes are principally of the bazár-type and are, therefore, mainly of local interest. Two firms, the “Pioneer Army Brush Co.” of Cawnpore, and “Messrs. P. Thompson” of Coonoor, Madras, manufacture brushes of the European pattern. Both firms gave some prominence a few years ago to the use of kittul-fibre (Ceipada urens) in place of bristles, from the belief that the sowars or Native cavalry would prefer vegetable fibre to animal bristles. Although Indian-made brushes may now be seen all over India, particulars are not available of the actual extent of manufacture. There is moreover a very considerable import by India from Europe of brushes, but complete statistics are not available. We read, for example, that from the United Kingdom there were received in 1903, 2,891 dozen brushes valued at £8,910.

Materials.—Turning now to the materials used. It would be undesirable to attempt a complete enumeration of all the substances which in India are employed, or which might be so, for brushes or brooms. Even in Europe the variety and diversity are extraordinary—e.g. bristles, kittul, broom, rattan, whalebone, wood, rushes, wire, spun-glass (specially serviceable for contact with acids), etc., etc. India at the same time exports a very considerable quantity of brush-making materials including both vegetable fibres and bristles, and the trade would appear to be improving. Thus in 1899–1900 the total exports were 54,388 cwt., valued at Rs. 11,49,998; whereas in 1903–4 they were 83,258 cwt., valued at Rs. 20,76,331; and in 1906–7, 88,158 cwt., valued at Rs. 17,68,930. Although in point of quantity Madras takes by far the largest share, viz. 79,350 cwt. in 1903–4 and 85,203 cwt. in 1906–7, the goods it exports are much lower priced (viz. Rs. 9,70,328 in 1903–4 and Rs. 9,71,212 in 1906–7) than those sent from Bengal (viz. 3,296 cwt., valued at Rs. 9,60,571 in 1903–4, and 2,360 cwt., valued at Rs. 6,52,827, in 1906–7). The Bengal exports are mainly in high-priced bristles. Of these Bengal exports for 1903, Rs. 5,75,790 represented the value of the bristles sent to England, whilst only Rs. 22,470 were attributable to vegetable brush-fibres with the same destination. The total exports of brush-making materials from all India to Great Britain in 1903 were 17,943 cwt., valued at Rs. 10,38,909, and of that amount Rs. 6,07,305 was the value of the Indian contribution of bristles to the British supply.

The following are some of the principal plants employed in brush-making:

Arenga saccharifera, Labill. (see p. 92).
Aristida setacea, Retz.: Fl. Br. Ind., vii., 225; Gramineae. Broomstick-grass, shipur-gaddi, vina-pullalu, thodapga-pullu, etc. A reed three to four feet in height, found in Western India from Bihár and the Konkan southward, also in Ceylon, the Mascarene Islands, etc. The roots attain a length of 15 inches to 3 feet and are said to be used in the manufacture of weavers' brushes in Madras and along the west coast (Ind. Agrt., Dec. 12, 1891). These roots are collected in South India by Yerukalas (a nomad tribe) and sold to the weavers at 3 or 4 annas a viss. The Telinga paper-makers construct their frames of the
BRUSH-MAKING MATERIALS

**BUCHANANIA LATIFOLIA**

Piayar

culms and these are also employed for making *tatties* in the same way as the *khas-khas* roots of Northern India.

Agave Cantala, *Baxa,* and other species (see p. 33).

Bambusa, various species (see pp. 99-101).

Bristles, see Live Stock (Hogs) (p. 752).

Caryota urens, *Linn.* (see p. 286).

Chloroxylon Swietenia, *B.C.* (backs of brushes) (see p. 294).

Chrysopogon Gryllus, *Trin.* The roots of this plant are said by Jackson, Hannan and others to be the Venetian whisk-fibre which in England and other countries is made into brushes of various kinds. The grass is abundant on the hills of North India, but except as a fodder plant it is apparently not known to be of any economic value.

Corvaba umbraculata, *Linn.* (see p. 429).

Hair of bears, squirrels, camels, badgers, goats, polecats, sables, ichneumons, etc., is used in the European brush industry, but no information is available as to the extent, if any, by which India contributes to the supply, or herself utilizes any of the hairs mentioned.

*Ischaemum angustifolium,* *Hook.* (see p. 694).

Pandanus odoratissimus, *Linn., f.*: the Screw-pine—the *keura, ketra, kenda, talum, mugali,* etc. A common and much-branched plant frequently grown on account of the fragrance of its flowers, but is wild on the coasts of South India, Burma and the Andaman Islands. The leaves contain a strong fibre used for cordage and for spinning into coarse yarn. The roots are used in basket and brush-making (Perfumery, see p. 821). [Cf. Forster, *Pl. Enc.*, 1786, 38-41; *Rept. Ind. Hemp Drugs Comm.,* 1894, i., 156; Marco Polo, *Travels,* ii., 250; *Ain-i-Akbari* (Jarrett, transl.), ii., 126; *etc.*]

Phoenix sylvestris, *Hook.* (see pp. 115, 884-5).

Saccharum arundinaceum, *Roth.* (see p. 930).

Sorghum vulgare, *Pers.* The Italian whisk (see p. 1031).

Tamarix, * spp.* see Baskets (p. 116).

Vetiveria zizanioides (see p. 1106).

D.E.P.,

i., 544-5.

Piayar.

Gum.

A pellucid Gum (peal or pin) which exudes from wounds in the stem is more than half soluble in water. It is said to resemble Bassara gum, to have adhesive properties like inferior gum arabic, and to be suitable for dressing textiles. As a consequence of inquiries organised by the Reporter on Economic Products it was found that in many provinces the gum is not collected, while it is reported from Jhansi (U. Prov.) as used in printing cloth, from Berar as employed in dying, and from the Central Provinces as sold mixed with dhawra gum (*Anogeissus latifolia*) to the banias. On some samples sent to the Imperial Institute, London, the Director reported that the gum was not entirely soluble, but could be mixed with twice its weight of water, about 10 per cent. formed a gelatinous mass; the sample examined, moreover, contained a large quantity of extraneous matter. The brokers reported that if it were carefully collected and a regular supply ensured, it might fetch 20s. per cwt. on the London market, and be employed for cheap manufacturing purposes. [Cf. *Agr. Ledg.,* 1900, No. 9, 92.] The bark and the fruits furnish a natural Varnish. The kernels yield a sweet and wholesome Oil (chironji), but owing to their being much prized as a sweetmeat when cooked, the oil is seldom expressed. The kernels, which have a flavour something between that of the pistachio and the almond, are eaten by
THE DHAK OR PALAS

Timber.

the Natives (Baber, Memoirs, 1519, (Engl. ed.), 326). They are also used to flavour ganja (Rept. Ind. Hemp Druga Comm., 1894, 157). In the hills of Central India the fruits with the kernels are pounded and dried and subsequently baked into a sort of bread (Church, Food-Grains of Ind., 177). From the Panjab and Haidarabadd the leaves are exported as sold for CURES. The Timber is not very hard nor durable and is of small value, though made into spoons, platters, toys and bedsteads, and is even employed for door and window frames, plough-handles, etc. White insect-wax has been found on the tree in the Central Provinces. The kernels of B. angustifolia, Roxb. are used like those of the above species. [Cf. Ait-i-Akbari (Blodhmann, transl.), 1590, 71; Tallej Shereef (Playfair, transl.), 1833, 65; Buchanan-Hamilton, Stat. Acc. Dinaf., 161; Lisbon, Useful Pl. Bomb., 1884, 53-4, 217, etc.; Moodeen Sheriff, Mat. Med. Mad., 1891, 128-9; Journ. Soc. Chem. Indus., xi., 404; Ind. For., Sept. 1895, xxi., 329; Bisoeo, Hyderabad Trees, 1896, 3; Kanny Lall Dey, Indig. Drugs Ind., 1896, 53; Rept. Coll. Ind. Mus. Calc., 1901, 61, etc., etc.]

This well-known tree is, when in flower, a conspicuous feature of open country and grass lands, owing to its brilliant flowers which appear at the beginning of the hot season. It is valuable for recovering salt-lands since it will grow even where there is a bad efflorescence of rēh (see Alkalis and Alkaline Earths—Rēh, p. 55). It yields naturally, or from artificial scars on the bark, a Gum called chāniā-gond, kamarkas, palas-kī-gond, etc., which occurs in round tears, as large as a pea, of an intense ruby colour and astringent taste. The gum is used in Native Medicine as a substitute for true kino (Pierocarpus Munsuphum, which see, p. 905). Roxburgh pointed out that it differed from true kino in being more soluble and the solution more astringent in water than in spirit, just the reverse being the case with the product of Pierocarpus. As has been written on the subject in chemical and pharmaceutical journals and other publications. However, for example, has dealt with it at length in the Pharmaceutical Journal (June 23, 1900, 4th ser., x., 604 et seq.).

The gum is usually very impure owing to careless collection, and it would be a matter of some difficulty to clean it for medicinal purposes. In any case with true kino available in India, in sufficient quantity to meet all medical requirements, there is not likely to be any market for this substitute. The Lac insect (p. 1053) is reared upon the tree in India, and it is regarded as affording the second best quality. [Cf. Tachardia lacca, Agri. Ledg., 1901, No. 9, 181, 211, 221, 224, 230-1, 233, 238-9, 242, 250, etc., etc.] The gum may be used both as a Dye and Tan, but for these purposes is hardly, if at all, in demand outside India. The Natives are said to use it to purify and precipitate blue indigo. It seems possible that if the bark or wood were utilised as in preparing Catechu, a pure tanning extract might be obtained. The flowers, called tešț, kěšț, etc., yield a brilliant yellow dye by simple decoction, but the colour is fleeting, though rendered a little less so by the addition of an alkali. Formerly it was much used at the Hād festival, the fleeting character being regarded as an advantage, but at the present time it appears to have lost its popularity, being supplanted by aniline dyes. Hummel and Perkin (Journ. Soc. Chem. Indus., 1895, xiv., 459-60) point out that under certain treatment the colours given by Butea flowers resemble those afforded by young fustic. Hence these chemists add that they "cannot therefore endorse Sir Thomas Wardle's opinion that if Butea flowers could be obtained in sufficient quantity and sufficiently cheap they
BUXUS SEMPERVIRENS

Boxwood

would be a useful addition to the yellow dyes we already possess (see p. 1053). The bark yields a Fmre used for rough cordage and for caulkling boats. A bright, clear Oil derived in small quantity from the seeds (palis-papri) is used in Medicine. Dymock (Mat. Med. W. Ind., 1885, 232) says, "I have tried the seeds as an anthelmintic and am inclined to think favourably of them: they have an aperient action." Pound with lemon-juice they are a powerful rubefacient, and have been known to cure hyster. B. superba, Roxb., is considered to possess similar properties to those of B. proutosa. [Cf. also Rept. Cent. Ind. Drugs. Comm., i., 45, 65, 81, 121, 150, 292.] The leaves are given as Fodder to buffaloes. The Trunk is not durable above ground, but is said to be much better under water, and is consequently used in Upper India for well-erubs and piles and also for the water-scops of Native woods. Gamble observes that if cut up green and seasoned in the plank, it is likely to be a fair wood for rough boxes. Buchanan-Hamilton (Stat. Acc. Dinaj., 159) says that the flowers are offered to the gods. [Cf. Journ. As. Soc., 1813, iii., 219–20; Taleef Shereef (Playfair, transl.), 1833, 40; Taylor, Topog. Stat. Dacca, 1840, 62; Wardle, Rept. Dyes and Tans, Ind., 1887, 7, 20, 36–8, 51; Forsyth, Highlands Cent. Ind., 1889, 380, 421, 463; Kanny Lall Dey, Indig. Drugs Ind., 1896, 53–4; Gaz. Karnal Dist. P. 2nd ed.), 1890, 18–9; Russell, Monog. Dyeing Induct. C. Prov., 1896, 17; Hooper, Rept. Labor. Ind. Mus. (Econ. Soc.), 1900–1, 17; Joret, Les. Pl. dans L’Antiq., etc., 1804, ii., 347, etc.]

BUXUS SEMPERVIRENS, Linn.; Fl. Br. Ind., v., 267; Gamble, Man. Ind. Timbs., 592–4; Brandis, Ind. Trees, 1906, 559; Euphorbiaceae. The Boxwood Tree, shanda laghine, chikri, papri, shamshad, shumaj, shibosashin, etc., etc. An evergreen shrub or small tree of the Suliman and Salt Ranges, the Himalaya eastward to Nepal and Bhutan (absent from Sikkim), at 4,000 to 8,000 feet, chiefly in shady ravines, more especially on calcareous soils. It is a slow-growing tree, very difficult to raise from seed.

A tincture from the bark is used in Medicine as a febrifuge, and the leaves are occasionally browsed by goats, though to most animals they are poisonous. Boxwood is found on the Himalaya of large size, occasionally over 5 feet in girth, 3 feet being not unusual. The Timber is very valuable, being in great demand for turnery, carving and other purposes for which a very hard, close-grained wood is required. The principal European use, since the 16th century, has been for wood-engraving, and it is regarded as the best substitute for ivory in many ornamental purposes. But the Indian areas are almost always difficult of access, and it has been found that the timber cannot be cut, seasoned and delivered at an Indian port, still less in London, at the prices usually offered. Hitherto the principal supplies for Europe have come from the Caucasus, but this is spoken of as being rapidly exhausted. The trade has accordingly asked for suitable substitutes that may at least meet certain of the purposes of boxwood. The following have been mentioned as the more likely Indian timbers:—

C. Bondue, flox., is perhaps only a variety of C. Bonducella. The properties of the two plants are identical, but the seeds of the former are brown-coloured (not steel-grey) and, owing to only one being usually in the pods, are not angled. The name bonduc was probably given because of the bullet-like seeds.

A scantly thorny bush found in India and Burma, ascending the hills to altitudes of 2,600 feet and often very gregarious. Frequent as a hedge, planted or self-sown. It is very common near the seashore in most tropical countries, the seeds being carried by the sea without losing their vitality. A littoral species that often forms impenetrable thickets. [Of Prain, Bot. Laccadives, 38.]

In India the seeds (nuts) are held in high esteem as a medicine used in the treatment of intermittent fever, especially if associated with skin disease. A powder was made official in the Indian Pharmacopoeia of 1868. It is recommended to be administered along with black pepper in doses of from 5 to 60 minims. It contains a bitter principle that may be separated as a white amorphous substance, by the circumstance that it is soluble in alcohol, chloroform, glacial acetic acid, etc. From its chloroform solution it may be precipitated on being poured into petroleum other, or from the glacial acetic acid solution on being thrown into water. A writer in Comptes Rendus (July 1886) says the medicinal virtue of the cotyledons contained within the seed is due to their bitter extractive principle, the properties of which have not been accurately ascertained.

Clinical experiments conducted by Isnard at Marseilles, however, would seem to confirm the Indian reputation of merit as an antiperiodic. Applied externally the powder, made into an ointment with castor oil, is held to be beneficial in hydrocele, and the burnt seeds reduced to a powder are regarded as a valuable dentifrice, especially in spongy gums. The seeds are also said to afford an oil which is employed as a Cosmcrum. The leaves and the root-bark are regarded as possessing similar properties to the seed, though weaker. [Of Hughes, Nat. Hist. Barbados, 1750, 193, t. 18 (drawn by G. D. Ehret); Taylor, Topog. Stat. Dacca, 1840, 52; Irving, Topog. Ajmir, 1841, 192; Pharmacq. C. coriaria, Willd.; Warburg, Der Tropenpflanzler, 1901, v., 85-8. A small tree, native of South America and the West Indies. Introduced into India shortly after the appearance of Dr. W. Hamilton's report (1834) on the merits of the pods as a tanning material. It is now fairly extensively grown, if not almost acclimatised in the Western Presidency, especially in Dharwar, Kistna, Bijapur, Bhadgoon (in Khandesh), Belgaum, etc. Also in South India, especially in North Arcot and South Kanara. In Mysore and Coorg it has been tried, and with some success, as a shade-tree for coffee and thus an auxiliary crop. In the United Provinces and in Bengal the tree has hitherto been experimentally cultivated only, and with questionable success. Of Chota Nagpur, for example, one report speaks favourably; a later one explains the want of vigour as owing to the seedlings not having been transplanted; four years later the failure then recorded is attributed to the seedlings having been transplanted; and lastly the plantation is abandoned. This is not the history of all experiments, but imperfect knowledge or want of continuity of knowledge is probably more responsible for the results attained than any other explanation as yet adduced. It is probable, however, that insular conditions might be anticipated to afford better results than continental.

Hooper reviews all available information but unfortunately does not furnish the results of any special chemical investigations into the varying qualities of the cultivated pods now procurable from the provinces of India, nor into the variations consequent on the seasons of Indian-grown Pods.
CÆSALPINIA DIGYNA

Tari Pods

THE DIVI-DIVI PLANT

collection and methods of preservation, etc. "Divi-divi," he affirms, "is classified by dyers and tanners as a true astringent and is associated with oak-galls and myrobalans in affording a maximum amount of tannin with a minimum amount of colouring matter." Crooke (Practical Handbook Dyeing and Calico Printing) speaks of divi-divi (or libi-divi as it is sometimes called) as being one of the most important astringents in the market. "The best pods," he writes, "are thick and fleshy and of a pale colour. Those which are dark, with black spots and blotches, have probably been gathered in a damp state, or have been subsequently exposed to moisture, which greatly reduces their value. The amount of tannin in divi-divi is greater than in sumach or even myrobalans." These opinions had reference of course more especially to the use of divi-divi dyeing, and accordingly Crooke adds that a great objection to divi-divi lies in the fact that fragments adhere to the textile, which act as resists and produce a mottled condition of the dyed surface. But from the tanner’s point of view divi-divi is an uncertain material, more especially if the seeds be contained within the pods. It is greatly influenced by atmospheric conditions, is very subject to injurious fermentation, and imparts weight to leather through the absorption of a gummy substance which is less waterproof than the materials imparted to skins by other tans.

In India, according to Thorpe (Madras Mail, 1888), divi-divi cannot be successfully used without the aid of an anti-ferment.

Hummel (in connection with the Colonial and Indian Exhibition of 1885-6) was the first of the modern chemists to examine the Indian-grown pods. He reported that they were inferior to the American and West-Indian. Proctor (Leather Indust., 1898, 77) gives a classification of tanning materials and shows divi-divi along with Aralia myristica pods, myrobalans, etc., as a pyrogallol tan. Mr. A. G. Perkins of the Yorkshire College gives the tannin of these pods as ellagitannic acid. Dunstan found an inferiority similar to that reported by Hummel. He had sent to him samples from Chota Nagpur in Bengal, and after examining these expressed the opinion that the pod from other parts of India (Bombay and Madras, etc.) might be found richer in tannin than the Bengal sample. American pods, Dunstan adds, usually contain from 30 to 50 per cent. of tannin matter. The Bengal pods were found to contain only from 10-73 to 32-79 per cent. Warburg discusses the cultivation of divi-divi in German East Africa and furnishes particulars of the imports into Hamburg. [Cf. Stewart, Tanning and Currying Leather, in Select. Rec. Govt. N.-W. Prov., 1870, also revised in Watt’s Select. Rec. Govt. Ind., 1888, 100-11; Ind. Agr., March 1882; Cooke, Fl. Pres. Bomb., i., 413; Gamble, Man. Ind. Trees., 268; Tabot, List. Trees, etc. (2nd ed.), 141; Rec. Bot. Surv. Ind., ii. (Plant Chota Nagpur, 90.)

C. digyna, Rottl.; Fl. Br. Ind., ii., 256; Hooper, Agri. Ledg., 1899, No. 9; 1902, No. 1, 27; Dunstan, Imp. Inst. Tech. Repts., 1903, 192-7; Prain, Beng. Plants, i., 1903, 449. It is best known by the following names:—vakeri, vakeri-mal, kunni, amal-kuchi (or kochi), nini-gatch, gaukungchi, sunlétte (or sun-lét-the).

History.—By what appears to be an error, the pods of this prickly climbing shrub have been called tari, tert, or tourhi. The earliest mention of them would seem to be in an article by Mr. John Teil which quotes two letters from Mr. Secone of Chittagong, dated April 23 and July 7, 1847, addressed to the Secretary of the Agri.-Horticultural Society of India. In the last letter Mr. Secone gives them their Chittagong name terti (vi., 246-51 and app., 6-8). It seems probable the true terti is C. napus; in fact terti is almost a generic word for tanning material and is applied very frequently to myrobalans. The plant is met with in Central and Eastern Bengal, Assam, the Circars and Burma, and according to Brandis it occurs also in the Central Provinces (Sambalpur) and in the Western Peninsula. Recently it has been experimentally cultivated in many parts of India and
TANNING (TARI) PODS

even in some foreign countries, the demand for the pods having been very considerable.

Properties and Uses.—Roxburgh named the bush *C. oleosperma* in allusion to the Oil afforded by the seeds, which he tells us was in some parts of the country employed as a lamp oil. He makes no mention of the still more valuable property of the pods as a source of tannic acid. None of the standard works published prior to 1890 make definite references to the use of the pods in medicine or as a tanning material, though Buchanan-Hamilton (Stat. Acc. Dinaj., 1833, 170) states that they were in his day much employed by the dyers. It may thus be said that while these pods had been favourably reported on by Mr. John Teil of Calcutta in 1848, they were subsequently forgotten for fully half a century. In 1892 Mr. E. M. Homes, Curator of the Museum of the Pharmaceutical Society of Great Britain, sent to the Reporter on Economic Products some "tari" pods that he had received from India as a medicine. He suggested that an inquiry might be instituted into the source and available supply, and accordingly they were identified. Tari pods were in consequence included in the programme of operations of the Reporter for 1893. A circular letter was issued to the Directors of Agriculture in Madras, Bengal, Assam and Burma. In 1894 samples came from many districts in Burma. About the same time the Director of Assam (in connection with a monograph on dyes of that province, which he had under preparation) sent a sample of "teri" pods to be determined. He was at once informed that they were the pods of *C. digyna* regarding which a special inquiry had been addressed to his office. Holmes had the pods analysed in 1892 (by Messrs. Gonne, Croft & Co.), when they were found to contain 33 1/2 per cent. of tannin. Shortly after Evans published in "Leather" a report in which he mentions a yield of about 33 per cent. Wiesner (Die Rohst. des Pflanzenr., 1903, ii., 344–5), quoting from Hartwich (Die Neun Arzneidrogen, Pfl., 1897, 27) under Acacia digyna? mentions that the pods contain 33-25 per cent. of tan, and, like Holmes, Evans and others, he adds that if procurable in quantity they might come into extensive use. In 1898 a large supply was in consequence procured from Sylhet, from many districts in Burma, and also from Chittagong. But it is remarkable that so far none have been procured from the Circars, where Roxburgh first found the plant.

The Forest Department have taken the greatest possible interest in this new product (consult the late Mr. H. C. Hill's letter of July 20, 1901, to all Conservators of Forests). The Annual Reports from Burma and Bengal record from year to year the progress made. The Report for Tenasserim (1901–2, 27) says, "There is no demand and the stock of 60 bags was sold for Rs. 4 per bag, a price that just covered expenses." The Report for the Southern Circle in 1902–3 states that the plant had proved easy of cultivation, but adds, "As there appear to be no present demands for the pods, further plantations of this species are not wanted." It will thus be seen to rest with the trade to say whether or not the expectations of writers on this subject are to be realised.

A fair quantity of two sets of pods, secured through the Forest Department of Burma, and a corresponding parcel from the Assam stock, were consigned to the Imperial Institute, London and in due course reported on by the Director. The two parcels (of pod-cases without the seeds) from Burma were found to contain 53.82 and 53.86 per cent.
tanning material, while the Assam sample was still richer, viz. 59-89 per cent. The report (l.c. 192) continues: "With the view of obtaining a practical opinion as to the tanning value of this powder, a sample was furnished to a well-known tanning expert, who reports that he is much impressed with the results that he has so far obtained; they compare very favourably with those furnished by the best divi-divi, whilst the aqueous liquor from _C. digyna_ did not appear to undergo the injurious fermentation which is the difficulty in the use of divi-divi." A second consignment from Assam was sent to the Imperial Institute in 1900 and found to contain a slightly lower percentage of tannic acid, viz. 45-45 per cent., also a third parcel from Burma, which, however, contained more than the previous, viz. 60-5 per cent. These results accordingly place the pods among the richest of tanning materials, and they undoubtedly impart an excellent colour to the skins. They are, in fact, much richer in tannic acid than was supposed some few years ago. It may therefore be added that it would be unfortunate (as seems likely) if they should be destined to a second half-century of oblivion, such as followed their original discovery by Mr. Sconce in 1847. [Cf. Gamble, _Man. Ind. Timbs._, 266; Brandis, _Ind. Trees_, 247; _Rec. Bot. Surv. Ind._, ii. (Plants, Chota Nagpur), 99; Hanausek, _Berichte der Deut. Bot. Gesell._, 1902, 77 (Gvsh.), (gives a long account of the microscopical structure of the pods); _Board of Trade Journ._, 1903, i., 146; Chandra, _Tanning, and Working in Leather_, Beng., 1904, 7; Chatterton, _Tanning, and Working in Leather_, Mad. _Pres._, 1904, 47.]

_C. Sappan_, _Linn._; _Tsa-Pangam_, Rheede, _Hort. Mai._, 1686, vi., t. 2; _Lignum Sappan_, Rumphius, _Herb. Amb._, 1750, iv., 56-8, t. 21; Roxb., _Corom. Pl._, i., 17; Beddome, _For. Man._, 90, pl. xiii., f. 1.; Greshoff, _Nutt. Ind._, 1894, 121-4, t. 29; _Fl. Br. Ind._, ii., 255. The Sappan- or Bakam-wood or Sampfen-wood, sometimes also called Brazilian-wood (the name Brazilian being derived from _braise_ (red coals) and thus originally unconnected with the country of that name; in fact, given long prior to the discovery of Brazil). The better known vernaculars of India are—_bakam_ (bokom), _tairi_, _teri_, _patang_, _pattânga_, _sappanga_, _chapangam_, _tein-nyet_, etc.

**History.**—This plant is frequently mentioned in letters from East India Co.'s servants at the beginning of the 17th century, showing that it was a well-known article of trade even then. One of the earliest detailed descriptions of it, however, is that given by Rheede, where it is called _tsia-pangam_. That account was followed by the _Herbarium Amboinense_, in which a long list of both the European and Native names for it are given, but of these the Bengali _russok_ need only be here specially mentioned—a name that does not appear to be in use at the present time since in Bengal it is generally known as _bokom_. It is also interesting to add in this connection that Rumphius suggests the derivation of Sappan from the demand of the Arabs for the wood to be employed in the construction of certain ornamental boats or portions of boats. Hence, adds Rumphius, comes the Malayan _sampil_, a decorated boat. He further tells us that the pegs (or wooden nails) employed in ship-building are chiefly made of this wood. But the Sappan is a small thorny tree of the Eastern and Western Peninsulas of India, also of Pegu, Tenasserim and the Shan plateau of Burma—cultivated where met with elsewhere in India and Burma. Hence with its Malay name _shappannam_ and its Tamil _shappu_, it is more likely, as suggested by Yule and Burnell (_Hobson-Jobson_ ed. Crooke), 794, that the wood sappan was derived direct from India itself and is not Malayan. Gamble (_Man. Ind. Timbs._, 1902, 267) says he has never seen it wild. Rheede observes that it prefers sandy places, is indigenous to Travancore and cultivated as an ornamental and useful tree all over Malabar.
BRAZILIAN (BAKAM) WOOD

Properties and Uses.—The wood yields a valuable red dye, which, before the days of aniline, was exported very largely from India to Europe. Recently the traffic has declined very materially. But the dye may also be obtained from the pods (taut) and from the bark, hence the necessity of not confusing the pods of this species with those of *C. digyna*, which are nowadays also called *teri* or *tari*. The accounts given by both Rheede and Rumphius of the methods pursued by the dyers of India or of the East might be given as a modern statement, so very accurate are these writers in most particulars. The use of *lodh* (leha) bark (*Symplocos racemosa*, p. 1053) as a dye auxiliary, and of chalk to deepen the colour and of alum to fix it, as also the circumstance that the colour is bleached or destroyed by acetic acid—these and such other circumstances are fully detailed. Rumphius tells us that in preparing the decoction the Natives throw a few grains of paddy into the boiling liquid. If the husk scales off, the boiling is regarded as sufficient, not otherwise.

Sir Thomas Wardle speaks very favourably of sappan in wool-dyeing and in calico-printing. Of the pods, he observes that they are astringent and much used in dyeing and tanning since they produce with salts of iron a rich black. It may be doubtful whether the pods alluded to are, however, those of this plant; they may be those of *C. digyna*. Sule, speaking of Berár, describes the manufacture of a special dye called *abashai* from the wood. Giles similarly says that in the Karenni country a plant known as the *sawku* (possibly *sappan*) affords from the powdered root a brick-red dye that on being boiled with cotton becomes permanent and requires no mordant to fix it.

By the Sanskrit authors *sappan* is often treated as a form or quality of sandal-wood. It is not generally recommended as a medicine either by the Hindus or by the Muhammadans of India, but has for years been employed by Europeans in India as a useful substitute for logwood. [Cf. Rept. Cent. Indig. Drugs Comm., i., 156.] Ainslie speaks of the emmenagogue properties of a decoction of the root.

According to the *Pharmacographia* there are two qualities of the wood met with in Indian shops, viz. the Singapore and the Dhunsari, with a third and less valuable obtained from Ceylon. It sells at from Rs. 30 to Rs. 42 per *kandy* of 7 cwt., according to quality. Fawcett (*Monog. Dyes Bomb.*, 15) calls it by the old name—"Brazilian-wood," and speaks of it as imported from Siam and Malabar. It sells at Rs. 2 per 12 seers (24 lb.) and is largely used in preparing *gulal*. Formerly it was extensively employed in Ahmedabad in cotton-dyeing but has been superseded by aniline, which is sold under the appropriated name of *patanga*. In this connection it may also be remarked that in Lahore I found a yellow aniline sold in packets under the name *piorina*; illustrations of the direct adaptation of the aniline wares to the markets of India, the former being intended to supplant the classic *patang* and the latter the *piori*. [For chemistry cf. Pharmacog. Ind., i., 500; Journ. Chem. Indust., 1898, xvii., 691; Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 252, etc.]

CAJANUS INDICUS

Arhar

H. G. Leveson, 6; B. B. Sule, 5; Notes on Dyes by Conserv. For. E. Circ. Burma, 1896; Liotard, Memo. Dyes, 24–6; Talbot, List Trees, etc., 141; Ree Bot. Surv. Ind., ii. (Plants, Chota Nagpur), 99.]

CAJANUS INDICUS, Spreng. ; Fl. Br. Ind., ii., 217; LEGUMINOSE. The Pigeon-pea, Embrevade, Pois d’Angole, Cytis des Indes, etc., dal, cadjan, tuvar (tuver), tur, thor, arhar (or aror, oror), rahar dal, lahar, oroha, gela-máh, togari, kanalu, pheh-yen-khyung, etc., etc.

History.—The pigeon-pea would seem to have been introduced into the West Indies (Grisebach, Fl. Br. West Ind., 191) and to America from Africa, and apparently through the slave trade. It has been long cultivated in India, but nevertheless no Indian botanist has recorded having found it wild, or even naturalised, so that there would seem little doubt that in India it is an introduced plant. It is not mentioned in any of the early Sanskrit works. In Rheede’s time (1686) it was regularly cultivated in Malabar, and bore practically the same vernacular names as at the present day. On the other hand, several travellers mention having found it wild in Africa. Schweinfurth, according to Jumelle (Les Cult. Colon., 191, 128), for example, discovered it wild in the region of the Upper Nile. Welwitsch (Cat. Af. Pl., i., pt. i., 260) speaks of it as cultivated and wild in the coast districts of Angola—its vernacular name being jinsonge or quinsonge. Loureiro makes mention of it as both cultivated and wild in China and Cochín-China, but as opposed to that view Bretschneider does not allude to it as having been known to the ancient Chinese scholars. Seemann speaks of it as introduced into Fiji by the missionaries. In Madagascar it is an important and apparently very anciently cultivated plant.

Varieties and Races.—There are two forms of this well-known pea, which by some authors have been viewed as species. They are apparently of independent economic value and hence may be here separately indicated:—

C. bicolor, dc.; Sloane, Hist. Jam., 1725, i., 31; Burmann, Thees. Zeyl, 1736, 86, t. 37; Hughes, Hist. Barbados, 1750, 199, t. 19; Cytisus pseudocaján, Jaoq., Hort. Bot. Vind., 1770, i., 54, t. 119; C. Caján, Tussac, Fl. des Antil., 1827, 4, 94, t. 32; Cytisus Caján, Descourt, Fl. Pittor. et Med. des Antil., 1827, iv., 221, pl. 280; Bot. Reg., 1845, xxxi., t. 31; Duthie and Fuller, Field and Garden Crops, 1882, ii., 20, t. 34. This might be described as a large bush, 6 to 8 feet in height, according to Roxburgh, with a circumference of 20 feet around the extremities of its branches—in other words, twice the size of the next form. The flowers are yellow streaked with purple, and there are four to five seeds in the pods, which are also marked with dark streaks. Roxburgh (the author from whom most recent writers have compiled) tells us that it is commonly sown with the first rains in June, ripens its main crop in about nine months, and yields 600-fold. It is in reality a perennial, but from its yielding a poor second crop, is in India usually treated as an annual. In the West Indies this is called Congo or Angola pea, and in India it is best known by the name arhar.

C. flavus, dc.; Rhode, Hort. Mal., 1866, vi., 23, t. 13; Plukenet, Ailm., 1696, ii., 293, Phyta, 213, f. 3; Rumphius, Herb. Amb., 1750, v., 377, t. 135, f. 2; Duthie and Fuller, Lc. 20, t. 33. This is a much smaller plant than the preceding. It has been described as having perfectly yellow flowers, and usually only two or three seeds in the pods, which are never spotted. It is known in the West Indies as the no-eye pea and in India as thrur or tuver. According to Roxburgh it is sown in September, occupies the soil as a rule for only three months, and yields 100-fold.

Crops.

Rabi and Kharif.—The recognition of these plants as distinct crops can hardly be viewed as having received in India the attention that the subject deserves. They practically correspond respectively to the rabi and kharif phases of most Indian cultivated plants. In the Botanical Magazine (1879, xxxiv., 3rd. ser., No. 6440) is given a beautiful illustration, and description by Sir J. D. Hooker of a form of cajanmus which was grown at the Royal Gardens, Kew, from seed supplied from Calcutta by Sir George King. This proved to be botanically an intermediate form that broke down the specific distinctions of C. flámus and C. bicolor. Subsequent writers accordingly accepted these as but varieties of one species. In the plant grown at Kew the flowers were pure yellow, and the

Cultivation.

Hot-season Peas.—Throughout the world pigeon-pea cultivation has been commended as desirable for all tropical countries, on account of the green peas it affords being an excellent substitute for the common garden pea, and it comes into season during the hot months when the ordinary pea is not available. With this object in view its cultivation has been extended into most temperate and moist tropical regions. An excellent
account of the plant, for example, will be found in *The Agricultural Gazette of New South Wales* (1892, iii., 6). In India it is most frequently grown as a mixed crop, especially *var. bicolor*, and more particularly as a rotation crop for cereals. The sowings are ordinarily in drills or lines that divide the field and often are so arranged as to protect the intervening crop from climatic inclemencies. A common system is every fourth row to be tur. The yield cannot, therefore, be stated without information as to the extent to which this crop occupies the soil. So again it frequently remains on the ground for a much longer period than its associated crop or crops. If grown alone on good soil the yield may be 2,000 lb. per acre, but as a mixed crop it averages about 500 to 700 lb. or even much less; some of the test experiments in the Central Provinces, for example, show a yield of only 400 lb. It is a hardy plant and thrives in seasons of drought when other crops fail. It is one of the best leguminous restorative plants known to the Indian agriculturist. [Cf. *Agr. Ledg.*, 1894, No. 7, 198.]

**Diseases and Pests.**—E. J. Butler (Agri. Journ. Ind., i., pt. i., 25–30) has rendered admirable service by his investigations into *The Wilt Disease of the Pigeon Pea and Pepper*. "The former plant," he says, "has been found to suffer habitually from a condition like that of flax (linseed) which is known as "flax sickness" in Europe and America, and which has thrown great difficulties in the way of successful flax cultivation in several countries. The flax disease is due to a parasitic fungus developed in the soil, and an allied fungus is responsible for *arhar* sickness in India." In consequence consecutive cultivation of flax or pigeon-pea on the same soil is followed by disastrous increase of the disease. At present it is "found over an immense extent of country; Bombay, the Central Provinces, the United Provinces and Bihar being the areas most affected." It has been reported from the Panjáb; in fact, "with the exception of Madras," where Butler says he has "neither seen nor heard of it," one may assume that wherever the crop is extensively grown, the disease is to be found. The reader desirous of full particulars should consult Butler's paper. It will there be found that the fungus in question is described to penetrate the tissue of the plant and to accumulate within the vessels that carry the food supplies, thereby causing the pigeon-pea to turn black and decay gradually until it is completely wilted. "It is thus clear that no direct treatment can be successful against a disease of this type. The parasite early enters the internal tissues of the plant, and is then out of reach of any curative application." Our author consequently explains that there remain but two possible methods of diminishing the ravages of this disease. The first is the introduction of longer systems of rotation than are usually followed with *arhar* cultivation, so as to give time for the soil to be freed from infection. The second, the discovery or production of wilt resistant forms of the plant. In 1894, while touring through the Central Provinces and Berá, I discovered a disease very prevalent on the tur, and ascertained that it was caused by a parasitic fungus on the roots (*Agri. Ledg.*, 1895, No. 20, 322); and very likely, therefore, it was the disease here dealt with.

Turning now to the pests, it may be observed that a caterpillar, *ilé*, often destroys the first crop of pods; but frost is by far the most serious danger. On *usar* (réh) soils it will not thrive. [Cf. *Agri. Ledg.*, 1897, No. 13, 281; 1901, No. 13, 424; Maxwell-Lefroy, *Mem. Dept. Agri. Ind.*, 1907, i., 142, 149, etc.]
THIRD IMPORTANT PULSE

Area and Production.—It is impossible to form any trustworthy conclusions regarding the total supply of this *dai* in India, or of the area under the crop. Mollison speaks of 700,000 acres in the Bombay Presidency. Duthie and Fuller estimate for 3½ million acres in the United Provinces as partly or entirely under it. In recent Bombay official papers mention is made of 566,465 acres *kharif* and 14,024 acres *rabi* having been in 1902–3 under this crop. It is not known if these figures were worked out as pure or as mixed crops. In the *Season and Crop Report* (1905–6), the area in the Presidency proper is said to have been 443,365 acres. In connection with the United Provinces we read of 2,039,692 acres, doubtless mixed crops, and for the Central Provinces 262,493 acres, both returns being for 1902–3. In connection with Berar it has been stated that for the year named there were 266,709 acres under this pulse, all grown as *kharif* crops. Regarding the other provinces of India no recent estimates are available, so that a full statement of the area for all India cannot be furnished for any one year. It is placed in official statistics under the heading of “Other Food-grains including Pulses,” of which the total for all India has, during recent years, ranged from 27 to 29 million acres.

Similarly particulars cannot be afforded regarding the trade in the pigeon-pea since it is placed under “Other sorts of Grains and Pulse.” Mollison says that the dry pulse sells at from 35 to 40 lb. per rupee, and in exceptionally cheap years 50 lb. or more to the rupee may be obtained. The official publication *Prices and Wages* (1906, 72–3) gives an elaborate statement of the annual returns (seers per rupee) of this pulse in all provinces of India back to 1861. A further table (l.c. 122–3) reduces these to quinquennial averages, and the following are the prices given for the five years 1901–5:—Eastern Bengal and Assam, 10:8 seers per rupee; Bengal, 11:75; Agra, 12:59; Oudh, 13:01; Rajputana, 14:18; Central India, 10:32; Panjab and N.W. Frontier Province, 10:49; Sind and Baluchistan, 9; Bombay, 9:56; Berar, 10:15; Central Provinces, 10:65; Nizam’s Territories, 15:97; Mysore, 7:02; Upper Burma, 8:19; Lower Burma, 8:37 (the seer equals approximately 2 lb.).

Economic Value.—In India the pulse is highly esteemed by the Natives, who regard it as the third in rank of importance among the leguminous seeds. *Taleef Shereef* (Playfair, transl., 1833, 10) describes it at length, adding that a decoction of the leaves makes an antiseptic wash. It enters very largely into the vegetarian diet of the Hindus and is sold either in the form of split peas or as pea-meal, of which sweet cakes are often made. Many of the early European authors, writing of the East Indies, speak of this pea as in demand by seafaring people. Rheede, for example, says it is specially valued as a food for ships’ companies. Burmann observes that pigeons live on it, and men chiefly when on board ship. Decourtiz (l.c. 222) remarks that from the peas may be prepared a sort of sago much sought after by British and American sailors—an observation that recalls the parody on “The Mariners of England” who lived on “yellow peas,” (see Cieer, p. 295).

Sometimes the tender green pods with their contained peas are in India cooked in curry like French-beans. They constitute in fact an excellent vegetable much neglected by the Europeans resident in India. Of the ripe peas there are, as already indicated, at least two seasons of their coming into market, viz. November to December for the early crop, and February to April for the late. The chief crop is the
THE PIGEON-PEA

Dal

The plants are cut off close to the ground by a sharp knife and conveyed to the homestead, where they are stacked on the threshing-floor. The leaves and pods are then stripped or shaken off and the grain threshed out. The leaves form a valuable FODDER, and occasionally a pruning of the young shoots is taken and given to cattle. The outer integument of the seed with part of the adhering kernel is a favourite food for milch-cows—it is known as chuni (Agri. Ledg., 1895, No. 6, 75). The pea or meal is largely employed as a cattle-medicine. [Cf. Cattle Diseases, Agri. Ledg., 1896, No. 28, 275, 283, etc.]

Church (Food-Grains of Ind.) gives the composition of the husked pea as:—water 10·5; albuminoids 22·3; starch 60·9; fat 2·1; fibre 1·2; and ash 3·0. The nutrient ratio is 1·3 and the nutrient value 80. “It is wholesome and nutritious when properly freed from the husk, its irritant and laxative character being thus greatly reduced. It is not unusual to find that the higher-priced and finer qualities of this pea have been slightly oiled before sale, to improve their appearance. This practice is not unknown in reference to wheat in the South of Europe.” Leather (Agri. Ledg., 1901, No. 10, 356) has published his analyses of some four samples of this pea: one, a white, and two, red peas from Poona, and a fourth from Cawnpore. His results for the white pea may be here given to allow of comparison with the above:—moisture 6·77; oil 6·93; albuminoids 13·25; soluble carbohydrates 51·38; fibre 18·10; soluble minerals 0·44; sand 3·13; total nitrogen 2·45; albuminoid nitrogen 2·12. Leather thus found higher proportions of fibre and minerals than given by most other chemists. [Cf. Greenhoff, Chem. Zeit., 1901, No. 421, 283.]

The stalks are used as fuel, the larger ones being prized for the charcoal sold to the makers of gunpowder. The thin straight branches are employed for roofing and basket-work, as also for the wattling of carts and the tubular wicker-work linings of wells.

In Northern Bengal and Assam the arhar is specially grown as a food-plant for the lac-insect. One of the earliest accounts of this special industry (lacerearing) was written by Buchanan-Hamilton in his Statistical Account of Rangpur (1809). He there gives the plant the name of mendu-kolai and says the seed is sown in the spring, generally in the form of a hedge around gardens. In the beginning of the cold season the insects are applied by tying to each bush a small branch containing those about to produce larvae. A year afterwards the twigs of the bushes are then found to be covered with the lac incrustations (Agri. Ledg., 1901, No. 9, 218). There would seem to be much less lac reared on arhar in Bengal nowadays than in former years. In Assam the opinion is held by the Garos and Miris that while the lac-insect may be reared on many plants, the arhar forms its most convenient and suitable food. If sown and well watered in November, the young plants are fit to be transplanted at the close of the following rains—end of October—and each should average 4 feet in height. They should be planted 4 feet by 8 feet apart (about 1,360 to the acre), and will be ready to receive the insects two years after date of sowing. They should be charged with stock-lac in November: about 40 lb. will be necessary to the acre. One year later, the crop should be obtained, each bush yielding about 8 lb. or 6 lb. of cleaned lac, which at present rate would fetch about £144 per acre, less expenses. If well cared for and properly pruned, to prevent flowering, seed for next year’s crop being left on the bushes, the same plants may continue to yield for several years. [Cf. Agri. Ledg., t.c. 282, 271.]

Jumelle (Les Cult. Colon. (Aliment.), 1901, 128–31) gives a most interesting account of the cultivation of this plant in Madagascar for the purpose of feeding a special silkworm (landibé) of that country. This industry exists mainly in the south of the island at Betiseleo. It would appear to be a silk that resembles tasar or eri. The landibé is said to be the Borocerus cajanti of entomologists. It lives in the open air, and forms its cocoons among tufts of grass placed within the bushes for that purpose. It lays its eggs in March, is in chrysalis for one month, and takes eight days to spin its cocoon. It requires a warm, sheltered situation. Tussac (Fl. des Antil., 1827, iv., 94–6) also alludes to the fact that a silkworm is reared on the leaves of the Angola-pea. Arhar silk would thus seem well worthy the attention of the Indian cultivators as a possible additional source of revenue.

200
CANES AND RATTANS

History.—Rattan, it may be explained, is synonymous with Cane, is in fact identical, being the Malay word rotan—a cane. In modern usage the word "reed" denotes as a rule a hollow grass-stem (the bamboo is an arborescent reed), and the word "cane" implies a solid palm-stem. The separation into canes and reeds, whether etymologically correct or not, is a convenient industrial distinction. In fact the only desirable exception might be made in the case of the solid bamboos (male bamboos, as they are often called). These are used as walking-sticks, lance-shafts, and even more directly for some of the purposes for which the true canes are specially employed. But certain species of one or two other genera of palms such as Dacomis and Plectocomia are used indiscriminately with those of Calamus as true canes.

Species and varieties.—Before proceeding to discuss the Indian trade in "Canes and Rattans" or to furnish particulars regarding the associated industry of Basket or Wicker-work, it may be desirable to enumerate the more important species and to exhibit, while doing so, their habitats, their better-known vernacular names, and their special or individual properties and uses:

C. acanthophalus, Grif., the gouris-bet, pukha-bet, rue, ru, etc. An extensive climber found in Eastern Nepal, Sikkim, Bhutan and the Khasia hills at altitudes of 2,000 to 6,000 feet. Gamble says, "the best of the rattan canes of Sikkim. The canes are rather thick, and where obtainable are used for cane-bridges, chair-making, and walking-sticks, but are now getting scarce."

C. gracilis, Roxb., Fl. Ind., iii., 781. The mapuribet, kraipang, hundibet. Upper Assam, the Khasia hills, Cachar and Chittagong—a species with very slender canes.

C. Gurba, Ham., in Mart., Hist. Nat. Palm, iii., 206, t. 175, f. 1; (Dacomis Gurba, Mart., i.e. 330, var. Mastersianus and var. Hamiltonianus). The kyi'ini (or kyeing-ni), sunibet, quabi-bet. A scendent plant met with in the forests of Bengal, Assam, the Khasia hills, Chittagong and Burma. The slender canes are used in basket-work.

C. latifolius, Roxb., Fl. Ind., iii., 775; Beccari (i.e. 211) regards macroycanthus as a subspecies. The dangribet, brul, korak-bet, saim, yama, yamata ky/^er (or yam-ma-sta); and var. macroycanthus—rupee, rabi, groor, phekori-bet. A stout climber found in the Sikkim Himalaya, the Terai and East Bengal to Assam, Chittagong and Burma. These canes are very strong and much in demand for walking-sticks and all forms of basket-work; the brul has the reputation of being best suited for walking-sticks. This is by far the strongest cane that finds its way into Indian trade at all plentifully. By most persons, in fact, it would very possibly be regarded as the true rattan of the commerce of the Eastern side of India and of the greater part of Burma.

C. leptopadix, Grif. The lat, chemchun—a scendent slender species of the damp valleys of the Eastern Himalaya and Terai swamps, the Khasia and Naga hills and Manipur. Canes thin and apparently not of much value, though used locally.

C. Rotang, Linn.; Roxb., Fl. Ind., iii., 777; Fl. Br. Ind., vi., 447; Mart., Hist. Nat. Palm, iii., 334, t. 116, f. 8; Blume, Rumphia, 1847, iii., 33; C. Roxburghii, Grif., in Calc. Journ. Nat. Hist., v., 43; C. monicus, Roxb., i.e. 785; C. scopionum, partly Lamk., Encycl., vi., 304; Dodge, Useful Fibre Plants of the World, 102. A very numerous assortment of vernaculars might be given for this plant such as:—bet, bent, pepa, pram, prabba, veia, natar, perambu, rotan, etc. An extensive climber found in the Central Provinces, the Deccan, Karnatak, Konkan and Ceylon. According to Roxburgh it is a native of Bengal and the
CALAMUS
Basket-work

Coromandel Coast, delights in a rich moist soil, where there are bushes and trees for it to climb on. It seems probable that Roxburgh may not have sufficiently separated this from the two following species as cane-yielding plants. C. Rotanum proper is not met with in Bengal. The slender stems are the common rattans of Central and Southern India; they are used for basket- and wicker-work, chairs, mats, blinds, etc., but are not strong though easily worked. [Cf Taylor, Topog. Stat. Dacca, 1840, 52; Brandis, Ind. For., 1887, xiii., 55; Thisolson-Dyer, Ind. For., l.c. 185.]

C. tenus, Roxb., Fl. Ind., iii., 780; Griff., Palms Brit. Ind., 1850, 57, t. 193, A, B, c.; Prain, Rec. Bot. Surv. Ind., ii., 347. This is the bet, bent, chachi-(samchi) bet, bandhari bet, kring, jolli bet, jali, etc. A very long scendent plant met within the Sub-Himalayan tracts from Dehra Dun eastwards to Assam, Sylhet, Chittagong and Pegu. This is the common cane of Northern India and Bengal. It is largely used for basket-work, mats, screens, chairs, etc., etc. The fruit is eaten in times of scarcity. [Cf. Innes, Jungle Prod., etc., 1898, 13.]

C. viminalis, Willd.: Palmajuncus viminalis, Rumph.—a Javan plant; var. fasciculatus, Becc. (C. fasciculatus, Roxb., Fl. Ind., iii., 779). The bara-bet, pepa bet, amla vetasamu, kyeinga, etc., and according to Roxburgh it is the umba-vetus of Sanskrit. It is a stout scrambling and climbing species of Lower Bengal, Orissa, the Kurnâtak, Chittagong, Burma, the Andaman Islands, Penang and Cochín-China. Cane thin but strong, makes excellent walking-sticks and is the chief rattan of the Eastern Peninsula.

Demonorops Jenkiniansus, Mart., Hist. Nat. Palm., ii., 327; Prain, Rec. Bot. Surv. Ind., ii., 347. This is the gola-bet, gallah, etc. A stout scendent rattan found in Eastern Bengal, Darjeeling Terai, Assam, the Khasia hills, the Sundrihans and Chittagong. The canes are long but are said to be rather soft, though extensively used for basket-work.

Canes and Rattans: Basket- and Wicker-work.—Few plants are more useful to the inhabitants of moist tropical regions than the canes and rattans. The long scendent stems constitute the canes of commerce.

The stems when freshly cut contain a large quantity of liquid, which may be collected by blowing through short lengths, and from this, by evaporation, a red resin may be obtained. One of the best-known qualities of that resin is sometimes called "East Indian Dragon's-blood." This is, however, for the most part prepared from the fruits of several species of Calamus, met with in Eastern Sumatra, South Borneo and Penang. The gum exudes naturally from between the scales of the fruit, but inferior qualities are obtained by boiling the fruits or by tapping the stems. The only Indian species hitherto reported as affording this resin is D. Kurzianus—a species already briefly indicated. The false Dragon's-blood, met with in Indian commerce, is imported into Bombay from Sumatra, Penang, etc., in large cakes or is found compressed into bamboo tubes. The true Dragon's-blood is, however, procured from Socotra and is derived by tapping the stems of several species of Dracaena not Calamus. [Cf. Yearbook of Pharmacy, 1884, 234–6; 1897, 180; Pharm. Journ., 1893, xxiv., 47, 108; Pharmacog. Ind., iii., 532–5; Kew Bull., 1906, 197–9.]

Edible Fruits.
value to the great strength more particularly of the outer woody layer of their long flexible stems. As substitutes for ropes these are invaluable, and in the countries where they abound, canes 300 to 400 feet in length are frequently employed as the bearing-ropes of suspension-bridges. They are also used in towing heavy objects, stones, logs of timber, etc., and formerly were much valued in the East as cables for ships. The smaller canes are extensively employed throughout the world in basket-work both entire and stripped. Chairs, sofas, couches, baskets, etc., are constructed of entire canes wound round and round and fastened to each other by thin strips of the cane-bark. When the interstices are filled up, they become water-tight baskets and granaries. A strong and durable floor-mat is similarly made of these canes placed close together and held in position by binders of cane-bark. Canes are also very largely used as walking-sticks, umbrella-handles, and to give strength in saddlery and harness. Loureiro (Fl. Cochinch., 1790, 210) under C. Scipionum says, "Pro baculis ex dignitare, vel elegantiâ manu gestandis"—a description fully applicable to the Malacca and Whangee canes of to-day. But of course the chief European use for canes is in furniture and basket-making. Machinery is now utilised in stripping the barks into cane-ribbons, thus leaving the core in the form of a perfectly round and even rod. These rods are employed in the construction of fancy baskets, chairs, window-blinds, where great strength is not essential, and they have the advantage over the silicious stronger bark-ribbons in that they take colour readily. The waste fibre obtained during stripping and trimming the ribbons and cane-rods is used in upholstery along with, or as a substitute for coir. Wiesner (Denkschr. Akad. Wiss. Wien. Math.-Nat., 1902, lxxii., 15–6) refers repeatedly to the Chinese employment of rattans in the manufacture of paper. Tschirsch (Indische Heil-und Nutzpflanzen, 1892, 169) very pictur-esquely describes the varied uses of the cane from caned boyhood to cane-seated dotage. His illustrations are forcible, but add little or nothing new. [Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 255–61.]

**Trade in Canes.** — The Forest Departments of the various provinces of India, including Burma, publish annual reports from which it might be gathered that the yearly crop of canes amounts to about 10,000,000 maunds and the annual revenue therefrom from Rs. 50,000 to 60,000. The Reports of the Conservators of Forests in India for the year 1904–5, for example, show a total revenue from canes amounting to Rs. 37,775. The imports of canes and rattans into India from foreign countries may be said to average from 30,000 to 40,000 cwt., valued at from 2 to 3½ lakhs of rupees (38,436 cwt., valued at Rs. 3,85,674 in 1906–7). These come mainly from the Straits Settlements and Siam. The exports to foreign countries of Indian canes come to from 1,000 to 3,000 cwt., valued at from Rs. 20,000 to Rs. 50,000 (2,427 cwt., valued at Rs. 38,100, in 1906–7), but in addition there is also a re-export trade (foreign canes exported) formerly of about the same quantity and value as that just mentioned, but showing a considerable diminution in recent years (673 cwt., Rs. 11,291, in 1906–7). It is thus significant that India, with its vast supplies of canes and rattans, should not be independent of foreign tropical countries, and the explanation may possibly lie in the cheaper sea as compared with land transit. Large towns like Bombay, Calcutta and Madras find it more economical to obtain their supplies from the Straits than from the inland forests of India. (See Baskets, p. 115; also Mats and Matting, p. 775).
CALOPHYLLUM
INOPHYLLUM
Mast-wood

D.E.P.,
i., 29-33.
Mast-wood.

Mast-wood, the sultana-champa, surpan, surangi, pinay, punang, puna, undi, ponnyet, etc.—punngaa (Sansk). An evergreen tree, which in some localities, especially when near the sea, attains a considerable size. It is indigenous throughout the Western Peninsula, Orissa, Ceylon, Burma and the Andaman Islands, and is distributed to the Malay, Polynesia, Australia and the islands of Eastern Africa.

Species and Varieties.—Besides the above there are four other species of Calophyllum worthy of special mention in this place. These are:—(1) C. polyanthum, Wall., the kande, kironli, kraidone—an evergreen tree of Northern and Eastern Bengal, the Khasia hills, Chittagong and Martaban. (2) C. spectabile, Wild., the pantaAg, lalchum, dekar-talada—a tall evergreen tree of Tenasserim, the Andaman Islands and Ceylon. (3) C. tomentosum, Wright,—the Poon Spar, nagari, surhoni, etc.; a large evergreen tree often 150 feet in height, self-propagated in the western coast forests from N. Kanara to Travancore. (4) C. Wightianum, Wall.; the bobbi, irai, cheru pinay, an evergreen tree found along the Western Ghats from the Konkan to Travancore.

Properties.—There appears to be little doubt that the true Gum Tzacmahacs, formerly attributed by some writers to C. inopphyllum, is neither obtained from that nor from any other Indian tree. But when wounded the stems and also the fruits of the mast-wood exude a small quantity of bright-green pleasantly scented Resin (soluble in alcohol) which is not collected nor made any use of at the present day. Rheede observes, however, that it is emetic and purgative, so that it would appear to have been formerly of medicinal value. From the seeds is expressed a greenish-coloured Oil, known as Pinay or Dombar Oil. According to some the yield is as great as 60 per cent. by weight, and the oil is said to coagulate when cooled below 50°. The seeds are collected twice a year, in August and again in February. The oil possesses a disagreeable odour and flavour, but is fairly extensively used for burning, and is valued, especially in Polynesia, as an external application in rheumatic affections. Mixed with chaulmogra oil (p. 1068) is also employed for exanthematous eruptions. In Pondicherry the oil is believed to be very useful in the treatment of scabies, a property specially mentioned by Rheede in 1686, and again by Rumphius in 1750. The chief centres of production are Bombay, Goa, Travancore, Tinnevelly, Tanjore, Puri, etc. It is said to fetch a little more than half the price of coconut oil and is fairly extensively exported from India to Burma. The oils of C. tomentosum and C. Wightianum are similarly expressed from the seeds, but do not differ in properties and uses from that of C. inopphyllum. Rumphius affirms that in his day the bark was boiled down along with that of a plant which he named Sideroxylon, and the decoction given as a purgative; he also states that warriors carried a little bottle of the oil by their sides and smeared it on their spears and bolts, believing that they were thereby more likely to pierce the objects against which they were thrust.

The Timber is moderately hard and close-grained, and by Sebert (Les Bois de la Nouvelle Calédonie) is believed to be magnificent for cabinet-work. All the species, and in particular the Poon Spar C. tomentosum, are highly serviceable for masts, spars, railway-sleepers, machinery, etc., but for these purposes they are much less in demand than formerly. Linschoten (Voy. E. Ind. (ed. Hakl. Soc.), i., 67) alludes to the “long masts for ships” sold at Cananor, and Hamilton (New Acc. E. Ind., 1744, i., 267) says the Poon-masts are heavier and stronger than fir. They are sometimes employed, especially C. polyanthum, in boat-building. [Cf. Elliot, Fl. Andhr., 1838, 153, 160; Mooden Sheriff, Mat.

Timber.

Masts, Spars, etc.
MADAR GUTTA-PERCHA

Habitat.—The two species indicated above are so nearly the same from the practical standpoint that they may here be treated conjointly. The former is an erect spreading perennial bush which chiefly frequents waste lands in the warm moist tracts of most tropical countries, in India being especially abundant in Bengal, Assam, South India, and distributed to Ceylon, Singapore, the Malay and China. The latter is a slightly smaller plant, met with chiefly in the drier regions, and so far as India is concerned is most abundant in the Sub-Himalaya (from the Indus to the Ganges), also in Central India, Rajputana, the Deccan and Upper Burma, and is distributed to Persia and Tropical Africa. Both species are known by the following names:—madár (sometimes written by Europeans as mudar or even muder), ðk, ðkanda, ðrku, rui (a name specially suggested by the silk-cotton), yerku, erukkm, jilledu, yekka, erukku, etc. But the former species is sometimes called the purple and the latter the white ðkanda—the ðrka and ðlarka. The name madár is derived from the Sanskrit mandára, hence the synonyms rudra, aditya, surya-pattrá. To its name arkaparna (sun or lightning-leaf) is doubtless due the tradition of its blinding properties.

History.—One of the earliest European writers to describe this plant was Prosper Alpinus (De Pl. Ògypti, 1592, ch. xxv.). He tells us that it is the beidelmar of Alexandria, where it grows in damp places. Rheedhe was the earliest Indian botanist to narrate its properties (Hort. Mal., 1679, ii., t. 31), and he furnished a most accurate drawing of it. He calls it ericu. Rumphius (Herb. Amb., 1755, vii., 24, t. 14, f. 1) gives a poor illustration but describes the plant in great detail under the name of mador. Jones (As. Res., 1798, iv., 267) deals with it under the name arca. Roxburgh placed it in the genus Asclepias, and Robert Brown a little later assigned to it a separate position under Calotropis. It is a sacred plant with certain Hindus, and is associated with the observances of the maruts or winds, the demigods of rudra. The ancient Arabs also appear to have had superstitious beliefs regarding it since they associated it with sun-worship. It is a popular tradition in many parts of India that the great Emperor Akbar was so named from having been born under the shade of an ak bush. It is the ushar of the Arabs and the khark of the Persians, but the former seems to be a generic word for milk-yielding plants and was possibly restricted to Calotropis at a comparatively late date. Abu Hanifeh perhaps was the first Arab writer to give an explicit account of it, but much useful information will be found in the writings of Ebn Baithar (Southeimer, transl., 1842, ii., 193). [Cf. Joret, Les Pl. dans L'Antig., 1904, ii., 354.]

Properties and Uses.—This plant may be said to yield Gutta-percha from the milky sap; a strong fibre from the bark; a useful floss from the seeds; and a medicine from the root-bark. Space cannot, however, be afforded to do more than review even these properties very briefly, and there are many minor ones that cannot even be mentioned.

The Gutta-percha.—The inspissated and sun-dried sap (milk) drawn from the stems constitutes the madar gutta of India. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1905-6, 29) calls it a pseudo-gutta and gives its composition as “37·9 insol.; 52·9 resin; and 9·2 ash.” He then adds that it contains large quantities of aban and fluveil resins (see p. 627). There are large tracts of the sandy deserts of Rajputana and Central India, as

205
also of Sind, in which this plant is not only the most prevalent but almost the only form of vegetation met with. In many instances also it has been observed to be the pioneer in the reclamation of sterile tracts (see Alkalis, Rich, p. 53). If, therefore, a demand could be originated for any one or all collectively of the products of this plant, much good might result to India. Its production could be fostered and by selection and cultivation the quality and quantity of the produce improved, until the plant assumed the condition of a regular crop for poor soils. But unless some method could be designed for extracting the milk from shoots cut on account of their fibre, it is feared that it would not pay to tap the plant specially for its gutta. The stems and twigs are too small and the yield from each too little to justify the opinion that methodic tapping would prove remunerative as an industry by itself. Moreover, it has been found by chemical experiment that Calotropis gutta, being a fairly good conductor of electricity, is not suited for electrical purposes and is thus very possibly debarred from one of the most profitable markets for this class of product. Heyne (Tracts, etc., Ind., 1814, 245) says that the milk instead of reddening vegetable blue colours, changes them to green. [Cf. Kew Bull., 1886, 45.]

**Bark Fibre.**—The bast fibre has attracted considerable attention and been spoken of as one of the best of Indian fibres. The great difficulty appears to consist in the inability to separate it rapidly and cheaply. Unfortunately the fibre cannot be prepared by retting the stems since it is reported to rot when so treated, and yet the cleaned fibre when made into fishing lines and nets (as is the case in Karachi) seems quite durable and very strong, especially when used in sea-water. Mr. Liottard, after many experiments performed in Calcutta with fibre-extracting machinery generally, arrived at the unfortunate conclusion that the hopes formerly entertained by himself and others regarding this particular fibre were never likely to be realised:—(1) because of the small percentage of fibre (1·56) to weight of stems, and (2) the shortness of the ultimate fibre. But in recent experiments conducted at the Imperial Institute with a sample procured from Madras, Dunstan found that the staple measured fully 12 inches. [Cf. Agri. Ledg., 1899, No. 2, 7.] Dodge (Useful Fibre Plants of the World, 1897, 104) observes that an acre of ground planted 4 by 4 feet with this plant will yield 10 tons of green stems and 582 lb. of fibre: this would mean a yield of roughly 2·6 per cent. He then adds that the fibre possesses many of the qualities of flax though somewhat finer. Its fineness, tenacity, lustre and softness, in fact, fit it for many industrial purposes. Cross and Bevan found that when nitrated it could hardly be distinguished from silk, and long years ago Wight showed that a rope of this fibre broke with a weight of 407 lb. when a similar rope of cotton gave way with 346 lb., and coir with 224 lb. It is, however, quite incorrect to affirm, as has been done by Wiesner (Die Rohst. des Pflanzenr., 1903, ii., 317), Dodge and others, that this fibre is widely used in India. Although prepared to a small extent for very special purposes, the greatest possible difficulty was experienced in procuring the few pounds required.

Mr. G. W. Strettell (New Source of Revenue to India) advocates the value of this plant as a paper material. Routledge did not form a high opinion of its qualities. [Cf. Kew Rept., 1877, 37.] It may thus be fittingly concluded that were it found possible to utilise the gutta as an additional source of revenue, the fibre, either for textile purposes or paper-making,
might, in spite of all that has been said to the contrary, prove worthy of special consideration. [Cf. Agri. Ledg., 1899, No. 2.]

Floss.—The coma of hairs or fluff from the seeds constitutes one of the so-called vegetable silks or silk-cottons. This was chemically examined by Cross (Agri. Ledg., 1897, No. 17, 365) and found to possess an abnormally high percentage of furfural. It was further believed to give evidence of being unsuited for some of the purposes of the textile industries. Dunstan, in a report dated November 18, 1904, speaks of Calotropis floss as containing a much smaller proportion of cellulose than cotton. He shows Calotropis gigantea floss to contain 64.3 per cent. cellulose, and Calotropis procera 69.8 per cent., while under similar conditions cotton yields 95 to 96.5 per cent. In practical experiments it has been found that the staple was too short and too light for existing machinery, the latter property allowing it to be blown away. It is, however, a soft, very white fluff, with a beautiful silky gloss, and has been repeatedly spun experimentally in Europe, and the textile produced much admired. Reporting on a sample of the floss submitted to him by the Imperial Institute in 1897, Mr. C. E. Collyer observed that some years previously the floss had been in demand for fancy textile purposes, but that it had dropped out of use owing to the difficulties arising from variation in the quality of the parcels sent and the intermittency of the supply when requirements arose. He thought that the trade might be revived if a moderate but continuous supply could be guaranteed. Good quality floss might realise 4d. to 5d. per lb. The pods and seeds should be removed but the floss left in its natural condition unopened and discoloured portions removed. Notwithstanding all this, no progress has been made in the utilisation of the fibre. In India it is largely employed for stuffing quilts, its lightness being of great advantage, and in upholstery it holds a recognised position, since pillows and cushions stuffed with it are said to be very cool and refreshing. It is also to some extent regularly spun and made into fishing lines and nets. At the Delhi Durbar Exhibition, His Highness the Nawab of Bahawalpur showed one or two rugs woven of madar floss, and these were much admired and supposed by many to have been made of silk. C. Latimer (Monog. Carpet-making Pb., 1907, 9) speaks of the attempt being made in Bahawalpur to grow the ak required in carpet-weaving. [Cf. Kew Rept., 1881, 32–3; Watt, Ind. Art at Delhi, 1903, 433; Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 70.]

Early Records of the Floss.—Such then is all that can be said of the utilisation of this floss at the present day. But there would appear to be little doubt that a few centuries ago this fibre was regularly spun and woven into some of the most beautiful textiles for which India was then famed. Human labour was of much less value then than at the present time. Modern advances coupled with the import of cheap European goods seem to have destroyed the old industry. It would appear fairly certain that the madar fluff was the "grass," the "cloth of herbes," "herba," etc., of early European travellers and traders in Bengal, more especially Orissa. Further that the traffic they allude to gave to the English language the expression "Grass-cloth," which later on became associated with a textile derived from China. Thus Cesar Frederike about 1563–7 (Habl. Voy., ii., 388) speaks of "Cloth of herbes,"—"a kind of silke which groweth amongst the woodes without any labour of man, and when the bole thereof is growen round as bigge as an orange, then they take care onely to gather them." Rhea could never have been found as a wild plant in Orissa, and the allusion to the "bole" or fruit from which the fibre was obtained precludes rhea from consideration altogether. The passage most unquestionably denotes Calotropis gigantea. This view is
CALOTROPIS
GIGANTEA
"Hearbe Bengalen."

Confirmed by Fitch in 1586 (Hakl. Voy. ii., 350), who gave an account of his explorations of the Ganges, including Orissa (Orika, as he calls it) where the plant was "great store of cloth which is made of Grasse which they call yerua." That vernacular name is clearly a form of the word that denotes Calotropis throughout Orissa and the Karnatâk to this day. Doubtless also Linschoten's "Hearbe Bengalen" was the same textile. I have purposely made reference to Linschoten under Behmeria nivea because all modern writers whom I have been able to consult quote the above passages, and several others to the same effect under rhea, in place of Calotropis, to which they most undoubtedly belong. Pyrard, who visited India in 1601-10, in his chapter on Bengal (Voy. E. Ind. (ed. Hakl. Soc.), l., 328-9) makes mention of the silk herb being brighter than silk itself. Coming to more recent dates, Alexander Hamilton (New Acc. E. Ind., 1727, 1, 333), who in 1688 visited Bengal and passed up the Ganges to Benares and Patna, describes Balasore as producing manufactures of cotton, silk, mixed silk and cotton, and of "herba (a sort of tough grass) of which they make ginghams, pinasses, and several other goods for exportation." Even so late as 1813 Milburn mentions among his Bengal piece goods "herba taffaties."

Though it is certainly most surprising that this ancient industry in silk-cotton textiles should have died out completely and been all but forgotten, it is a useful object-lesson of the possibilities of the future, which manufacturers would do well to consider. (For other Silk-cottons, see Bombax, p. 168.)

Medicine.—It would take many pages to indicate even a tithe of the information that exists on the varied medicinal properties of the milk, the flowers, the leaves and the root-bark. The late Dr. Kanny Lall Dey regarded madar as a useful medicine when given during remission of intermittent fevers, and especially if these were associated with eczema. The majority of Indian medical writers extol the merits of the root-bark in the treatment of dysentery. In order to verify these opinions, the study of madar was taken up by the Central Indigenous Drugs Committee of India. Authentic parcels of the root-bark were procured and made up in the form of both a powder and liquid extract. These preparations were issued to a selected number of Hospitals and Dispensaries throughout India, with the suggestion that they should be used as alteratives and alternative tonics. By chemical tests it had been previously ascertained that the bark of mature plants was preferable to that of immature ones, since they contained a higher percentage of the acid and bitter resinous matter on which the property depended.

Ultimately an extensive series of reports came to hand (Rept. Cent. Indig. Drugs Comm., 1901, i., many passages), the combined verdict of which would seem to be that as a substitute for ipecacuanha it is not so satisfactory as its reputation would seem to imply. In fact in acute dysentery and chronic diarrhea it is found undesirable and certainly less efficacious than ipecacuanha. When given in large doses it frequently occasioned nausea and vomiting, so persistent and severe as to make the drug objectionable if not dangerous. In small doses of say 3 to 5 grains of the powder (preferably) its action on the stomach was that of a mild stimulant, hence the opinion was often expressed that it might with advantage be combined with cinchona in the treatment of certain fevers. As an emetic the powder, in doses of 30 to 40 grains, was found very effectual.

In the Hemp Drugs Commission's Report (1893-4, i., 156) it is mentioned that the juice of the madar is employed to enhance the potency of ganja. [Cf. Taleef Shereef (Playfair, transl.), 1833, 5; Taylor, Topog. Stat. Dacca, 1840, 57; Hooker, Htim. Journ., 1854, 1, 36-7 (temperature of leaves and sap); Elliot, Fl. Andh., 1859, 74, 111, 162, 176; Jackson, Comm. Bot. 19th Cent., 1890, 127; Pharmacog. Ind., ii., 428-37; Kanny Lall Dey, Indig. Drugs Ind., 1896, 56-7; Collett, Fl. Sim., 1902, 315; Gaz. Multan, 1901-2, 17.]
THE TEA PLANT

CAMELLIA, Linn.; Fl. Br. Ind., i., 292-3; Frutex Thea, Jacobus Bontius, Hist. Nat. et Med. Ind. Or., 1631 in Piso, Ind. Utr. re Nat. et Med., 1658, pl. 88; The Sinensium, Jacob Bryen, Exot. Pl., 1677, 111-5, with plate (said to have been made after a sketch by William ten Rhynye);

Species and Varieties of Tea.—Linnaeus (Gen. Pl., 1737) indicated two genera, Thea and Camellia. The differences he established turned on whether or not the stamens were free from each other or united, and on the number of cells and seeds in the fruit. Accordingly he placed Thea in Polyandria Monogynia and Camellia in Monadelphia Polyandria. Subsequently (Sp. Pl., 1733, 515, 698) Linnaeus assigned the tea plant as the type of Thea and the Japanese Camellia as the type of Camellia. But it has since been abundantly established that Linnaeus was incorrect in regarding the stamens as being free in the tea plant; and it is a matter of everyday knowledge that on the same tea plant fruits may be found with one, two, three or more seeds. Modern botanists are accordingly agreed that the two genera cannot be separately upheld. Hence it may be regarded that priority of accurate generic recognition of the structural peculiarity of the stamens (were there no other considerations) necessitates the retention of the name Camellia, and the reduction of Thea. Turning now to the specific name.

In the first edition of the Species Plantarum, Linnaeus (without giving any description) called the tea plant Thea sinensis and remarked that he had seen some specimens with six petals and others with nine, but he left it to those who had the opportunity of studying the living plants to say whether that peculiarity denoted two or only one species. In the second edition of his work (published 1762) Linnaeus discarded the name T. sinensis (without giving any reason) and accepted Hill’s conclusion that there were two plants, which he named T. bohea—the plant with six petals—and T. viridis—the plant with nine petals. Linnaeus then adds (still following Hill) that the leaves are longer in viridis than in bohea, but he says nothing of Hill’s contention that the former yields “green” and the latter “black tea.” In the third edition of his work Linnaeus made no alterations, but in the fourth (prepared by Willdenow, 1797) a few additional particulars are given (of the two forms above indicated) and T. bohea is referred to two varieties:—

(a) inae—a plant with rough elliptic oblong leaves—and (b) stricta—a plant with plane lanceolate leaves.

Seemann pointed out that on his own copy of the sixth edition of the Genera Plantarum, Linnaeus had written certain corrections which show that the material then to hand had induced him once more to amend and amplify his description. Since then many botanists have striven to uphold the two Linnaean genera, their recognition being regarded as justified by certain trivial peculiarities of the calyx or, as Seemann affirms, of the stamens, but the final conclusion of the majority of writers, as already indicated, seems to be that the constitutions of the two genera and one species of tea. Engler and Prantl (Pflanzenfam., 1895, iii., 6, 182-3), the most recent authors, reduce Camellia to Thea, and restore the rejected name Thea sinensis. But it would seem that that specific name cannot be given as a collective appellation for the many races of the cultivated

the tea plant, since it was rejected by Linnaeus and, as Seemann points out, is geographically hardly correct. Long years ago Sims (Bot. Mag., 1807, 998) recorded the conviction that there was but one species of tea, and further that Thea would have to be reduced to Camellia. Link, however, accepted two forms of the tea plant, and called them Camellia Thea and C. viridis, and thus reduced Thea to Camellia.

Bohea.
The name Bohea is a corruption of Wu-i (Bu-i) mountains in Fuh-kien, long famous for Black Tea. According to Martyn (Miller, Gard. Dict., 1807), Linnaeus gave the name Camellia in honour of Kamel, a Moravian Jesuit, who collected plants in the Philippine Islands and sent them to Ray and Petiver between the years 1683 and 1700. The Abbé Berlese thinks, however, that the genus was named after an Italian, Father Camelli, who is said to have introduced C. japonica from Japan to Europe in 1739. Linnaeus (Hort. Cliff., 1737, 204) makes the interesting observation that although seven separate consignments of seed had been received at Clifford's garden in Holland, none had germinated, nor was he aware of any garden in Europe where the plant had been grown. Commenting on that statement, Breyn refers to J. Connelin (Cat. Pl. Hort. Amstel., 1689, 346), who makes mention of the cultivation of the tea plant, but whether, adds Breyn, raised from seeds or live plants transported to Europe, he was unable to ascertain. This little episode brings to mind the repeated references to the sacred associations of the Chinese and Japanese with their tea industry and their unwillingness to furnish information regarding it. In fact the explanation of the failure to germinate the seeds may very probably have been due to the not unusual circumstance of these having been boiled before being allowed to be exported. Du Halde (Gen. Hist. China (Engl. transl.), 1736, iv., 21) speaks of tea as "another plant made use of in Physick." He then tells us that "the best tea grows in the middle of the trees which are most exposed to the sun. The tea whose leaves are long and large is the best, on the contrary that which hath small short leaves is not esteemed good; that which hath its leaves curled is the most valuable, and that which hath them quite smooth is the worst." Here we have the practical man discussing the large- and small-leaved forms of the plant for which the botanist of that time invented names. But history is only repeating itself. Had the Indian planters considered these and other such passages they might have saved themselves the trouble and expense of introducing the small smooth-leaved Chinese plant, and taken at once to the large and bullate-leaved Assam indigenous.

There are several cultivated and wild forms of Camellia, but only the two that are of economic interest and, it might be said, of exceptional value to man, need be here dealt with:—

1. Camellia japonica (including C. Sasanqua). The Cultivated or Garden Camellias are not fit to be spoken of as a modern introduction to the gardens of Europe and India. It is accordingly not described by the early fathers on gardening. The year 1792 is generally mentioned as that of greatest interest in the history of the camellias, since all the better known kinds may be said to have appeared simultaneously about that time. For twenty to thirty years subsequently considerable interest was taken in their cultivation, and the number of forms, grown in hothouses, multiplied rapidly. But the great delay in their first arrival may be accounted for by the maritime struggles for supremacy in the Eastern trade, between the Portuguese, Dutch and Spanish, which culminated in their temporary expulsion from both Japan and China. To this same circumstance also is largely due the shroud of religious secrecy that opposed the development of the trade in—

2. C. Thea. The Tea Plant; the t'ea or chá, she, theh of the Chinese and teja, cha, ts-chá of the Japanese—words which have practically accompanied the prepared leaves as tea, te, tay, the, cha, chait etc., etc., into most of the languages of Europe and Asia. The English word tea was originally pronounced like the Chinese te or tay, hence Pope (Rape of the Lock, 1712) rhymes it with obey. It changed, however, very shortly after, since Edward Moore rhymes it (1750) with "Mrs. P."

Habitat.—Several writers report having met with the tea plant in a wild condition in certain parts of China and Cochin-China. It was discovered wild, or at all events completely acclimatised, in various parts of Assam by Bruce, Scott, Jenkins and Charlton, and the so-called indigenous habitats were examined by the "Tea Commission" and specially reported on by Griffith. In 1882 the wild tea plant was found by me as a forest tree or large bush in the eastern tracts.
of Manipur, and again, in 1894, was specially investigated in the Naga hills in connection with an effort to ascertain to what extent the pests and blights of the cultivated tea plant existed on the wild or acclimatised stocks. There would seem little doubt that it has been cultivated for several centuries at least, in Upper Burma and the Shan States, and doubtless may be wild in these countries also, though according to most observers it occurs in isolated spots, similar to those in the greater part of the Assam area; hence it could of course under these conditions be upheld as a survival of former cultivation rather than as manifesting a truly indigenous habitat. [Cf. Agri. Ledg., 1896, No. 27.]

History.—Bretschneider (Bot. Sin., 1892, ii., 20, 130–1) states that the tea plant is mentioned in the ancient Chinese Dictionary, the Rh-ya. It is there called kia and k'u-tu (k'u meaning bitter). He further explains that the Chinese character T'u, which has so many other meanings in the early Chinese classics, may, however, have specially meant tea. He then adds that the comparatively modern Chinese character ch'a arose through a confusion with that of t'u, somewhere between 202 B.C. and 25 A.D., but that it did not come into general use much before the 7th or 8th centuries. So in the same way the character ming, which would appear to denote the tea plant, occurs as ming ts'ai (= tea vegetable) in works written some centuries B.C. The Shans and Burmans to this day use pickled tea-leaves (see Letpet below) more as a vegetable relish than as a beverage, and it seems possible that this may have been the condition of use during the earliest classic times of China. We read that Wang Meng, father-in-law of the Emperor, in the middle of the 4th century, was fond of drinking tea, and set it before his friends, but they found it too bitter and generally declined, feigning indisposition. So again Bretschneider tells us that according to the Ch'a-pu—a special treatise on tea, published between the 10th and 13th centuries—the Emperor Wen-ti (580–605 A.D.) was recommended by a Buddhist priest to drink boiled ming leaves as a medicine for headache. It is somewhat curious that Kempfer relates a similar Japanese tradition that would seem to attribute the introduction of the plant to that country by Daruma, the third son of an Indian king. But if the t'u of ancient Chinese classics be accepted as denoting tea, it may have originally been viewed as a medicine obtained from the plant known as ming, ch'uan and kütu. The habit of drinking a decoction of the specially prepared leaves, there would seem no doubt, is of comparatively modern origin. In the 8th century A.D. we have the first undoubted evidence of tea having become a regular industry, for in the annals of the T'ang Dynasty we learn of its being subjected to an imperial duty. It was not regularly cultivated in Japan until the 13th century. That tea drinking in the rest of the world is quite a modern habit may be inferred from there being no classic names either for the plant, the prepared leaves or the beverage, in Japanese, Sanskrit, Arabic, Persian, Hebrew, Greek or Latin.

Marco Polo, who travelled in China (in the tea districts of Fuh-kien) in the 13th century, makes no mention of tea, neither the plant, the vegetable nor the beverage, and yet it is well established that the plant and its preparation were as fully known then as to-day. [Cf. ed. Yule, ii., 37–8, n.] But in passing it may be added that he similarly does not record having found the people in any part of his long travels drinking coffee. His omission to record tea is the more curious, however, since four centuries previously (9th century) the Muhammadan merchant Solaiman (according to Reinaud, Relat. des Voy. faits par les Arabes et les Persians dans l'Inde et à la Chine, 1845, i., 40) wrote, "The people of China are accustomed to use as a beverage an infusion of the plant, which they call satkh." "It is considered very wholesome. This plant (the leaves) is sold in all cities of the Empire." [Cf. Macpherson, Hist. Europ. Comm. Ind., 1812, n. 130.] Ramusio (in the introduction to his edition of Marco Polo published in 1545) mentions having learned of the tea beverage from a Persian merchant, Hajji Muhammad. It was used all over the country of Cathay, where it was called chia. In 1590, Gaspar da Cruz (in Purchas' Pilgrimes, iii., 180) refers to the porcelain used by the Chinese in presenting to their friends the beverage cho. Maffeius (Hist. Indianarum (Select. Epist. ex Ind.) 90), in a letter from Ludovic Almeida dated Nov. 1565, similarly says that it was the custom with the Japanese to show their friends with pleasure the pots, cups, etc., employed by them in drinking of a certain herb, reduced to powder, which was called chia. Maffeius (in the text of his work which was originally published in 1588) attributes the freedom of the Chinese from certain diseases (stone, etc.) to their habit of tea-drinking, and the Chinese (like the Japanese),

211
he adds, take great pride in the teapot which they use in giving a friendly cup. Tulpus (Observ. Medic., 1641) extols the merits of tea as a medicine. It is somewhat significant that Garcia de Orta makes no mention of tea as one of the commodities brought from China and Japan to India. Linschoten (Voy. E. Ind., 1598 (ed. Hakl. Soc.), 1886, i. 157), who usually compiles from Garcia, practically repeats Maffeiuss's account of tea-drinking in Japan. Trigantius (De Christ. Exp. in Sinas, 1616, i., 68—9) speaks of the hot-tea drink of the Chinese. Casper Bauhin (Pinax, Theat. Bot., 1623, 147) was apparently the first scientific or botanical writer who makes mention of what would appear to have been tea. But the passage in question does not occur in his earlier work (the Phytopinax, 1596). He calls it cha & describes it as his seventh variety of Fennicum (Fennel)! Absurd though this may seem there would appear to be no occasion to doubt that he is speaking of tea. Bontius, a Dutch physician resident in Batavia——(Hist. Nat. et Med. Ind. Or., 1631, in Piso, Ind. Utr. re Nat. et Med., 1658, 87)—tells us that his friend General Spex had removed all doubt as to the nature of the tea plant, since he had studied its cultivation in Japan. Bontius then goes on to say that the finer qualities of the decoction are often so bitter that sugar has to be added to make it palatable, and he compares the beverage to the "cave" (coffee) of the Muhammadans (see p. 364). He then urges that the difference between black and green tea is only in the method of preparation—a fact that took Europe nearly two centuries to accept. In Piso there is an excellent engraving of *Camellia Thea* (the Chinese form) drawn from nature in Japan by D. Caron, and presented to Piso; Caron went to Japan in 1638 under the Dutch E.I. Company. [Breit Schneider, Hist. Europ. Bot. Disc. in China, 1898, 25.]

Albert de Mandelslo (Travels, in Olearius, Hist. Muscovy, etc., 1662, 15, 18) says, "At our ordinary meetings every day we took one leg Thae, which is commonly used all over the Indies, not only among those of the Country but also among the Dutch and English, who take it as a drug: The Persians instead of *The* drink their *Kohua.*" This statement occurs in Ovington's Voyage to Surat (1689, 305—9, 427). It is curious, however, that in the *Annals* of Akbar (1566—1605) no mention is made of tea. It was conveyed to Europe by the Dutch East India Company, and from Holland was carried to England by Lord Arlington and others. In 1660 tea-drinking had become so general that it was taxed along with coffee, chocolate, etc., and sold at the coffee-houses. The English East India Company soon gave attention to it. In 1664 they made a present of some tea to King Charles II., and in 1667 the Company had taken steps to secure a regular supply. At this time tea sold in London at £5 to £10 a pound. A few years later (1689) a direct duty on imports (which amounted to 5d. a pound) was imposed. It is further noteworthy that at that time the East India Company drew its supplies for Europe via Madras and Surat and not direct from China. This circumstance would thus give an air of plausibility to the statement made by Mandelslo that tea was drunk in India about the time when he visited the place in 1628. It was introduced into England. Evelyn (Mem., 1690, ii. 20) speaks of having examined a specimen of the "roote of thea which was so perplexed large and intricate that it was wonderful to consider." Petiver (Op. Hist. Nat., 1707, i., t. 21) shows a chair made of the roots of the tea plant which was presented by the "New East India Company" to Lord Somers. Curiously enough, one of the earliest and at the same time most instructive botanical specimens of the tea plant extant is in the Sloane Herbarium of the British Museum (lxxxvi., f. 48). It belongs to a series of specimens said to have been collected in Malabar, between 1698 and 1702, by Samuel Browne and Edward Bulkeley. Browne was a surgeon in the service of the East India Company, and died some time prior to 1703. He was succeeded by Bulkeley. Both of these officers made extensive botanical collections, which were sent for the most part to James Petiver. It is just possible that long prior to the discovery of the indigenous tea plant in India or to the importations from China of seeds and plants accomplished by Gordon and Fortune (presently to be described), the tea plant had actually been conveyed to India and cultivated experimentally somewhere on the Malabar coast. But what is most curious of all is that the plant so grown was *not* _Camellia Thea_, *Link* var. *bohea* (the plant presently being cultivated most frequently in the plantations of South India), but *var. virdis_, and was thus very similar to the so-called "Assam Indigenous." It is, moreover, just possible that upon this very specimen was based the name *Thea virdis_, as given by Hill and adopted subsequently by Linnaeus. In fact Linnaeus pos-

Early Imports

Story of Black and Green Teas.

Chinese Plant in India.

Taxation of Tea.

Species and Varieties.

Species and Varieties of the Tea Plant.—In the first days of tea planting in India, though the presence of a wild tea plant was regarded as an indication of the suitability of the land, the wild plant itself was not viewed with favour as the stock to be employed. In fact, as already pointed out, the opinion was expressed most strongly by all or nearly all the experts of 1834–7 in favour of imported Chinese stock.

While that is so it may be said that for the past thirty or forty years the
planters have deplored the day when the so-called Chinese tea plant was brought to India. At present no planter would for a moment dream of planting China tea, few would even grow the hybrid, while the majority would cultivate but one only of the several so-called indigenous stocks. The China plants imported in the early years of the industry still exist, however, and have furnished the seed for a considerable part of the present tea area. In consequence of the crossing of the Indian and Chinese plants there has come into existence the extensive series of so-called hybrids. Perhaps the clearest conception may, therefore, be obtained by an attempt to classify the forms, as near as may be possible, on botanical standards.

In a paper read by me before the Royal Horticultural Society (to which reference has already been made) I have given my views in some detail. Link (l.c. ii., 73) was the first botanist who definitely placed the tea plant under the genus *Camellia*, and as already observed he recognised two forms, viz. *C. Thea* and *C. viridis*. There would seem, however, no great advantage in regarding the forms indicated as anything more than varieties if not cultivated states of one species. Thus:—

Under this I assimilate the following races and cultivated states:—

1. **Assam Indigenous**—This has the mature leaf ranging from 6 to 7½ inches in length, and from 2½ to 2¾ inches in breadth. It contains about 16 veins on each side of the midrib. In passing it may be here observed that the value of the number and condition of the veins in the classification of the cultivated races of tea, was first pointed out in the *Pests and Blights of the Tea Plant* (ed. 1898, 15, 46–9). But there are numerous subraces of the Assam stock, such as the Singlo, Bazelona, etc. Collectively they are the most highly prized and most widely cultivated of all the Indian forms of the tea plant. It is, however, somewhat curious to read in Ovington's *Voyage to Suratt* (1689, 308) that three kinds of tea were in his time conveyed from China to India, namely, "Bing, Singlo and Bohe." This is apparently the first mention by a European writer of "Singlo," and the surmise naturally arises, how came that name to be given to one of the best of the Assam indigenous plants?

2. **Lushai**—Sometimes called "Cachar Indigenous" or "Light-leaved Manipur." Under favourable conditions this forms the largest leaf of all the Indian tea plants. It has been measured from 12 to 14 by 7¼ inches and recorded as possessing from 20 to 24 veins. It is not found wild outside the Lushai hills and South Cachar. It is a rather delicate plant and will not safely bear the hard pruning which may be given with impunity to other teas.

3. **Naga Tea**—This has a long, narrow leaf, generally from 6 to 9 by 2 to 3½ inches, with as a rule from 16 to 18 veins. It is very little cultivated except in one or two gardens on the borders of the Naga hills, such as Anguri, but is reported to be often used as a crossing stock.

4. **Manipur**—This is the wild tea of the Native State of that name. It exists there purely and simply as a forest plant, the seed of which, but not the leaf, is valued. It is now grown fairly extensively in Cachar and some parts of Assam. It is a larger, coarser and broader-leaved plant than the Assam indigenous. The average mature leaf is from 6 to 8 inches in length and 2½ to 3½ inches in breadth and usually contains 22 veins.

5. **Burma and Shan**—Too little is known of these teas to allow of their critical separation from the Manipur plant. The leaves are smaller, thicker, more acutely serrated and distinctly more elliptic in shape than with the other teas. The plant in question has possibly been grown for centuries more as a vegetable than as a source of the beverage. This circumstance may be found to have produced properties with which we are at present not familiar. (See p. 235 under Letpet.)

6. **Yunnan and China**—Fortune (Three Years' Wanderings in China, 1847, 68) speaks of the country south of the Yang-tse-Kiang as the region of Chinese *T. viridis*, the tea being shipped from Shanghai and Ningpo. Crawford (Journ. Emb. to Stiam and Cochín-China, 1830, ii., 264) speaks of the plant seen by him having leaves "twice or three times the size of that of Bohea tea."

Early Endeavours.

Introduction of Tea Plant.

Discovery in India.

Var. (3) bohea; Thea bohea, Linn., l.c. 734; Lettsom, l.c. 41; Hayne, l.c. vii., t. 28; Bot. Mag., 1807, xxxv., t. 988; etc., etc. The Bohea Tea of Fortune and others; the Hybrid Tea of Indian tea-planters.

Fortune (l.c. 197–224) found this as the chief plant in the great black-tea country of Fuh-kien, the tea which is shipped from Canton and Hongkong. It is a small-leaved plant with not more than 12 to 14 veins on either side of the midrib. It is freely admitted by planters to be a cross between viridis and stricata, the plant presently to be indicated.

Var. (7) stricta; this is the form represented in the Linnean Herbarium by a specimen, No. 1, but which bears no name nor any record. It is also the T. Chusul in Petiver (Mss. Rar. Nat., 1695, n. 983, in Brit. Museum); Thea stricta, Hayne (l.c. 1821, vii., t. 27); Chinese Tea of the Indian tea-planters. This small bush may be seen in Indian seed-gardens flowering and fruiting freely, and though never pruned it preserves all its characteristics and rarely shows any departure toward var. viridis. The leaves are thick and leathery, from 1\(\frac{1}{2}\) to 2\(\frac{1}{2}\) inches long, and vary from \(\frac{1}{6}\) to \(\frac{1}{2}\) inch in breadth. It has rarely ever more than 8 definite nerves, while viridis has 16 and bohea usually 12 to 14. It is essentially a bush, and even if given the chance it rarely if ever takes the poplar-tree form of the other races. No one has recorded the existence of this plant in a truly wild condition; and what is much more curious, it is more abundantly represented in herbaria as coming from India than from China.

Var. (5) lasiocalyx; T. lasiocalyx, Planch., M.S.; T. viridis, Wall., Cat., n. 979; ?? C. axillaris, Roxb., M.S. (Bot. Reg., t. 349, for description). This interesting form appears to have been met with alone in Malacca and Penang, and is perhaps the most tropical of all the forms of Camellia actually cultivated as tea. It seems probable that it may have originated by hybridisation with var. viridis some of the better known forms of tea, such as var. stricta. In this light the suggestion above made that it may be the plant Roxburgh designated as Camellia becomes of more than botanical interest. At all events both the locality and description given by Roxburgh suit var. lasiocalyx to a remarkable degree. This is the plant seen by Griffith at Pringett near Malacca.

In order to obtain the true value of the characters above indicated that are dependent on the veins of the leaves, it is necessary to examine the shoots which spring directly from old wood, that is to say, shoots low down on the stem. Of the Manipur and Assam plants—those in most favour in India at present—it may be said that the former is much more hardy than the latter and should accordingly be used wherever liability to drought exists. The Assam gives, however, a thinner and more delicate leaf with more flavour, and the value of the tea made from it is decidedly greater. All hybrids, so Dr. Harold H. Mann affirms, should be avoided; in other words, all plants that show from 10 to 14 veins—the intermediates between var. viridis and stricta. [Cf. Pests and Blights (1st ed.), 42–50; Mann, Factors Deter. Quality of Tea, Ind. Tea Assoc., 1907, No. 4.]

EARLY ENDEAVOURS IN INDIAN TEA-PLANTING.

Discovery of Tea Plant in India.—Difficulties having arisen with China, the British Government realised the danger of having no other source of tea supply than China. They accordingly interested the East India Company in an effort to produce tea in India. Sir Joseph Banks, in 1788, recommended Warren Hastings to attempt its cultivation in Bihar, Rangpur or Kuch Bihar. It appears to have been discovered in Assam, perhaps originally by Major Bruce, subsequently in Manipur by Mr. Scott, somewhere between 1821 and 1826, but little attention was paid to that circumstance until some years later. Lord William Bentinck, Governor-General of India, in a Resolution dated January 24, 1834, warmly took up the matter of Indian tea cultivation. A Committee was appointed by him, with Dr. N. Wallich as Secretary, to report on the most hopeful situations for an experimental cultivation. Mr. G. J. Gordon, of the firm of Mackintosh & Co., was dispatched to China to procure seed, to collect information, and to bring to India Chinese cultivators. He was, however, shortly after recalled because wild tea had been re-discovered by Jenkins and Charlton in Assam. But had Bruce and
Scott's discoveries received the attention they deserved, Gordon very possibly would never have been sent to China. As it was, Wallich refused to believe that even Jenkins's plant was the true tea plant until he had a sample of tea made from it and sent to him. In due time a Commission was appointed to visit Assam in order to report on the discovery of Indian indigenous tea. It consisted of Drs. Wallich, Griffith and McClelland. They could not agree as to the plant, but for the purpose of the Government experiments recommended that the Himalaya should be first tried, then Assam, and lastly the mountains of South India. They then added that "the China plant and not the degraded Assam plant" should be experimented with. The controversy about black and green tea and of the separate plants from which these were supposed to be made was doubtless the will-o'-the-wisp that largely influenced Wallich to lay down the dictum that the Indian plant was a Camellia and not a Thea—a distinction, as has been shown, without a difference, and one which greatly retarded the Indian tea industry. Unfortunately for Wallich his so-called Camellia has since proved very much more valuable than the Thea, the merits of which he extolled and which alone, in his opinion, should have been cultivated. It may be here added that it is remarkable, when so much difference of opinion prevailed and the existence of wild tea in Assam had even been challenged, that no one thought of drawing attention to the specimen of the tea plant from Malabar preserved in the Sloane Herbarium. Had this been done, we should in all probability have been told the history of that sample more definitely than we are ever likely now to learn, and at the same time a fuller conception of the Chinese tea plant would have been obtained than possessed byWallich and others, who denied that the Assam stock was the true tea-yielding species.

Wallich, Royle and Falconer (Journ. As. Soc., Beng., 1834, iii., 178-88) upheld the Himalaya as the preferable locality, while Griffith and McClelland urged the claims of Assam, which they regarded as the indigenous habitat of the plant. In guarded yet unmistakable language Griffith gave his opinions, even though these were inimical to the views of his superior and colleague, Dr. Wallich. Gordon was in consequence re-deputed to China, and on his return to India with a supply of plants, seeds, etc., he resigned his connection with the Commission without having written an account of his journeys in China. A third mission to China (the expenses of which were partly borne by the Royal Horticultural Society of England) was organised and successfully conducted by Mr. R. Fortune, who wrote in consequence, Three Years' Wanderings in China (1847), Tea Districts of China (1852), and A Residence Among the Chinese (1857). These works contain full particulars of his studies of the Chinese industry, as also details regarding the plants, seeds, etc., conveyed by him to India.

on Ceylon Tea Soils, Colombo, 1900; Schulte im Hofe, *Tropenpflanzer*, 1901, ii. (Heft.), 37-117.] These may, therefore, be viewed as amplifying the citation of more or less botanical publications mentioned in the opening paragraph. But it is essential to mention, still two other works, viz:—(a) Bretschneider's *History of European Botanical Discoveries in China*—a truly stupendous volume which reviews and indeed often quotes very fully most of the scientific authors who have written on the Chinese Tea Plant. And lastly (b) Prof. J. J. Rein's *Industries of Japan*, 1889, which gives a delightful sketch of the early history and modern development of the industry in that country.

Numerous reports were issued by the Government of India, from the date of the appointment of Mr. C. A. Bruce in 1836, as Superintendent of their Assam plantations, to the time when they ceased in 1865 to have any direct interest in tea. These made public the discoveries accomplished and the experience gained. It had been freely announced that when the industry no longer required the fostering care of Government, it would be handed over to private enterprise. The progress in Assam was such that long before Government could resign their Himalayan plantations they had retired from Assam. It may be here mentioned that the first sample of Assam-made tea was sent to England in 1838. From that date the progress was rapid. The other day, while examining the numerous papers on tea preserved in the India Office, I came across what purports to have been the first fly-leaf of a commercial sale of tea made by Government. It is signed by Mr. Thos. Watkins, Superintendent of the Government Plantations, and endorsed by N. Wallach, M.D., Superintendent H.C. Botanic Gardens. It is dated Jaipur, Upper Assam, March 5, 1841, and headed, "A Novel and Interesting Sale of Assam Teas—the First Importation into the Calcutta Market." That circular (reproduced, *Journ. Roy. Hort. Soc.*, 1907, xxxii., 69) announces, in fact, two parcels of tea offered for sale, namely thirty chests manufactured by the Singhfo chief Ningroola, and ninety-five the produce of the Government tea plantations. It may thus be noted that the Singhfos were actually manufacturing tea in Assam at the very time apparently that Wallach challenged the production of tea as the evidence necessary to convince him that the Assam indigenous plant was the true tea-yielding species.

**First Public Tea Gardens.**—The Sibasagar (Jaipur) plantations of the Government were sold in 1840 to the Assam Company—the first tea concern, and to this day very much the largest Company in India. It was anything but prosperous during the first 15 years of its existence, and its shares fell so low that they could hardly be sold. But about 1852 it began to improve, and with that success the tea industry appeared so promising and attractive that speculators eagerly rushed into it. The discovery of the indigenous tea in Sylhet and Cachar gave the impetus for an expansion of the industry into the Surma valley, and in a few years thereafter the whole of the upper portions of the province of Assam (both the Brahmaputra and Surma valleys) might be described as converted into a huge tea plantation. About this time (1853-5) tea-planting was organised in Darjeeling, and shortly after followed Chittagong, Chota Nagpur and the Duras. Ultimately tea cultivation spread over every district of India where there was the least hope of success, but with a rapidity that was certain to culminate as it did in the great disaster of 1865-7. It is needless to dwell on the causes of that disaster, but the reader is referred to Mr. (afterwards Sir) John Ware-Edgar’s full report. It was, briefly, a natural consequence of reckless impetuosity, ignorant supervision and positive dishonesty. Fortunes were made by the few who realised that the tide
would turn. The better situated gardens were purchased for fewer rupees than they had cost pounds sterling to construct. New companies were formed to work these and with the avowed purpose of growing tea for its own merits, as a commercial article, and not for the purpose of selling gardens at a profit. Out of these trying times the industry rose on a firmer foundation, and the subsequent prosperity is one of the marvels of modern commerce.

It is not known how much money the Government of India actually spent, from first to last, in their efforts to ingraft the tea industry on India, but it would appear that Gordon’s missions to China and the expenditure of the Indian Tea Commission came to close on £18,000. If we assume that sum to have represented but one quarter of the total expenditure actually incurred, the result might still in perfect fairness be characterised as one of the most profitable undertakings of the Administration of the Empire of India. There has been organised a new industry the value of which may be judged of from the following circumstances:—

Tea now occupies half a million acres of land formerly waste, and of this 64 per cent. are in the province of Assam: the industry now gives lucrative employment to close on 600,000 persons: the capital invested in it comes to well over £20,000,000: the first exports (1838) amounted to 488 lb., and in 1904 they stood at 200 million pounds valued at, say, £6,000,000: still further, it may be claimed that, as an offshoot of the Indian industry, Ceylon has been saved from absolute bankruptcy by the substitution of tea for coffee: and lastly that India and Ceylon have given to England a regular supply of a much purer and infinitely cheaper article than it formerly received from China (see p. 240).

**CULTIVATION OF TEA.**

*(Contributed by Harold H. Mann, D.SC., Scientific Officer to the Indian Tea Association, pp. 218–39).*

**Object.**—The object to be attained in tea-planting is the production on the tea plants of a constant succession of young shoots throughout the season. The youngest leaves on each shoot only are capable of being made into tea, and hence it is easy to see that the growth of tea occupies a unique position among agricultural industries. Few of these concern themselves, except indirectly, in the production of leaf: still fewer limit the crop on a perennial plant to the youngest shoots. To obtain the results needed, the methods applied have a very special character, which has made tea-planting one of the most technical of those industries which depend on the culture of the land.

**Past Failures.**—The first years of tea-planting in India were, for the reason just indicated, almost a hopeless failure. A very small crop was obtained, the leaf was plucked when too old, and a large part of the tea was hence all but unsaleable, and the early planters had to buy very dearly the experience which has made the tea industry such a great and profitable speculation. In Assam, till 1848, continual losses occurred; from that time for the next four or five years the Assam Company, the pioneer and only company in the province, just succeeded in paying its way; thereafter, tea culture became exceedingly profitable, and if checks were received, such as the memorable panic of 1866, it was not owing to the character of tea culture, but rather to financial dealings in Calcutta and in England, coupled with certain fraudulent operations on the spot. Though tea culture has been a profitable industry since 1853, yet the
methods adopted have been continually improved. So far as the plants are concerned, the methods of pruning, of plucking, of cultivation in general, have constantly been ameliorated, and the improvement is still going on. The result is shown in the increase of crop; in 1873 the crop in Assam was roughly from 250 to 280 lb. per acre, and in 1904–5, in Assam, Cachar, Sylhet and the Duars, it ranged between 450 and 500 lb. per acre, and, as a rule, the leaf plucked was finer and more capable of making good tea than at the earlier date. The manufacture of the leaf has undergone a total revolution: the rolling by hand, as also the drying or firing over charcoal (and the attendant evils and risks of these methods) have been entirely abandoned. Since the introduction of the first feeble efforts at manufacture by machinery in the early 'sixties, stage by stage the older methods have disappeared, and now the work in a tea-factory is or can be made, in a very large measure, an automatic process.

Space cannot be afforded to trace the development of tea culture and manufacture in India from the earliest to the latest stages, interesting though such a story would be: all that can be attempted here is to state the most approved conditions for the culture of the tea plant, to describe the methods adopted in planting and maintaining an estate, and to give some account of the principles of manufacture at present in vogue.

Localities and Climates.—The most suitable localities for the culture of tea have been, from the beginning, a source of fruitful discussion. Already in 1836, of the men best qualified to judge, some maintained that the North-West Himalaya with a temperate climate and occasional frost would be found the ideal situation: others, that Assam, where the plant had been found apparently indigenous, possessed conditions very similar to those of the best tea districts of China: while the equable climate of the Nilgiris was also recommended. Truth to tell, there were elements of vantage in all these localities. The ideal tea climate, however, is probably that of Upper Assam, and perhaps of Cachar—those districts, in fact, where the apparently indigenous tea had been discovered. The hilly colder districts of Darjeeling, Kumaon, the Nilgiris and of the Kangra Valley have produced very successful plantations, but in all these the crop per acre is very considerably smaller than that of Upper Assam, though this smallness of crop is often (though not always) compensated for by an increase in quality in the tea. On the other hand, very satisfactory results have been achieved in the hotter and drier districts of Lower Assam, of Sylhet, and in a less measure of Chittagong; but here the tea produced has always been inferior in character. Tea requires, in fact, neither a tropical nor a temperate climate, but a sub-tropical one, with a fairly moist atmosphere throughout at least the greater part of the year. In point of temperature the best growth is produced with a daily variation of temperature, say, from 75° to 85° F. If it goes far above the latter point, damage results, unless the high temperature is accompanied by very moist conditions: the highest shade temperature usually reached in Upper Assam is from 95° F. to 98° F., and this always during the rainy season. Only very slow growth, on the other hand, takes place much below 70° F., and though plucking continues in many districts when the daily maximum does not reach this point, yet the intervals between the crops of leaf become very long. During part of the year, almost all over the Indian tea area, no plucking is attempted, and then the temperature may go down almost to freezing

point without damage. Frost, however, always blackens the leaves, and, if severe, damages the younger twigs on the bush. As to rainfall, the distribution is of more importance than the amount. Sixty inches per annum, well distributed, is ample. The best Indian tea areas receive about one hundred inches, though there are many on which a much greater amount falls. This rainfall should, however, occur, as far as possible, throughout the year. A long drought, at any season, is fatal, and this fact has had a good deal to do with the comparative failure of both Chittagong and Chota Nagpur as tea districts.

Situation and Soil.—Equally important with the climate in determining the suitability or otherwise of a locality for tea culture is the character of the situation and of the soil. Early in the history of Indian tea there was a considerable prejudice, doubtless drawn from the accounts of Chinese travellers, in favour of planting on hills or steep slopes. But there was really nothing in the preference: if the soil is suitable, it is better on flat than on sloping land, especially if the latter faces south or south-west; if the land is not suitable, it is certainly no more so on a hillside than on the level. Nowadays it is recognised that the flatter the land the better, other things being equal.

There are two points in connection with the physical texture of the soil which are essential, if tea is to be successfully grown. It must first be well drained, and secondly it must be easily penetrable by the tea-roots. A hard and waterlogged soil are equally fatal to successful tea culture: in the former case the bushes cease to yield, and become the prey of disease; in the latter they die out. It may be said that tea will grow in almost any soil provided it be well drained, but it flourishes best in a light, sandy, deep loam. If the physical texture of a clayey soil is such as to give it the porous and soft character required (as is often the case in South India and in a large area in the Duars), it may form excellent land for tea culture. There are two classes of soil specially to be avoided: first a stiff clay, of any kind or colour, impervious to rain and which cakes or hardens in the sun; and second a very loose soil overlying gravel, which in the absence of regular and very constant rain will ultimately produce a stunted bush yielding little leaf. Wherever the land is deep, moist, fairly porous, well drained or drainable at all seasons, and with a sufficiency of plant-food, the tea is likely to do well, so far as soil conditions are concerned.

Chemically, tea demands a rich soil, and has usually, except in the south (where old coffee land has been employed), been planted on virgin soil, either forest or grass land being utilised for the purpose. Where the attempt has been made to put it out on soil previously used for the cultivation of sugar-cane or cotton, it has almost uniformly grown very badly. It refuses to flourish where houses have long stood, even though the soil may be quite rich, but this is possibly largely due to the hardening and compacting of the soil. Exception being made of special conditions such as that just described, and provided the physical character of the land is equally good, the luxuriance of tea seems to vary directly with the amount of organic matter and nitrogen in the soil. In virgin soils these two constituents seem, in India, to be closely proportioned to one another. Excess of vegetable matter leads to the production of a large crop of weak, watery tea without flavour; on the other hand, a soil deficient in these constituents produces only a small crop, and, moreover, the

220
plants will almost certainly be attacked by blights at an early age. Much controversy has arisen as to the cause of flavour in the tea, produced from certain soils, notably those of Darjeeling, and it now seems, most probably, to be connected closely with the presence of relatively large quantities of phosphoric acid and potash in the land. Other causes complicate the question, but it is almost certain that the mineral plant-food constituents hold a very important relationship to flavour. The presence of more than a very small quantity of lime in a soil seems almost fatal to successful tea culture: the average amount present in India is under 0.2 per cent.

**CHEMICAL CHARACTERISTICS OF TEA SOILS.**—**Assam.**—The soils actually under tea culture at present in India are of very great variety. In the Brahmaputra valley (Assam), while all the tea land is alluvium, the best results have been obtained on fairly light, red, rather coarse sand or silt, or on the stiffer, older, and redder alluvium which forms small plateaux in certain districts (Tezpur, Bishnath). The following are typical analyses, the samples having been taken from the surface to 15 inches deep:

**Cachar and Sylhet.**—The tea in the Surma valley (Cachar and Sylhet) was originally planted almost entirely on small hills (teelas) which occur over almost all these districts, and which were surrounded by low-lying flat land, often swamp. Much of this low land was in later years found to be perfectly capable of drainage, and when drained formed very rich beds, sometimes of peat, sometimes of black soil highly charged with organic matter. Tea has been found to flourish exceedingly on these so-called "bheel" soils, which produce enormous crops of low-quality tea. In Sylhet in addition to these types of land, much tea has been planted on plateau land very similar to that in the Brahmaputra valley. The "teela" and "bheel" soils of Cachar and Sylhet are typified in the following analyses:

THE TEA PLANT

The tea land of Chittagong resembles that in Sylhet.

Duars, Terai and Darjeeling.—The Duars and Terai, districts lying in a strip 10 miles or more wide at the foot of the Himalaya, south from Sikkim and Bhutan, contain soils of several types. The most characteristic is, however, a huge bank of stiff and yet porous red soil on which lie some of the most successful tea estates in India. In Darjeeling the land differs from the foregoing in not being alluvium, but formed in situ from the rocks of the districts. It is a clayey and yet highly porous soil, which is rich in mineral plant-food constituents. The following are analyses of type soils from the Duars and Darjeeling:

South India.

South India.—The soils of the remainder of the districts of North India hardly call for remark. Those of the south country—the Nilgiris, Travancore and the Wynad—are as a whole characterised by a large proportion of clay, and yet by a very granular texture. They are all hill soils probably formed in situ. The analyses (due to Bamber) of two fairly typical soils from Travancore are shown below:

<table>

Propag.ation.

PROPAGATION.—The tea plant is invariably grown from seed. Attempts to propagate on a large scale from cuttings or by layerings have never been very successful. It is difficult, in fact, to get the cuttings to strike, and the method of layering does not allow of rapid enough increase of plants to be ever used. The real reason, however, of the avoidance of these methods is the ease with which plants are grown from seed; and for supply of seed, special bushes or even special seed-gardens are reserved.

Seed.—Plants used for seed-production are allowed to grow naturally, without any pruning. They thus form trees up to 30 or even 40 feet high, more or less resembling a poplar in shape. The “China” plant is, however, an exception, and rarely grows to a height of more than 10 or 12 feet. All the forms flower in North India from September, and the fruits take a year to come to maturity. A second small lot of flowers often

Flowering.
NUMBER OF PLANTS TO THE ACRE

forms in February and March. The seed is procurable about November, collected in the latter half of October, and packed for transmission in almost dry soil. A box containing 40 lb. of shelled seed will usually weigh from 120 to 180 lb. The seed does not keep well, and ought to be sown as soon as possible after being plucked. It has often been upheld that the seeds being rich in oil might be systematically collected and sold by the planters as an additional source of revenue.

Nurseries.—The sowing is now almost universally made in nurseries. The seed, sometimes previously germinated, is deposited at either 4 or 6 inches apart and 1 inch deep. A piece of particularly good land is chosen, and formed into beds from 3 to 5 feet wide. Such a nursery must be well drained and very careful attention given to the preparation of the soil, which should be raked as for a flower-bed. If previously under tea culture, the land must be richly manured with cattle-dung. If the situation is hot and dry, the beds should be covered with grass immediately after sowing; in any case water must be accessible for watering the nurseries. Forty pounds of seed may be expected to give about 10,000 plants, and will put about 2 to 2½ acres of land under tea. As soon as the young plants are visible above the surface, the beds should be shaded by raised frames covered with grass or mats, be frequently weeded, and, if the weather be dry, watered in the evenings. As a rule, the plants sown in the nursery in November or December can be planted out in the following May or June (six months old planting), or when a year old in the following November or December.

Preparation of Land.—In order to ensure a good result, it is necessary to bestow much care on the preparation of land for tea. If it has previously been under forest, the whole of the trees should be cut down, the stumps removed as far as possible (since many of them are liable to cause root disease in the tea), and the land hoed carefully all over. If grass land is to be planted, the roots should be carefully removed when the land is being hoed up. If hillsides are to be put out, it is advisable to arrange before planting for terraces, running along the contour of the slopes. If stones exist in the soil, they should be brought to the surface and utilised in making the terraces. On level land the lines of drainage should be arranged, and, where necessary, narrow drains, 3 feet deep, put in before planting out the tea.

Planting Out.—These arrangements having been completed, planting can be commenced. In order to secure regularity, lines must be marked out and the seedlings placed at definite distances apart along these lines. What these distances should be varies with the type of plant, the richness of the land, and the method of planting. Speaking generally it is not wise to put the plants nearer than 4 feet apart in any direction, nor wider than 5 feet apart. If planted in rows at right angles to one another (square planting), this means in the one case 2,722 and on the other 1,742 plants per acre. Four and a half feet apart is perhaps the most generally advisable, equal to a little over 2,000 plants per acre. In recent years it has become usual to plant in rows at an angle of 60 degrees to one another (triangular planting), thus making the plants equi-distant from each other. In this case a distance of 5 feet between the bushes gives a number of plants per acre about equal to that obtained at 4½ feet apart in square planting, and is thus to be preferred. When the spacing and condition have been decided upon, lines should be formed, and stakes
THE TEA PLANT

Period of Transplanting.—Planting may be done either when the seedlings are 6 months old or when they have been in the nursery for a year. Under ordinary circumstances 6-months planting is gradually being more and more adopted. Under this system the plants are taken from the nursery when 4 to 8 inches high, and have a small ball of earth 6 to 8 inches deep attached. They are conveyed to the holes which have been made ready, as above described, but if the ends of the tap-roots are seen protruding or bent they are either straightened or nipped off. Each ball of earth with its plant is then placed in the centre of a hole, loose earth filled in all round, and rammed down moderately. If the rain follows immediately the only attention required afterwards will be to see that weeds are cleared all round the plants, and that the surface earth is kept loose. If rain does not come at once, the plants will need watering. If planting be done with older seedlings in November or December it is necessary to have a very much larger block of earth (at least 12 inches deep and 6 inches in diameter) attached to the root, and correspondingly larger holes in which the seedlings are to be deposited. In this case, as the planting takes place in the dry weather, a considerable quantity of water should be given, and a mulch of dry grass placed around the plants.

Rules. In planting, according to one of the best and most recent authorities (C. Bald, *Ind. Tea, its Culture and Manufacture*, Calcutta, 1903, 60), the following rules should be observed, viz.:

"(a) The end of tap-root may be cut clean off, but it must not be bent or doubled up.

"(b) The plant must be placed so that the collar is level with the surface of the ground. If placed too high, some of the roots will be exposed; if too deep, the bark of the stem will be injured by being buried. The plant should be at the same depth in the ground as it was in the nursery.

"(c) The laterals should be spread out, not driven into a clump round the tap root."

Drainage.—Mention has already been made of the necessity for drainage on most tea soils. On the flat or nearly flat land, the drains should be at least 3 feet deep, as narrow as possible, banked up a little on the sides to prevent the water running off the surface into the drains, and should follow the natural course of the drainage of the land. For ordinary tea soils they should be from 30 to 60 feet apart. On slopes the object of the drains is not only to cause percolation of the water, but also to prevent wash of soil. They should hence run along the contour of the land, and be slightly banked up on the upper side. At intervals, main drains (running down the slope and thus crossing the contour drains) will be required to carry away the water. [Cf. Mann, *Treat. Deter. Tea in India*, *Tea Assoc.*, 1906, No. 4, 8–12.]

Hoeing.—In all the districts of Northern India it is found that careful hoeing of the land is needed from the early days of the plantation, both in order to prevent the growth of weeds and to keep the surface of the land loose. With young plants the principal cultivation (apart from
GREEN MANURING

keeping the weeds down) is done by frequent loosening of the soil to a depth of 3 inches and for a distance of 12 inches round the bushes. Among tea more than 2 years old, the following hoeings may be said to be usually required:

(a) A deep hoeing at the commencement of the annual dry weather—at least 8 inches deep—should be given. This preserves the moisture in the lower layers of the land, during the drought which follows, as well as softens the soil and thus prevents the formation of a hard pan near the surface.

(b) From 4 to 6 light hoeings per annum. Each of these loosens the soil to a depth of about 4 inches. They should take place at intervals of about 6 weeks.

In South India and Ceylon, owing to the extremely granular character of the soils, and to the fact that there is no long season of drought such as is experienced in Northern India, much less cultivation of the land is done than that above recommended, the hoeing being replaced in a great measure by hand-weeding.

Manure.—Manuring is not usually needed for some years after a plantation is started. Nitrogenous fertilisers are then principally required, best in the form of organic manures, and nothing is better than cattle manure, if it can be obtained. The cattle manure generally to be had in India is extremely poor, and so twenty tons per acre would not be an excessive dressing. Little more than a third of that quantity of good stall-fed dung would be of equal value. With the cattle manure all the waste materials of the tea estate, such as the wood-ashes (if wood is burnt in the factory), the thatch, the sweepings from houses, etc., are mixed and heaped together in special manure sheds and thus made ready for use. This so-called cattle manure is best applied early in the year, before the first hoeing of the season. In default of cattle manure, oilcake—usually from castor or rape seed—has given the best results, and is now used largely both in the districts of North and South India. It is commonly applied broadcast, at the rate of about half a ton per acre. In Ceylon a good deal of artificial manure—chiefly superphosphate and basic slag with or without sulphate of potash—has been and is being used, but the application of such manures has been elsewhere on a very limited scale. [Cf. Pests and Blights, etc., 119-34; Mann and Hutchinson, Heeleaka Exp. St., Assam, in Ind. Tea Assoc., 1907, No. 2.]

In recent years very good results have been obtained by green manuring. The plant chiefly employed in North India has hitherto been Phaseolus Mungo, which is sown broadcast in April or May at the rate of 40 lb. of seed per acre, and is hoed into the land after 6 to 8 weeks. Other plants have been suggested for the purpose, and from recent experiments it seems probable that good results may be obtained with Crotalaria striata and Sesbania cannabina. In Ceylon the best returns have been given by the use of Crotalaria striata as a green manuring crop, but the ground-nut (Arachis hypogea) has also been employed. Stumps of the dadap tree (Erythrina littosperma) have been planted and the growth periodically pruned off and buried. It is essential, however, that the stumps should not remain in the tea for more than one year, as otherwise they are very apt to cause stump-rot, due to the fungus Rosellinia radiciperda. The leguminous bush Tephrosia candida has been used similarly in India, but this is grown from

seed, and the bushes retained in the land for 3 years. [Cf. Mann and Hutchinson, Green Manuring in Tea, l.c. 1906, No. 2.]

Certain trees growing among tea are found to be beneficial. The best of these is *Albizia stipulata*, but *Dalbergia assamica* has given similar results. These are planted from 40 to 60 feet apart throughout the garden. The lower branches are annually removed, so that the shade given may be as light as possible. [Cf. Pests and Blights, etc., 136–47.]

**Pruning.**—The pruning of tea is an extremely technical process which can hardly be adequately described in a general notice such as the present. In nearly all the Indian districts it is an annual operation, and in North India is always carried out between December and March. In South India and Ceylon the time is not nearly so fixed, but if possible it should be always done during the non-growing period of the plant. Commencing with a tea seedling, one of the best systems of pruning on the plains of India is perhaps as follows:—After the tea seedlings have been on the ground 1 to 6 months (according to whether they have been planted out at a year old or at 6 months old respectively) they should be cut down in December or January. If of the “Assam” indigenous type this should be not lower than 6 inches from the ground; if of the “Manipur,” 6 to 8 inches. Each plant ought then to be thrown out, from the stump, 3 or 4 stems, which are allowed to grow for 2 years before being pruned again. Then when they are 3 years old from seed, they are cut at 14 to 18 inches from the ground. After this, each year’s pruning will be at a point from 1 to 2 inches above that of the previous year (light pruning), until the yield begins to diminish, when it will be necessary to cut back to 12 to 15 inches from the ground (heavy pruning). This ought not to be necessary till the bushes are more than 10 years old. At a later age, if the bushes are found to give a very low yield, it may be necessary to go even lower than this, and even in extreme cases to cut the bush down level with the ground (collar pruning), but this should not be necessary till after many years, if the garden be properly cultivated, manured and plucked.

In light pruning it is important:—

(a) To leave only a small length of new wood, say not more than 2 inches all over the bush.

(b) To cut the shoots at the sides of the bushes to the same length as those in the middle.

(c) To remove everything which is not likely to yield a new vigorous shoot in the following season. For example, remove all dead branches, all gnarled twigs and crow’s-foot formations (clumps of imperfectly formed shoots), all trailing shoots on the outside of the bush, and all small useless twiggy shoots throughout the bush.

At high elevations growth is very much slower than in the plains, and heavy pruning will naturally be much less frequent than under ordinary conditions. And moreover there appears no doubt that growth made immediately after heavy or collar pruning gives a much lower grade of tea than can be obtained after light pruning. As the tea grown at the high elevations of hill districts usually depends for its commercial success on its high quality, heavy pruning is generally avoided as far as possible. [Cf. Pests and Blights, etc., 78–100; Mann, Exper. Heavy Pruning in Assam, in Ind. Tea Assoc., 1907, No. 3; also Factors Deter. Quality of Tea, l.c. 1907, No. 4, 17.]

226
SEASONS OF PLUCKING

Plucking.—The annual course of plucking, after light pruning, is about as follows:—When the tea has been pruned, new shoots begin to grow, and after 2 to 3 months have attained a length of 9 inches or more. At this stage the bushes can be “tipped,” that is to say, the first lot of leaf may be taken off, the object not being so much to get the leaf as to force the production of secondary shoots on the plant. This “tipping” should be done when there are, on the shoots of the centre of the bush, on the average 6 leaves, without counting either the unopened tip-leaf nor the so-called “janum” leaf (really a bud scale) at the base of each shoot. Then the topmost two leaves may be plucked off, the plucking being done not by pulling, but by breaking (or nipping) the shoots with the thumb-nail. The level at which the average shoot, in the centre of the bush, is thus to be plucked is fixed, and it is a plan often followed to let the pluckers have a stick cut to the required height as a measure. Nothing is then plucked under this height at any part of the bush.

This tipping forces a secondary growth from the axils of the leaves on the original shoots, and after about 3 weeks the secondary growth is ready to pluck, the uppermost 2 leaves and the unopened bud only being taken, and 2 mature leaves left on each of these secondary shoots. This plucking brings about the growth of a third series of shoots which rise from the axils of the leaves on the secondary growth, and on these one mature leaf is usually left behind when plucking the youngest “two leaves and a bud” as before. A fourth, fifth, sixth and seventh series of shoots arise in similar manner, and are known as “flushes.” Eight distinct series of shoots is usually the largest number given by bushes in one season.

In the early part of the season the pluckings are almost coincident with the growth of the “flushes.” After this they are much more frequent, and bushes are usually plucked from 20 to 30 times during the year, at intervals of from 7 to 9 days, during the greater part of the season. As has already been said, 4 mature leaves ought to be left on an average shoot in the first plucking, and nothing plucked below this level in the bush. The use of a levelling-stick is often continued for the first three or four pluckings of the season in order to prevent the premature plucking of the weaker shoots. Two leaves should be left behind in plucking the secondary growth, and one leaf in the next few pluckings at least, after which the shoots can be safely plucked as they grow. [Cf. Mann, Factors Deter. Quality, in Ind. Tea Assoc., 1907, No. 4, 19 et seq.]

Premature Plucking.

Seasons.—It is essential to leave plenty of growth below the plucking-level in the earlier part of the season, and especially so after any heavy pruning. The growth and health of the bush are only secured by allowing abundant leaf to remain. Many fine tea estates have been seriously damaged by plucking off too much of the spring growth.

In Assam, and in fact North-East India in general, plucking commences about the end of March in each year. July, August, September and the first half of October are the months of greatest yield. After that time the crop gradually diminishes, and in Upper Assam plucking ceases for the season about the middle of December, while in Sylhet it may continue till the new year. The yield at each plucking during the height of the season from good yielding mature tea may go up to about 120 lb. of leaf per acre or even more, giving about 30 lb. of made tea. [Cf. Pests and Blights, etc., 101-18.]
THE TEA PLANT

Yield.—The object of the tea-grower is to get the maximum number of young shoots on the bushes in each year, as it is only the two, three, or at most four youngest leaves on any shoot which can be made into tea. A very small leaf crop can be obtained, under the system of pruning already set out, in the second year after planting; in the third year about 150 lb. per acre ought to be obtained, if in the plains. By the sixth year the tea (on the plains) is yielding a full crop, which varies, according to the soil, from 400 to nearly 1,000 lb. per acre per annum. Any crop above 700 to 800 lb. per acre is very abnormal, and due to special conditions. The average on the plains of India is rather under 500 lb. per acre.

Deterioration of the Tea Plant.—This subject has been so fully dealt with in recent publications that it may suffice to give a reference to the literature. [Cf. Watt, Pests and Blights (1st. ed.), 155-60; Mann, Treat. Deter. Tea in Ind., Tea Assoc., 1906, No. 4; also Renov. Deter. Tea, in Agri. Journ. Ind., 1906, i., pt. ii., 85-96.]

Enemies of the Tea Plant.—The tea bush is attacked by quite a legion of pests and blights, but owing to the fact that the tea crop is a continuous one for 8 or 9 months in the year, it is rare indeed that it is wholly destroyed. In the worst cases the yield is reduced possibly 20, 30 or even 40 per cent. In spite of this fact the damage done is in many cases extremely serious. For a complete treatment of the enemies of the tea plant the reader is referred to technical publications (more especially the Pests and Blights, etc., 165-416). All that it is possible to attempt in this work is to furnish a list of the more serious pests and blights.

Red Spider.—The pest which is almost always the first to appear in a garden is the “Red Spider” (Tetranychus bioculatus, Wood-Mason), a small red mite which sucks the leaves in the hot, dry weather of April, May and June, and afterwards, if dry weather continues. This leads to the checking of the growth and the weakness of the new shoots, and, hence, loss of crop as well as thinner and less vigorous wood as a basis for the next year’s growth. The use of sulphur, applied by dusting on previously wetted bushes in February and March, is becoming very general as a means of counteracting this pest. [Cf. Pests and Blights, etc., 348-59.]

Mosquito Blight.—The insect which causes by far the greatest damage to tea in India is, however, the so-called Mosquito Blight (Helopeltis theivoria, Waterhouse). The losses due to this pest may be put down at 7 or 8 lakhs of rupees per annum. The insect itself is a capsid plant- bug, which passes the whole of its life-history on the tea bush, feeding on the leaves. It works by puncturing the youngest leaf and sucking the juice. The leaves thus quickly become a mass of brown, dry and withered material. It can be apparently combated and almost entirely eradicated from isolated gardens by spraying the bushes soon after pruning with kerosene emulsion and having a squad of children catching the insects throughout the year. Such a method is expensive, but has well repaid the cost on estates where mosquito blight has been serious. [Cf. Pests and Blights, etc., 247-85; Mann, Variations in Helopeltis theivora, in Mem. Dept. Agri. Ind. (Entom.), i., No. 4.]

Green Fly.—The growth of the shoots on the tea bushes is often greatly retarded in the early part of the year, apparently by the activity of a jassid bug (Chlorita flavescens, Fabr.) known in the tea districts by the unfortunate name of the “Green Fly.” It seems to completely
PESTS AND BLIGHTS

stunt the second, third and fourth flushes of the season chiefly, but has the compensating consideration that the tea made from shoots so stunted is invariably of higher quality than when they grow freely. No method of dealing with this pest has yet been devised. [Cf. Pests and Blights, etc., 286-92; Mann, Factors Deter. Quality Tea., Ind. Tea. Assoc., 1907, No. 4, 16.]

Caterpillars.—The number of caterpillar pests of the tea plant is very great, those of the Psychidae and Limacodidae being perhaps the most numerous and most injurious. Little more than systematic catching has been attempted against these. Scale insects are of little or no importance in the plains, but become serious at higher elevations. The brown coffee-bug (Leconium hemisphericum) has done serious damage in the Nilgiris, while in the north of India the most common species are Chionaspis theae, Erichthion theae, and Carteria decorvella. [Cf. Mann and Antram, Red Slug, in Ind. Tea Assoc., 1906, No. 5.]

Red Rust.—Among blights of vegetable origin perhaps the most serious and widely distributed is the so-called “Red Rust,” caused by an alga (Cephalotus virescens, Kunz.), which attacks tea of deficient vigour almost everywhere and kills nearly all the shoots on which it occurs. [Cf. Mann and Hutchinson, Red Rust—a Serious Blight of the Tea Plant, in Ind. Tea. Assoc., Calcutta, 1904, No. 4.] Its treatment consists largely in increasing the vitality of the bushes by manuring, better drainage, and improved methods of pruning and plucking, but in serious cases Bordeaux Mixture, applied to the bushes immediately after pruning, is also advised. [Cf. Pests and Blights, etc., 396-408; Mann and Hutchinson, Red Rust of Tea, in Mem. Dept. Agri. Ind. (Botany), 1907, i., No. 6.]

Fungal Blights.—Thread Blight, caused by a fungus (Stilbnum nanum, Massee) on the leaves and twigs of the bushes, has done considerable damage to individual plants, but can be got rid of by treatment with sulphide of lime (made by boiling lime and sulphur together in water). Grey Blight (Pestalozzia guepini, Desmaz.) is the most serious leaf-blight of the tea plant, and is very generally distributed. Blister Blight (Exobasidium vexans, Massee), another fungus which attacks the leaves and green shoots, is fortunately restricted to a small area at present in Upper Assam (Mann, Ind. Tea Assoc., 1906, No. 3). Tea Canker (Nectria sp.) destroys both young and old tea stems, more especially in damp situations. Lastly, Root Rot (Rosellinia radiciperda) causes the death of large numbers of bushes, more particularly round the dead stumps of certain trees.

Having dealt with CULTIVATION as fully as the available space will allow, it is now necessary to consider the methods presently adopted for the manufacture of the leaf into the commercial article Tea.

MANUFACTURE OF TEA.

The methods pursued have undergone a complete change in practice, if not in principle, by the introduction of machinery. Previous to 1860, and almost entirely previous to 1870, hand labour was exclusively employed to prepare the leaf for market; now (except for an occasional garden at the commencement of the season) the whole work is done by machinery, much of which is largely automatic. The machines used for the several processes in Black Tea preparation have been produced by three or four inventors, and the names of Kinmond, Jackson and Davidson

almost entirely cover the field. It is not proposed to describe here the older methods of tea manufacture by hand, since these can be found in many of the books already referred to, but we shall limit attention to those at present in vogue. [Cf. Watt, Journ. Roy. Hort. Soc., 1907, xxxii., 90-3.]

Grades of Tea.—The tea-leaf when plucked may be manufactured into various classes of tea. Black Tea, at present, absorbs almost the whole of the leaf produced in India. The preparation of Green Tea has made, however, considerable progress in the past five years, largely owing to the invention of special machinery for its production and partly to the depressed prices obtainable for Black Tea. An effort has recently been put forth to introduce the manufacture of Oolong teas into India, but so far with no success. A small quantity of Brick Tea is made by a few estates in Darjeeling and Kumaon, for the Tibet and Bhutan market. “Letpet” or Pickled tea is prepared in Burma and on the hills lying between that country and Assam. These various grades of tea may be separately dealt with:

1. Black Tea.—Withering.—The leaf, plucked as already described, is brought in from the estate, and immediately spread as thinly as possible in a cool and shady house on trays of hessian, bamboo, or wire netting to “wither.” In the colder hill districts this operation is nearly always conducted in lofts, situated over the factory itself, which can be closed and warmed with hot air. In the plains similar lofts, fitted with fans to draw the air over the tea, are sometimes used, but the general consensus of opinion seems to be that when such lofts are used to shorten the withering by raising the temperature above 80° F., the quality of the tea invariably suffers. In the districts producing the best-grade tea (Upper Assam) the withering is almost entirely carried on in houses open to the outside air. Lofts in which hot air can be introduced are, however, very useful in ensuring that the withering is completed within a reasonable time, for the leaf must wither until it is flaccid, and if this takes too long, the tea is always inferior. At a temperature of 80° F. the ideal time required for withering is about 20 hours; if delayed beyond that time a lower-grade tea is almost inevitable. If not flaccid at the end of the withering time it is a common custom to allow the leaf to remain for thirty hours, when it must then be taken away and rolled. The process of withering is a very important one in tea manufacture; if well carried out, the amount of tea ferment (enzyme), which afterwards causes the change in the leaf termed “fermentation,” nearly doubles in quantity during the operation; the soluble matter in the leaf considerably increases as well as the tannin, to which the pungency of the finished leaf is due.

Rolling.—When, by withering, flaccid leaf has been produced, it is ready to roll. This operation was formerly carried out by placing the withered leaf on a table, where it was rolled to and fro under the pressure of the hands, till the juice was pressed out on to the surface of the leaf, and the material well twisted. As the pressing out of the juice from the cells into contact with the air is the essential part of the process, it was soon apparent that a machine might be devised which would bring about this result and allow of a much larger amount of leaf being treated at once. Hence during the last forty years there has been invented a constant succession of machines. The earlier ones, by trying too closely to imitate hand rolling, were many of them cumbersome and unwieldy, but
gradual improvement has taken place, and those now in use leave little to be desired except the making of the process continuous. In principle, all the machines work by rubbing the leaf between two surfaces either rotating in opposite directions or working at right angles to one another. In some cases the pressure on the top of the leaf is supplied by the weight of a large quantity of the leaf itself; in others, and more commonly, by a special heavy lid to the machine. By raising or lowering this lid, the pressure on the rolling leaf may be altered, and the amount of juice expressed diminished or increased. Other things being equal, the lighter the rolling the more juice remains in the cells, and a pungent light-liquoring tea is obtained, in which the whitish colour of the immature tip-leaf is only slightly stained, thus giving a pretty-looking tea, full of "golden tip." If the rolling be hard, much juice is pressed out, the golden tips largely disappear, and a much darker liquor is afforded by the finished tea, but one with more "body" and less pungency. The time taken by this operation varies from a quarter of an hour to an hour or even more. Often the rolling is partly carried out, and the leaf is then sifted through rotating sieves. The finer portions (containing most of the golden tip) are not again put in the machine, while the coarser portions are subjected to rolling under a greater pressure.

The juice has been brought into contact with the air by rolling; now occurs the so-called "fermentation." Before the rolling is completed the edges of the leaves and the ends of the stalks have begun to change from a green to a brown colour, and to take on an altered smell. This is the commencement of the fermentation, which is allowed to go on from two to six hours according to the conditions. For this purpose the rolled leaf is spread out about one to two inches thick in a moist, cool, darkened room, under conditions of the greatest cleanliness possible, and allowed to remain there. The material quickly becomes brown, and commences to smell like finished tea. The end of the operation is judged by the eye and the smell, and requires a good deal of experience to decide. The final product should be coppery brown in colour, like a new penny, and should have quite lost its leafy smell, taking on, as has already been said, that of finished tea. The changes which take place during the fermentation are still very obscure, and it will be better to leave their discussion till a little later (see p. 238).

**Firing.**—Fermentation finished, the leaf must be dried or fired as quickly as possible. Formerly the firing was done over clear charcoal fires; now machines which make use of a current of hot air are exclusively employed. The earliest invented simply placed the leaf in trays through which a current of heated air passed, by natural draught, and as each tray was dried the material was removed and replaced. Now such machines are chiefly employed for finishing the tea-firing, and the greater part of the work is done on large automatic machines working with strong currents of air induced by fans. They are capable, some of them, of drying as much as two hundred pounds of finished tea per hour. The machines used for this purpose are simple in construction, and though ingenious, do not embody any new principle of drying. The "firing" is usually commenced at a high temperature, the air entering the machine being often kept at from 220° to 240° F., though naturally the drying leaf itself never reaches this temperature. After the drying is about three-quarters completed, a somewhat lower temperature is employed, from 180° to
200° F. It is essential that the whole drying should be carried out as rapidly as possible, since if protracted, much of the pungency of the tea is lost.

Grading.—After drying, the tea is graded. The marks known on the market are—"Orange Pekoe," "Pekoe," "Souchong," "Congou," etc. These are old Chinese terms, but now used somewhat loosely on the supposition that certain leaves on the shoot form the bulk of the grade named. Thus the unopened tip (bud) and the first opened leaf are generally supposed to constitute the "Orange Pekoe," the next in descent is the "Pekoe" leaf, and still lower the "Souchong" leaf. The grades, however, are now merely commercial terms which have little relationship to any particular leaves. There is a corresponding class for the fine particles or so-called "Broken" leaf of each grade, which generally gives a stronger tea than the grade itself, and is hence higher in price. The principal market names in use at present are:

In addition there is a grade known as "Fannings," composed of the very small and light fragments of leaf not capable of being placed under any of these names, and "Dust," the extremely fine portions got out by sieving through a fine-mesh sieve, but even this has still a market value.

In the *Kew Bulletin* (June 1890, 109-2) will be found particulars of the Hankow manufacture of the compressed tablets of the common tea-dust. These are said to be used throughout Russian Siberia.

These various grades are obtained from the tea just after being fired and by systematic sieving through sieves of various sizes, generally machine driven, coupled with the passage of the tea through "breakers" or "equalisers" in which the coarser leaf is broken down to a uniform length. After sorting in this way, each grade is packed separately in wooden boxes lined with sheet lead.

**Tea Boxes.** *Packing and Tea Boxes.*—Almost all the woods found in the tea districts have been used at one time or another for making tea boxes. Teak has even been imported from Burma for that purpose. For a long time *toon* or *poma* (*Cedrela Toona*) was the favourite, but as this became scarcer inferior woods have had to be employed. In the Brahmaputra valley practically the only timber now used locally for box-making is *semul* (*Bombax malabaricum*); in Sylhet and Cachar a greater variety is still employed, most being cut in the forests of the Lushai and Manipur hills and floated down the rivers to the saw-mills. There is, however, an increasing tendency to import boxes from other countries, even from China, Japan and Sweden—chiefly pine. Some patent boxes, made of Russian pine in three layers cemented together in opposite directions to the grain, have in recent years become popular under the name "Venesta," "Acme," "Columbia," etc. Their chief objection is their high price. Steel chests were introduced some years ago, but have been abandoned. It may be mentioned that the wood of which the chest is made is by no means a matter of indifference. Some timbers have the reputation of tainting the tea placed in them, giving it a so-called "cheesy" flavour, and quite a large number of timbers can only be used after long seasoning under water. Chests are always lined with thin sheet-lead, carefully
soldered. It is of the utmost importance that the package should be as airtight as possible, since tea is exceedingly quick in absorbing moisture from the air (up to the amount of 16 to 17 per cent.) and then becomes rapidly mouldy and useless. Before packing, each grade of tea is always refired at a temperature of 180° to 200°F., and packed while still just warm. As put in the boxes, it commonly contains from 2 to 3 per cent. of moisture.

2. Green Tea.—For many years the manufacture of Green Tea in India may be said to have died out except in the Kangra Valley and in Kumaon. It was formerly made in some quantity, but black tea being the more marketable article, the green gradually ceased to be manufactured, especially after the introduction of machinery, since no apparatus had been devised for green-tea manufacture. While the object aimed at in preparing black tea is to change the materials in the leaf, by fermentation, the green colour becomes brown or black, the astringency is reduced, and the aroma altered in character; in manufacturing green tea, the aim is to prepare the leaf without any alteration taking place.

Fermentation Prevented.—The first operation in manufacture is, always, therefore, to heat the leaf, immediately it is received from the pluckers and without any withering, so as to destroy the ferment (enzyme) and prevent any after-colouring of the leaf, and at the same time to bring the leaf into the soft condition required for rolling. When small quantities are dealt with, this result is obtained by panning. The pan is a large cast-iron basin 2 feet wide let into brickwork and with the hinder part about 1 foot higher than the front. This is heated from below. When the pan is ”roasting hot” a small quantity of leaf is thrown into it and kept tossed about by hand so that no portion is allowed to rest on the hot iron long enough to get singed. When soft enough it is slightly rolled by hand, then panned again, and so panned and rolled alternately until the edges of the leaf become very slightly crisp. The leaf thus prepared is then dried off as quickly as possible, by methods and appliances similar to those described for black tea.

Where large quantities of leaf have to be dealt with, machines have recently been invented by means of which the panning operation is replaced by a steaming of the leaf, under pressure, in a rotating cylinder. The steaming must be very short or the leaf gets a boiled-cabbage appearance and is then useless, and yet it must be treated long enough to ensure the destruction of the ferment. About 1 1/2 to 2 minutes under a steam pressure of 20 lb. to the square inch is generally sufficient. After steaming, the excess of water is usually got rid of in a centrifugal machine, though much juice is lost at the same time. Then the leaf is rolled slightly in machines similar to those used for black tea. The rolling must only be slight, for broken grades are almost worthless in green tea. It is immediately thereafter dried off as rapidly as possible.

In order to obtain a green appearance in the final product it has been customary in China to “face” the tea by rubbing it, when finished, in a hot pan with a small quantity of indigo and gypsum or other similar mixture. In Kangra the Native manufacturers use a small quantity of greenish-coloured soapstone for this purpose. But the employment of such materials is to be deprecated, and a very fair finished surface can be given to the tea by rubbing it in a hot pan alone without any foreign material, which only too frequently assumes the condition of an adulterant.
Grades of Green Tea.—As already stated, in grading green tea "broken grades" are worth very little. The grades (as with black tea) are given Chinese names:—"Young Hyson" is the finest part of the tea, principally made from the youngest leaf on the shoots; "Hyson No. 1" corresponds with Pekoe among black teas; and "Hyson No. 2" is a coarser grade. "Twankay" is composed of the flat broken fragments of the coarser leaves; "Gunpowder," which has the appearance of balls about the size of small peas, is formed by the smaller leaves (which are very sticky after panning, and hence adhere together and so form themselves into small balls during rolling). The packing is similar to that for black tea.

Speaking of green tea, the following passage from Vigne (Trav. Kashmir, Ladakh and Iskardo, 1842, ii., 265) will be found interesting: "Tea, made or rather boiled with water, as in Europe, is called Moguli chá, or the tea of the Moguls, as they call the Persians. But Tibeti chá, or tea as made in Tibet, is a very different composition, for which the following is the recipe for a party of five or six people: a teacupful of the finest green tea is put into three pints of water, and upon this is strewed a large spoonful of soda, and all three are boiled together. About a pound of fresh butter or ghi, and a pinch of salt, are then placed at the bottom of the milling churn, and part of the boiling contents are poured out and milled like chocolate; a little cream or milk is then added to what has remained in the saucepan, and on this the milled tea is poured and boiled again, and part of it again transferred to the churn, and so on till it is all properly milled. All that then remains to be done is to strain it through a clean cloth. Much depends upon the quality of the tea, and the manner of making it. I have nowhere drank it so good as with Ahmed Shah. It was always made before or after a march, and on a cold morning I found it, after a little time, quite as palatable as tea made in the ordinary way, and far more nourishing. When well made, it resembles chocolate in appearance, in consequence of the reddish tinge imparted to the tea by the presence of the soda, which prevents it also from cloying. Sutu, or the flour of roasted barley, is frequently eaten with it."

3. Oolong Tea.—So far no oolong tea has been made in India; its manufacture is a speciality of Formosa, though also made in China and Japan. But Formosa oolongs have a recognised place on the tea market, principally on account of a very characteristic and much-desired flavour. Commissioners were sent from both India and Ceylon in 1904 to ascertain the methods by which this was produced. They reported that the flavour was principally due to the particular variety of plant grown. But that variety was not to be recommended on any other ground, as the yield was small, the plant was difficult to grow, and could only be satisfactorily propagated by layering. The manufacture was quite special in character, and in essentials was carried out as follows:—On the leaf being brought into the factory at midday, it is put out in the sun to be warmed, first spread thinly and then thicker, for twenty minutes to one hour. The leaf so treated is taken into a house and spread on bamboo trays in a layer about 3 to 4 inches thick. At intervals of 15 minutes it is collected together and shaken up with the hand. With this treatment continued for two hours a change occurs in the smell of the leaf, and a tinge of brown takes place on the softer leaf and on the edges of the others. When the discoloration has spread over the softer leaves in spots, the tea is ready.
OOLONG, BRICK AND LETPET TEAS

CAMELLIA THEA

Manufacture

Panning.

Brick Tea.

Manufacture of.

Panning.

Rolling.

Long Fermentation.

Manufacture.

Letpet Tea.

The process is carried out by keeping the leaf constantly and evenly on the move in a pan about 2 feet in diameter, retained at a temperature of 360° to 400° F. and for about 10 minutes. Rolling follows, and finally firing in the small charcoal stoves used universally in tea manufacture in China and Japan. For further particulars the report of the Indian Commissioner, Mr. J. Hutchinson (Cult. and Manuf. of Formosa Oolong Tea, Calcutta, 1904) should be consulted.

4. Brick Tea.—Hitherto little attempt has been made to manufacture Brick Tea in India, though it is the staple of the Central Asian trade. In view of the possibility that this trade may be opened up in the near future, a careful investigation was made in 1905 of the methods employed in Western China by a special commissioner sent by the Indian Tea Association to the districts in which it is produced. He describes in his report how it can be made either from the young shoots (as with black tea), which gives the highest quality of brick, or from coarse leaf with many stalks and twigs. In some cases, indeed, stalk and twig predominate in the material used.

The manufacture involves (1) Panning, in pans as described under green tea, kept at such a temperature that the leaf emits a sharp crackling sound, due to the bursting of the cells as it is rubbed over the surface. This operation takes from 6 to 10 minutes. (2) Rolling.—This process is carried out by hand in the usual manner, only light rolling, however, being done. (3) Fermenting.—Here the peculiar part of the manufacture comes in, for the leaf spread in heaps 3 to 4 inches deep is allowed to ferment for 3 to 4 days, the temperature rising in the meantime to 105° to 115° F. The resultant product is then dried in the sun. After preparation it has to be formed into bricks, and for this purpose it is first steamed over a boiler (5 lb. at a time) for 2 to 3 minutes, and will then have a temperature of 150° to 170° F. If few stalks are mixed with the leaf it will be found that a fairly firm brick may be turned out without any addition; if not, a mixture of boiled glutinous rice-flour is necessary to give sufficient adhesiveness. The whole is then put into a wooden mould of suitable size and shape and pounded down lightly with a wooden rammer weighing 17 lb. Several bricks are, usually, put in the same frame, separated by a layer of bamboo matting. The whole frame when filled is put aside for several days to set and dry; after which the bricks are taken out, trimmed, wrapped in paper, and put back into the case again. The bricks usually made are 10½ inches in length by 4 inches thick. [Cf. Horace Della Penna in Markham, Journ. of T. Manning to Lhasa, 1879, 119, 317.] The manufacture of brick tea differs in quality and material rather than in principle from the compressed tablets of tea-dust to which reference has already been made.

5. Letpet or Leppett Tea and Lao Mieng Tea.—The manufacture of this kind of tea is peculiar to Burma, the Shan States and some of the hills lying between Assam and Burma. A fairly complete account of this whole subject of its production will be found in the Kew Bulletin (1896, 10) and in The Agricultural Ledger (1896, No. 27, 235–66). There seem to be two ways of preparing it, as follows:—The leaves are first thrown into boiling water and allowed to remain for a short time or until they become soft, then are taken out and rolled by hand on mats and allowed to cool. The process which follows consists in ramming the leaves down tight into the internode of a bamboo (the
CAMELLIA
MANUFACTURE

"Wabo"), a wooden ramrod being used for the purpose. A stopper is then made of jack or guava leaves, and the bamboos thus charged are then kept in the shade for a couple of days with the stoppered ends downwards to allow of any water there may be within to drain off. The bamboos are not filled up quite to the top with letpet, and in the space thus left ashes mixed with a little water are now filled in. The object of the ashes is to prevent insects getting to the tea. The bamboos are now buried underground till the letpet has matured and is required for sale. If not buried the letpet becomes black and spoilt; to be good it should be of a yellowish colour. It is carried to market for sale in bamboo baskets of open wicker-work (kyin) lined with leaves. The tea is taken out of the bamboos, filled into the baskets, and pressed down tight so as to prevent air injuring it.

The above is the method in vogue west of the Irrawaddy. East of that river the method seems to consist in steaming the leaf and then rolling by hand. After this the leaves are allowed to cool and are then deposited in a pit, lined with planks or bamboo matting, and covered over and pressed down by heavy weights. The pit is not opened till a purchaser turns up to buy the whole pitful, but when opened the letpet tea is removed in bamboo crates.

[It may be useful to amplify Dr. Mann’s account of this tea (above) by a few quotations and observations:—The earliest mention of it (apparently) is in Hamilton’s *New Account of the East Indies* (1688–1722, pub. 1727, ii., 62), where he says, “They never leave mediating till there be a reconciliation, and, in Token of Friendship, according to an ancient Custom there, they eat Champock from one another’s Hand, and this seals the Friendship. This Champock is Tea of a very unsavoury Taste; it grows, as other Tea does, on Bushes, and is in use on such occasions all over Pegu.” Crawfurd, Ferrars, Nisbet, etc., all speak of its use at ceremonials.

The account given by Mr. C. E. W. Stringer (*Kew Bull.*, 1892, 221) of the manufacture of Mieng or Lao Tea in Bangkok does not differ in any material sense from the practice in Burma. These may therefore be described as Siloed teas, and their chief peculiarity may be said to be that they are eaten as a pickled vegetable and only rarely used as a beverage. Crawfurd says the leaves are elliptic, oblong, and serrated like the Chinese plant; and the Burmese, not following the practice of other nations, designate the latter by the native name of their own plant, Lap’het. There is little doubt, therefore, but that it is a genuine *Thea*, and most probably a native of the country. Crawfurd speaks of Wallich as his friend, and yet at the very time indicated the latter disbelieved in tea being indigenous in Assam. Crawfurd (*Journ. to Ava*, 1834, i., 199, 236; ii., 147, 214) says, “The Burmese eat the leaf prepared with oil and garlic, and never use the infusion as they do that of Chinese tea, which they call Lap’het-re, or tea water.” Ferrars (*Burma, 1900*, 65, 70, 72) speaks of pickled tea as made by the hill tribes to the north. Nisbet (*Burma Under Brit. Rule and Before*, i., 175, 446; ii., 191) observes, “In Upper Burma and the Shan States a good deal of this tea is consumed as a drink, for which purpose it is sold in a dry state. It is prepared by boiling it in an earthen kettle, and is drunk with salt. The greater bulk, however, is sold by the Mandalay brokers to merchants in Lower Burma, where it is largely consumed in the solid. The leaves are soaked in oil, a little garlic and dried fish, etc.,
added, and the concoction thus formed is eaten and considered a great luxury. Besides being regarded as a dainty, however, the "leppett," is a traditional food among Burmans. At the important junctures of a man's life, such as birth, initiation into the church, marriage and death, "leppett" plays an important part, and no ceremony is complete without the consumption of that article. The tea remains in the same basket from the time it is bought at the gardens until it is sold by the merchant to the actual consumer. Large numbers of baskets are to be seen at every wharf along the Irrawaddy banks and in the bazaars throughout the country."

It would seem probable, however, that in Burma the word *lapet* denotes *Camellia drupifera*, and that that species may possibly have been employed in the manufacture of *lepet* tea before the adoption of *C. Thea* as the preferable plant. Further, there appears little doubt that tea was first used as a medicine, then as a vegetable, and finally as a beverage. It was the discovery of this final property that gave the greatest impetus to the cultivation of *C. Thea* in China and Japan, and possibly also in Burma long anterior to any records of the introduction and cultivation of the plant in India. Symes (Emb. to Ava, 1795, ii., 255) mentions *leipa* or pickled tea, and Mason (Burma and Its People, 1860, 505) has a similar reference.

6. *Jyree Tea.*—Some few years ago a tea was much talked of in the public press as having special merits. This was found to consist of ordinary tea mixed with a certain percentage of the leaves of *Albizia amara* (see p. 45).

**CHEMISTRY OF TEA.**—Within the scope of this work it is neither possible nor desirable to give a detailed account of all the substances which have up to the present time been found to occur in the tea-leaf. The soluble materials combine to make the liquor produced by infusing the manufactured tea. But it may be observed that both the commercial and the hygienic value of tea as a beverage depend on three or four substances. The first of these is the so-called Essential Oil, the supposed cause of the flavour. It is impossible to deal with this substance here; briefly its character is all but unknown, its quantity remarkably small even in the most flavoury teas, for though Mulder (Poggend, Annalen, xliii., 133) obtained 0.6 to 1 per cent., no one since his time has been able to isolate anything like that amount. In fact it has been denied that he was dealing with the oil which was subsequently extracted by Van Romburgh (1895) by the distillation of freshly fermented leaves, the yield being only 0.006 per cent. It is a product of fermentation. The essential oil has, generally speaking, almost entirely eluded investigation. Its connection with flavour is well known, but the oil itself remains almost unexamined. [Cf. Gildemeister and Hoffmann, Volatile Oils, 1900, 501-2.]

The second of the important constituents of tea is the Caffeine or Theine, to which almost the whole of the stimulating power of the tea seems to be due. From a medical point of view it is the most important substance: from a commercial standpoint it appears to have little value. The higher-priced grades of tea certainly contain more caffeine than the lower, but this is simply because the younger leaves (which have a higher percentage) form the bulk of the finer grades. Given two Broken Orange Pekoes, however, the relative quantities of caffeine they contain will bear little or no relation to their prices.
Tea Refuse.

Tannin.

Estimation.

The total quantity of caffeine present in tea varies from 3 to 5 per cent., and this quantity undergoes no change during the processes of manufacture. On the other hand, the case with which it is extracted is by no means so great in the fresh leaf as in the finished black tea. Nanninga (Mededeelingen uit 'slands Plantentuin, 1901, xlvi., 3) gives figures, for instance, where the quantity extracted by the same method increased from 2.51 to 3.77 per cent. in passing from fresh leaf to fermented and finished black tea.

In this connection it might be pointed out that tea refuse is practically the only commercial source of caffeine. From this it is, however, produced at the rate of 30,000 lb. yearly, or thereabouts, the manufacture being carried on in England, Germany, France, and America. Recently successful attempts have been made to extract the caffeine on a commercial scale, from the tea on the spot in India, and it is probable that this manufacture, as an attachment to tea estates, may take a considerable development in the tea districts of the country.

The third constituent of great importance in the tea-leaf and also in the tea is the tannin. A great deal has been written of the evil effect of the tannin in tea, most of which is, however, not based on exact experiment, but rather on general impressions. Whatever be its physiological action it is certain that it is the constituent which gives tea its pungency, and, in its form oxidised during fermentation, it also imparts the colour to infusions of tea. In short, from a commercial point of view the value of Indian tea, in so far as it is determined by pungency and colour of liquor, varies with the quantity of tannin easily extractable by water.

The quantity of tannin is, however, very variable, and during manufacture alters to a very great extent. If we take the quantity extracted by water in ten minutes at 212° F. from finely divided tea as the standard, the following represents the reduction which normally takes place (as determined by bide powder) during the manufacture. All the figures are calculated on the dried material.

\[
\begin{array}{ccc}
\text{Tannin in leaf as rolled} & 15.51 & 16.90 & 16.98 \\
\text{Tannin in finished black tea} & 13.94 & 12.53 & 13.78 \\
\end{array}
\]

The colour of the liquor given by fermented tea is due to the oxidised tannin produced during the fermentation process, and in practice it always becomes a question of skilful management to know how far "to sacrifice pungency to colour"; in other words, how much of the tannin is to be allowed to oxidise during manufacture.

In a normal fermentation conducted below about 82° F., the oxidation, produced by the enzyme already mentioned, is a perfectly definite and complete operation. All the tannin pressed out of the cells and brought in contact with the air is oxidised in from four to six hours according to the temperature. The relative colour and pungency of the final product depend, if a complete fermentation is allowed, on the amount of rolling and hence of juice expressed. If the process is conducted much above 82° F., other oxidations take place, independent of enzyme action, and these give the tea a "stewed" taste, while rapidly lowering the tannin percentage without increasing the colour of the infusion. The explanation is probably that the fermentation of the tannin by means of the tea oxidase (enzyme) only carries the oxidation one stage forward, and though the
products are not as soluble as the original tannin, they are still fairly soluble, and have a brown colour. At higher temperatures still more deeply brown oxidation products are formed, much less soluble in water. The result is disastrous to the tea, and hence no fermentation should be conducted at a temperature above 80° to 82° F., if this is possible. [Cf. Mann, Ferment. of Tea, in Ind. Tea Assoc., 1906, No. 19, pt. i.; 1907, No. 1, pt. ii.]

The tannin present in the original leaf has been carefully examined and described by Nannings (l.c. 7). He found it to be a crystalline powder, so hydroscopic that an instant’s exposure to the air turned it into a yellowish-brown syrupy mass. It is not soluble in chloroform, benzine or petroleum ether, and very little in anhydrous ether. On the other hand it is very soluble in alcohol, acetone, or acetic ether. It has a very astringent, but not bitter taste. It is precipitated by copper sulphate and lead acetate. Ferric chloride gives a deep blue precipitate. It is optically active.

The other substances present in tea-leaf are of minor importance. A trace of gallic acid can always be found, as well as quercitrin. An acid, to which the name of Boheic acid was given, has been described by Roehleder (Ann. Chem. Pharm., 63, 202), but its existence as a definite chemical substance is very doubtful. Other constituents it seems unnecessary to describe. [Harold H. Mann.]

TRADE IN INDIAN TEA.—The prosperity of the Indian Tea Trade may be mentioned as one of the many striking results of the British Administration in India. The East India Company enjoyed for many years a monopoly in the Chinese exports of tea, and they were therefore, and perhaps naturally, not over-anxious at first to establish a tea industry in India. In the year 1721 the imports of tea from China into Great Britain became one million pounds, and during the century from 1710 to 1810 the aggregate sales of the Company were 751 million pounds, valued at close on 130 million pounds sterling. It may be useful to recapitulate some of the historic facts already mentioned. In 1788 Sir Joseph Banks suggested the desirability of cultivating tea in India. Little was accomplished, however, until Lord William Bentinck became Viceroy in 1834. But the success shortly after attained was such that in 1840 the Government were able to withdraw from tea-planting, and by 1865 had handed over all their experimental plantations to private enterprise. The first public sales of Indian-grown tea took place in Calcutta during 1841, when 4,613 lb. were sold. A sample of Indian-made tea had, however, been sent to England a few years earlier (1838). By way of contrast with these beginnings it may be added that sales of Indian tea in 1904 stood at 200 million pounds, valued at £6,000,000 (see p. 218).

Area and Localities of Production—Capital and Labour, etc.—

The area under tea at the end of 1903 extended over 524,827 acres, nearly two-thirds (64.4 per cent.) being in Assam (viz. 338,278 acres, or 204,702 in Assam proper, and 133,576 in Cachar and Sylhet). In Bengal the area was 135,956 acres (25.9 per cent.). Thus these two provinces (Assam and Bengal) have nine-tenths of the Indian tea area, the remaining tenth being in the United Provinces, Panjâb, Madras and Travancore, a total of 49,073 acres, of which one-half is in the Native State of Travancore. In addition to all these there is a small area of 1,520

239
THE TEA PLANT

Recent Returns. Acres in Burma. In the latest report of the Commercial Intelligence Department on the Production of Tea in India, the area for 1906 is stated to be 531,808 acres, distributed thus:—423,828 in Eastern Bengal and Assam; 51,219 in Bengal; 7,997 in the United Provinces; 9,425 in the Panjáb, and 39,339 in South India (Madras and Travancore). Hence the partition of Bengal may be spoken of as having reduced the area in that province and increased that of the new provinces of Eastern Bengal and Assam. It may also be said that the record years in the normal or continuous expansion of the tea area were 1897 and 1898, but recently the low prices that have prevailed have suggested the desirability of curtailing rather than increasing the area, and accordingly in 1903 a decrease of 430 acres was recorded. The policy presently pursued may be described as the abandonment either permanently or temporarily of a percentage of indifferent tea, also the reduction of the quantity taken annually from the plant. Both factors have combined to improve the stock and raise the quality of the tea, and have thus proved beneficial. The reduction of area mentioned is therefore the balance between fallowed tea and new extensions, showing a small net decrease.

Yield. Yield.—But a significant feature of Indian tea-planting is the fact that production has increased in a higher ratio than the expansion of the area of cultivation. Since 1885 the area has increased by 85 per cent. and the production by 192 per cent. This doubtless denotes improvement in cultivation and manufacture. But the published estimates of production are usually considerably below the actuals, hence the trade returns show higher totals than the estimates of supply. Obviously there are many explanations, such as the fluctuations in seasons which render averages fallacious and the returns of private concerns not being as a rule furnished. On the average of the last five years the yield per acre (dividing total yield by area) was in the four chief tea localities: Brahmaputra valley, 401 lb.; Surma valley, 503 lb.; Duras, 476 lb.; and Darjeeling, 267 lb. to the acre. But according to the report of the Commercial Intelligence Department for 1906, the total production in this year was 240,411,266 lb., assorted thus:—Assam, 162,468,034; Eastern Bengal, 44,602,885; Bengal, 15,531,692; Northern India (United Provinces and Panjáb), 3,527,863; and Southern India (Madras and Travancore), 14,280,792 lb.

Distribution. Capital. The total registered capital invested in the industry comes to 22 crores of rupees (£14½ millions), thus:—companies registered in India, Rs. 3,41,82,985, and companies registered in London, Rs. 18,39,30,135. Divided by the area this capital comes to Rs. 412 (£27) per acre. But there is a further unknown figure representing the capital of private owners (above alluded to), who, as a rule, refuse to furnish any information of their business, so that the total capital has been estimated at £20,000,000 (see p. 218).

Labour. Persons Employed.—In 1906 the number of persons employed in the industry was returned at 491,457 permanently and 81,642 temporarily, or just a little more than half a million, and this expressed to the area of cultivation comes to about 1.08 persons to the acre. These figures do not, of course, include those engaged in the carrying agencies nor those concerned in cultivating locally the food, etc., of the special immigrant tea population.

Foreign. Foreign Trade.—The economies due to the establishment of large plantations, and the discovery of machinery to do all and more than
INDIA AND CEYLON

manual labour could accomplish, cheapened production, and with this arose a rapidly increasing demand. The freedom from adulteration and impurity, incidental to all Asiatic hand labour, also tended to enhance the appreciation of the Indian tea in European markets, and with that success came the downfall of the Chinese trade. In 1859 China supplied England with 76 million pounds of tea, and in 1880–1 with 175 million pounds. In 1864 India commenced to export in sufficient quantity to justify the traffic being recorded separately. In that year the United Kingdom obtained 2,800,000 lb. of tea from India. A decade later the coffee industry of Ceylon began to show signs of the ruin that finally overtook it. Profiting by the experience and knowledge gained in India, Ceylon planters abandoned coffee and took to tea, and to-day Ceylon is India’s chief competitor in the tea markets of the world. In 1875–6 the exports from Ceylon were 784 lb. valued at £180, while the Indian of that year were £4,361,599 lb. valued at £1,444,278. In 1885–6 the Ceylon exports became 7,851,562 lb. valued at £382,996, and the Indian 69,666,000 lb. valued at £3,298,000. In 1895–6 the Ceylon exports were 110,095,000 lb. valued at £3,075,000, and the Indian 142,080,000 lb. valued at £4,682,000. Five years later (1900) the corresponding figures were: Ceylon exports, 149,265,000 lb. valued at £3,582,000, and Indian, 176,387,000 lb. valued at £6,118,000. By way of comparison it may be added that the total exports from China in 1900 were 184,533,000 lb. valued at £3,949,000, and Japan, 61,028,000 lb. valued at £1,406,000; the world’s increasing demands were thus met by India and Ceylon mainly. This may be still further exemplified by later figures drawn from the report issued by the Commercial Intelligence Department of the Government of India for 1906. The total exports by sea and land routes for that year came to 236,731,623 lb. from India and 170,527,146 lb. from Ceylon, while from China came 108,864,534 lb. black and green tea, with 79,506,133 lb. brick, tablet and dust.

Prices Realised.—During the later years of the period indicated by these returns the price paid for Indian tea fell from 13–33d. to 8–32d. per lb. in 1900; for Ceylon from 11–63d. to 5–40d. per lb.; for China from 7–26d. to 5–14d. per lb.; and for Japan from 7–17d. to 5–53d. per lb. Thus, while India has maintained her position as the leading producing country, she has also preserved, in a remarkable degree, her supremacy in quality and price. Indian teas fetch the highest average price in the world. Expressed to head of population (census of 1900), the consumption of tea is interesting, and throws a flood of light on the influences that have led to the world’s increased consumption of tea. The list is headed by Western Australia, 10–07 lb. per head of population; South Australia, 8–87 lb.; United Kingdom, 8–44 lb.; New South Wales, 8–01 lb.; Victoria, 7–38 lb.; Queensland, 7–09 lb.; New Zealand, 6–78 lb.; Tasmania, 6–62 lb.; Canada, 4–29 lb.; Holland, 1–48 lb.; United States, 1–14 lb.; Russian Empire, 0–93 lb.; German Empire, 0–13 lb.; and France, 0–05 lb. Thus India and Ceylon owe their prosperous tea trades, primarily, to the demands of Great Britain and her Colonies, but the low prices that have recently prevailed have led to great efforts being made to open out new markets, and these are held to have been so successful that the average price has improved. The relief afforded, moreover, by the endeavour to produce and sell green tea may also be said to have considerably strengthened the position of the Indian planter, so that it is thought there is now no longer any fear of supply outrunning demand.
Exports from India (Black and Green Teas).—It may now be useful to furnish more direct and explicit information regarding the recent Indian traffic in Tea. The following figures show the trade every fifth year since 1876-7:

<table>
<thead>
<tr>

Imports into India (Black and Green Teas).—With such a record of producing enterprise it is somewhat surprising that India nevertheless should continue to import tea from China, Java, etc., and become the emporium of a re-export trade in these teas to Persia, Arabia, Turkey-in-Asia, Africa, Egypt, etc. The following table records the transactions during the past five years:

<table>

</table>
Drawn from these foreign supplies the exports (re-exports) shown above are made, and it is distinctly interesting to have to add that recent special endeavours (already alluded to) have been directed toward securing for Indian production a larger share in the Tibetan and Central Asiatic green-tea traffic. But, more interesting still, the re-exports of China tea to Persia have as rapidly declined as the exports of Indian tea have increased. The growth of a trade with Persia and Turkey-in-Asia in Indian-grown teas is one of the most satisfactory results of the efforts to find markets outside the British Empire.

Coasting Trade.—A study of the amount of tea carried coastwise to and from the provinces of India helps greatly to elucidate the particulars available regarding local consumption. In 1903–4 the total quantity carried by these routes came to 4,806,674 lb. valued at Rs. 23,94,580, and in 1905–6 to 4,179,040 lb. valued at Rs. 29,81,036. Of that amount, Bombay alone in 1903–4 took 3,089,500 lb., of which 3,000,000 lb. were drawn from Calcutta and thus doubtless consisted of Assam or Bengal teas, and in 1905–6, 2,093,516 lb., of which 2,000,000 lb. came from Calcutta. To a large extent perhaps this represents the Persian Gulf traffic. The only other item of importance manifested by the coastwise trade is concerned with the port of Chittagong.

Rail and River-borne Trade.—The study of the official publications that have appeared under this heading reveals two important features: (a) the sources of supply upon which the great centres of the trade depend; (b) the expanding local consumption. The total exports from the producing centres were in 1903–4 as follows:—From Assam, 150,841,296 lb.; from Bengal, 46,936,472 lb.; from Madras, 5,084,328 lb.; from the United Provinces, 1,911,912 lb.; and from the Panjáb, 635,918 lb. These show a total of 205,429,926 lb. as the exported production of 1903–4; but later statistics for 1906–7 show a slight increase to 224,873,712 lb. It is just possible that there is in addition, however, a small export traffic by road, not recorded in the above figures, more especially from small private gardens that run for special, often local markets.

Calcutta imported in 1903–4 (from all these areas of production) a total of 170,735,726 lb.; Bombay (town) secured 2,205,308 lb. (from the United Provinces and Panjáb, in addition to its supplies coastwise above mentioned); the Madras (port) towns received 4,912,292 lb. (drawn from the Nilgiri hills, Wynaad, Travancore, etc.); and Karachi 29,326 lb. (from the Panjáb and United Provinces). From these receipts, by the port towns mentioned, have to be drawn the foreign exports (already shown), the balance being one item more of local consumption. So in the same way the supply procured from the chief towns concerned in the foreign trade (177,899,082 lb.) deducted from the total recorded imports from the areas of production would leave a balance which either goes into local (provincial) consumption, or is exported from other ports towns not dealt with above, such as Chittagong. The balance in question (in 1903–4) was 27,550,844 lb. Now that Chittagong has become the chief town of the new province of Eastern Bengal and Assam, its trade will doubtless be separately returned. In the Administration Report of Bengal (1903–4, 82), it is observed that the running of a direct line of steamers from that port to the United Kingdom and the through connection with Assam, established by the completion of the Assam-Bengal Railway, have already caused a large increase in the foreign trade, the total value of which was Rs. 2,50,66,000 in 1903–4 as against Rs. 1,69,71,000 in 1902–3. Of these returns tea represented a traffic of Rs. 75,60,000 in 1902-3, which expanded to Rs. 1,02,40,000 in 1903–4. It is thus certain that Chittagong will in the near future play an important rôle in the tea trade. But to conclude these observations on internal trade and local consumption, a balance sheet might be given by showing production less foreign exports and foreign imports less re-exports, and these two sums would doubtless represent very largely local demands; but for the reasons indicated it often happens that the exports exceed the estimated production by as much as a million pounds, so that we are not in a position to give any very satisfactory conception of India's own consumption of tea. Recently, however, a special company has been organised to pioneer the Indian home trade, and it is believed the results are fulfilling all expectations.

Trans-frontier Land Trade.—The trade in tea across the frontier of India by land routes is not very important, though worthy of consideration. The most surprising feature is that (including Burma) India imports if anything more than she exports. The supply comes mainly from the Northern Shan States, is carried into Burma, and is mostly picked tea. The total traffic was
in 1903-4, 2,020,256 lb., valued at Rs. 9,31,943; in 1904-5, 2,314,816 lb., valued at Rs. 10,78,031; and in 1906-7, 2,120,048 lb., valued at Rs. 8,80,068. Turning now to the Exports: these go mainly to Afghanistan, Kashmir, Dir, Swat and Bajaur. The following were the amounts exported— in 1903-4, 2,439,248 lb., valued at Rs. 10,68,916; in 1904-5, 2,731,008 lb., valued at Rs. 12,40,253; and in 1906-7, 2,991,072 lb., valued at Rs. 14,53,888. The chief item in this traffic is India's contribution to the Tibet and Central Asiatic demand for green tea.

In conclusion, it is perhaps scarcely necessary to enter into the details of the strenuous efforts that have been made and are being made by the Tea Association and tea merchants of India and England to extend the area of demand for all grades of Indian tea. The enlightened action which has resulted in securing the services of expert scientific officers to investigate the disabilities of the industry and to improve the methods of production and manufacture deserve the highest commendation. The initial stage in this reform was accomplished by the Government of India in 1895, namely the deputation of the Reporter on Economic Products to the tea districts with instructions to institute inquiries into and to publish a report on the "Pests and Blights of the Tea Plant." In consequence the first scientific officer—Dr. Harold H. Mann—was appointed by the Association. The subsequent history is one of progress. Mann's investigations cover every possible aspect of inquiry, and the results of his labours may be described as both highly interesting scientifically and of the greatest practical importance to the industry.

**CAMPHOR:** *Pharmacog. Ind.*, iii., 200.

The vernacular names in India, like the majority of the European names, are very similar, viz. Camphor (Engl.), camphre (Fr.), kamfer (Germ.), canfora (Ital.), कार्पुरा (Sansk.), کاپر (Arab.), and कपुर (Hind.), etc., etc. It has been suggested that they may have been derived from the Javanese कापुर, which seems to denote both lime and camphor. The Sanskrit medical writers were familiar with the two qualities pakva and apakeva. The former would mean prepared by the aid of heat, and might thus be viewed as the Camphor of *Cinnamomum Camphora*, while the latter would be native or natural camphor, and be accepted as denoting the camphor of *Dryobalanops Camphora*. The last-mentioned was historically first known. But neither of the plants named are indigenous to India, nor even cultivated plentifully to-day, and therefore the pakva and apakva कार्पुरा could only have been known to the people of India subsequent to the establishment of the Chinese and Arab commerce. But the history of the names for the clove (and there are many other examples) show that it is not necessarily the case that commercial names, at present in use, originated from the indigenous names of the plants in question, so that the Sanskrit कार्पुरा might easily enough have given the Javan कापुर.
CINNAMOMUM AND DRYOBALANOPS

doubtless the Malay Peninsula. Adams (Comment., Pauha Egineta, iii., 427-9) reviews the early information regarding camphor, and says that Serapion is the first authority who gives a full account of it. Isaac Elia Amram, one of the writers quoted by Serapion, furnishes a brief account of the method of refining, which is practically that pursued at the present time. Lastly, Adams adds that Sylvon Seth is the only one of the Greek authors who treats of camphor (caprha). [For further information see Cinnamonum zeylanicum, pp. 313-6.] Garcia de Orta discussed in the 16th century the two chief forms of Camphor. These are:

Cinnamomum Camphora, Nees and Eberm.; Fl. Br. Ind., v., 134; Graumann, Mittheil. d. deutsch. Gesellassch., etc., Tokio, 1895, vi., 277-328; Ind. For., xix., 459; xxiii., 469; Gamble, Man. Ind. Timbs., 504; Brandis, Ind. Trees, 534; Lauraceae. The Japan Camphor Tree. A moderate-sized evergreen tree, native of China, Japan, Cochin-China and Formosa, much planted in India, where it grows admirably in suitable places. There are fine trees in the Botanic Gardens of Calcutta and Saharanpur; it grows very well in Dehra Dun, and thrives in the Nilgiris, even up to altitudes of 7,000 feet.

This is by far the most important of the natural sources of camphor, and practically constitutes the monopoly of the Japanese Government since thecession to them of Formosa, whence the largest quantity and best quality of camphor is derived. The production in 1900 is said to have been 134 tons in Japan, 98 tons in China, and 2,680 tons in Formosa. But it is affirmed that Japan has effected an agreement with China whereby she exercises a preponderating influence over the export of camphor from Chinchew (Fukien) on the Chinese mainland, which formerly shared the Indian and European trade with the province of Tost in Sikok (Japan) and the Eastern or aboriginal districts of Formosa. [Cf. Pickering, Pioneer. Formosa, 1898, 202, 220.]

For a description of various processes of refinement the reader may consult the article given in the Dictionary. Herren Tschirch and Shirasawa published a careful account of the formation of this camphor, and Bamber (Lecture May 14, 1906, delivered before the Ceylon Agricultural Society) gives particulars of the still that should be used. [Cf. Archiv. der Pharmacie, Berlin, 1902, No. 40; Revue. Bull., 1899, 37-83; 1907, 53-90.]

In the stem are formed coarse crystals which constitute the Barus Camphor called in Indian trade returns bhimesa11 or baras. The crystals are often found in concrete masses in the heart of the tree, or in the knots and swellings where the branches issue, but camphor is also found beneath the bark. To obtain the product, which is valued by some of the Chinese at from 40 to 80 and even 100 times the price of ordinary camphor, the tree is destroyed and cut into small splinters. An average tree is said to yield about 11 lb., but the old trees are the most remunerative, and only about 10 per cent. of those destroyed really repay the labour. This camphor is used by the Malays for embalming and for ritualistic purposes, and is well paid for. Probably the camphor first known to the world was obtained from this tree, and not from Cinnamomum Camphora. [Cf. Pluckiger and Hanbury, Pharmacog., 458; Gildemeister and Hoffmann, Volatile Oils, 370-7, 502.]

Other Camphors are obtained from several plants, as for example thyme, patchouli, tobacco, etc., etc., but the production from these sources would appear not to be a paying industry. The widespread reputation of Balsamifera as a source of Ngai Camphor is probably delusive, so far as least as India and Burma are concerned, though the leaves would appear still to be employed for the distillation of a powerful camphor in Upper Tonkin. [Cf. Revue Bull., 1896, 275-7; 1896, 73; Bhaduri, Rept. Labor. Ind. Mus. (Indust. Sec.), 1902-3, 29; Bull. Econ. L’Indo-Chine, 1903, vi., n.s., 512.]

Production.—The camphor monopoly established by Japan had the effect of raising the price of the natural product, and this led to the fairly successful synthetical fabrication of the commodity in America. It would be beyond the scope and purpose of this work to do more than indicate the directions and possibilities of the camphor industry, and it must suffice therefore to state that it can be and is being produced

THE CAMPHOR TREES

chemically. But the rise in the price of camphor has had another effect, namely of turning the attention of planters in other lands to the possibility of competing with Japan in the supply of natural camphor. Willis and Bamber in an able article have dealt with every aspect of cultivation and manufacture (Circ. Roy. Bot. Gard. Ceylon, 1901, No. 24). In The Agricultural Ledger (1896, No. 5) Hooper detailed certain experiments which went to show that a fairly large supply of camphor might be obtained from an oil distilled from the leaves of Cinnamomum Camphora. It had been supposed that camphor was only obtainable from the timber and roots of trees 50 to 100 years old, and obviously only Governments could undertake to plant such on a large scale and wait so long for remuneration; but as a consequence of experiments made in India, Algeria, United States and some German colonies, it was thought that Cinnamomum Camphora might be planted as a catch crop by tea, coffee and indigo planters. The results, however, do not appear to have justified the hopes that were once formed. It would be beyond the scope of this work to deal with the European uses of camphor, but it may be mentioned that one of the most interesting is its employment in the manufacture of celluloid. [Cf. Heuze, Les Pl. Industr., 1895, iv., 269–72; Kew Bull., 1895, 305; Trop. Agr., April 1, 1904, 659; Komppa, Pharm. Journ., lxixii., 77; Gallenberg (reviewed) in Capital, June 4, 1903; Collins, Scient. American, lxxxix., 368; Madras Weekly Mail, May 9, 1903; March 20, 1905; Hauxwell, Rept. For. Admin. N. Circ. Burma, 1904–5, 52; Copleston, Notes on Cult. Camphor, in Agri. Journ. Ind., 1907, ii., pt. i., 92–4.]

Commerce and Trade.—India possesses a fairly large industry in the refining of camphor, chiefly at Bombay, Delhi, etc. The refiner sells the article at nearly the same price as he purchased it for, the profit being made on its mechanical absorption and retention of a large amount of water. It appears, however, that an increasingly large proportion of Japanese camphor is sublimed before being exported to India. The imports of Barus camphor are now of little or no consequence, having decreased from 528 lb. in 1899–1900 to 106 lb. in 1903–4, and in value from Rs. 32,898 to Rs. 3,170, and in 1906–7 were nil. The total amount of other camphors imported was 1,071,714 lb., valued at Rs. 9,96,336, in 1899–1900; 1,091,002 lb. at Rs. 12,97,482 in 1903–4; 1,169,238 lb. at Rs. 16,17,943 in 1904–5; 703,716 lb. at Rs. 13,37,938 in 1905–6; and 849,261 lb. at Rs. 22,99,783 in 1906–7. In the first-mentioned year Japan contributed only 135,010 lb., valued at Rs. 1,82,680; whilst in 1903–4 the amount was 671,220 lb. at Rs. 8,42,391; and in 1904–5, 856,130 lb. at Rs. 12,51,846; though it fell off in 1906–7 to 426,007 lb. at Rs. 14,11,926. Doubtless a large proportion of this must be the Formosan camphor, which was previously exported to India vid Hongkong. The increase in the Japanese trade corresponds with a rapid decrease in the quantities obtained from the United Kingdom (English refined camphor), Hongkong and the Straits Settlements, the totals for these three having been in 1899–1900: United Kingdom, 84,460 lb. valued at Rs. 77,658; Hongkong, 440,458 lb. at Rs. 3,80,598; Straits Settlements, 411,696 lb. at Rs. 3,55,261. In 1906–7 the quantities and values were respectively: United Kingdom, 22,311 lb. at Rs. 76,778; Hongkong, 277,360 lb. at Rs. 5,43,304; Straits Settlements, 74,803 lb. at Rs. 1,61,295. The increased proportionate value of Japanese camphor compared to European camphor may show that more of it is imported in a refined state. The
re-exports manifest an increase from 38,517 lb, at Rs. 38,375 in 1889-1900 to 121,023 lb, at Rs. 2,14,369 in 1905-6. In 1906-7 they fell, however, to 44,776 lb. at Rs. 1,01,132. Bombay and Bengal are the chief ports of departure, and Natal is ordinarily the best customer, though since 1904 the United Kingdom has stood first.

**Oil of Camphor.**—There are two very distinct substances known by this name. One is the oleo-resin of Borneo, obtained by distillation of the wood or by tapping the trunks of *Dryobalanops Camphora*, which, being unable to resist the pressure of the liquid, sometimes burst open or have their tissue broken into large hollow chambers. According to Gildeimeister and Hoffmann (Volatiles Oils, 563) this oil is not obtainable on the market. The other so-called camphor-oil of Formosa and Japan is a brown liquid holding in solution much common camphor, which is precipitated when the temperature of the liquid falls. The crude oil is made by distilling chips of camphor-wood in water. After removal of the camphor which crystallises out on cooling, it represents a transparent bright-yellow to brownish-yellow liquid oil having a penetrating odour. In Formosa it was formerly thrown away as worthless, but the Japanese used and still use it to a considerable extent in connection with lacquer and varnish-work, besides extracting a considerable residue of camphor from it. A long and interesting paper on the various qualities of camphor-oil together with a description of the method of extracting refined camphor therefrom and of manufacturing salol from the “red oil” (crude oil after the removal of the essential white oil and camphor) will be found in *Schimmel & Co.’s Semi-Annual Report* (Oct.—Nov., 1902), being taken in part from the *Journal of the Pharmaceutical Society of Japan* (April, 1902, No. 242). It would appear that the camphor is now extracted in Japan, whereas the oil was previously exported in a crude state, largely to Germany. [Cf. Shimoyama, Acc. in *Trop. Agrist.*, Nov. 1901, xxii.]

**CANARIAUM, Linn.; Fl. Br. Ind., 1., 531–6; BURSEACEAE.**

There are about 9 species in this genus, all large trees, and several of them afford useful resins. Considerable confusion exists, however, regarding their respective products, so much so that the most satisfactory course is to accept the available information geographically.

*C. bengalense*, Roxb., is the *nerebi* of Sibugap and Sylhet of which Roxburgh wrote, "From fissures or wounds in the bark, a large quantity of a very pure, clear, amber-coloured resin exudes, which soon becomes hard and brittle, and is not unlike copal, yet the Natives set no value on it." "In the Calcutta bazar, it is only valued at from 2 to 3 rupees for 7 maunds of 80 pounds weight each." Most writers have repeated the above without either correcting or amplifying the information, so that it is not known whether or not the resin is used economically.

*C. commune*, Linn., is the Java almond and the *rata-kekuna* of Ceylon. A large tree of the Malay, but cultivated occasionally in India and Ceylon.

*C. resiniferum*, Bosc, is the *dhuna*, *duka*, *tekrenge*, etc. A large tree of Assam, the Khasia and Garo hills. It would seem highly probable that this is the chief source of the *Canarium* resin of Assam which has hitherto been mostly supposed to be afforded by *C. bengalense*. Gamble says it gives a resin which

THE SWORD BEAN

CanaValia Ensiformis

Makham-shim

Torch.

is used for torches. A sample of Assam resin, weighing over 13 lb., received by the Reporter on Economic Products as "a fairly average quality of the Black Dammar" was sent to the Imperial Institute, London, for examination and report. Dunstan replied that the results obtained "indicate that the resin is of the dammar type although it differs to some extent from the black dammar of commerce, stated to be derived from C. strictum, especially in possessing lower acid and saponification values." Some varnish manufacturers to whom the resin had been supplied reported that it was suitable for the preparation of a hard drying varnish, such as is required for enamel paints, though the dark colour of the resin would prejudice its sale and it was not likely to fetch more than 18s. per cwt.

C. sikkimense, king. Journ. As. Soc. Beng., lixii., pt. ii., 187; is the gugal dhup, nar-pa, etc. A very tall tree of Nepal and Sikkim—the inner valleys of the Eastern Himalaya up to altitudes of 3,000 feet. It yields a clear amber-coloured brittle resin that is burnt in incense by the Lepchas. Dylock (Journ. Bomb. Nat. Hist. Soc., 1891, vi., 409) speaks of an amber-coloured resin—the incense (gokal-dhup)—and he was thus doubtless speaking of this plant and not of C. bentigtenose as he supposed. C. sikkimense has of late years become a scarce tree, due apparently to the demand for tea-box woods. The timber is said not to warp but to decay rapidly.

C. strictum, Poly. Fl. Ind., iii., 138; Talbot, List. Trees, etc., 1902, 70. The Black Dammar, gugal, kula-dammar, karpu kong-dam, kong, kundirkum, kundirkim, kundrikam, manu-dhup, ralikhup, thelli, etc. A tall tree of Western and Southern India from the Konkan southwards. When in young foliage it is almost crimson and is in consequence very conspicuous on the Ghats, up to altitudes of 5,000 feet. It yields the resin known as the black dammar of South India. The timber is worthless, and to obtain the resin the trees are felled. Vertical cuts are made on the bark and a mass of brushwood thereafter fired around the base of the trunk. In about two years' time the dammar is said to begin to exude from the stem and to continue to flow for ten years afterwards, during the months of April to November. This is collected in January and traded in all over Southern and Western India, but owing to its high price is not much exported. The supply comes chiefly from Travancore and the resin fetches about Rs. 3 per 18 lb. It is employed in the manufacture of a bottling wax or for varnish, etc., and in medicine as a substitute for Burgundy pitch in the manufacture of plasters. Full particulars of the chemical properties and medicinal uses will be found in the Dictionary. The substance was examined and reported on by the late Mr. Broughton. [Cf. King, Journ. As. Soc. Beng., 1893, lixii., 184-8, tt. 10-3; Gamble, Man. Ind. Timbs., 140-1; Cooke, Fl. Pres. Bomb., i., 201-2; Brandis, Ind. Trees., 130.]

A perennial climber cultivated throughout India, from the Himalaya to Ceylon and Siam, common in gardens or on the borders of fields and the roofs of huts. The young and half-grown pods constitute the so-called "French-beans" of Europeans in India, but they are also eaten by the Natives, especially in curry. Some five kinds, probably only races, are reported to be grown, of which the form known as hikwa, a white narrow-podded kind, is considered the best. The mature seeds are said to be eaten fairly extensively in Mysore and in some parts of the Bombay Presidency. By the Muhammadians, here and there all over India, they are appreciated as a vegetable and eaten along with meat, especially that of the white-seeded form. There are three wild species, viz. C. virens, W. & A. (katha-shim, kala-shim), very plentiful throughout India and by some writers regarded as the origin of the cultivated plant. It has been reputed to be poisonous, C. lineata, DC, a littoral species creeping along the sand, and C. obtusifolia, DC. (c. ensiformis, var. turrita), a common climber along the banks of tidal creeks and rivers.

248

The following may be given as the more important names:—Hemp (fibre), Indian-hemp (the narcotics), Canvas ( coarse textile), English; cannabis, Greek and Latin; canabis, Keltic; canas, Modern Breton; chanvre, Fr.; canamo, Sp.; canhamo, Port.; canape, It.; canapa, Ruman.; canep, kerp, Albanian; konope, Rus.; konopj, penka, pienku and penek, Polish and Old Slav.; Kemp, Belg.; hampa, hamp, Swed. and Danish; hanf or hanaf, Old High Germ.; hemp, N. Germ.; knapios, Pruss.; Hanfr., Iceland; hennup, knnipp, Dutch; kenevir, Bulg.; kentyr, Tartar; kant, Erse; kanaq, Armen.; schema, Mughal; descoma, Tanjut; nasha, asaram, malach, Turk.; kin-dur, Turko-Tart.; kirs, Bokhara; kandiir, Kashgar; kanabira, Syrian; kinif, Kurd.; kief, Morocco; ta-ma, si-ma (great or male) and tsu-ma, chu-ma (seed-bearing or female), Chinese; asa (the plant and fibre), nuno or jofu (the hempen cloth), Japanese; bhangâ, vijayâ, indrâsana, Sanskrit; bhang, beng bhang, haschisch, siddhi, eabzi, ganja, charas, majaf, jia, kus, Hind., Bong., Nepal, Pb., C. Prov., Kaeh., Guj., Deccan; siâ, sirin, Sind.; ganjyâi, korkkar, kalpam, Tam. and Tel.; gingi-lacki-lacki, gingil-achi-lachi, (kalengi-canajava) (male) or bhangi, etc., of Rhodee, gingi of Rumphius), Malay; kinnab, hinnab, of younger Sarapan, schechedenig in Matthiolius, and azir or assis in Acosta, Linschoten, Rumphius, etc., Arabic (axis, assis are doubtless the Arabic haschisch); dakka, docha, Hottentot, and riamba, diambe, or jamba, W. Africa (Negro); darakhte-kinnab, bang, nabanat-gunnab, Persian; bhên, sejav, Burmese; matskansa, ganja-gaha, Sinhalo; akhet-mangha, rongoyne, Madagascar.

Habitat.—The Hemp plant grows in a wild or spontaneous state over so wide an area, but at the same time is always so closely associated with places that are or may have been inhabited or used as trade routes, that it is difficult to say where it originated. The widest range claimed for wild hemp covers the area from Trans-Baikal and Dahuria westward and southward to Bokhara, the Trans-Caspian province, Russia south of the Caucasus, and, according to Hooker, the North-Western Himalaya. It is, however, as plentiful in an acclimatised state in Japan and Northern China, and in the Sub-Himalayan zone of Northern India, as in any part of the region indicated, though it is admittedly there only a plant of waysides and waste places. Having regard to the value of the situations it affects, Prain, in his report on ganja, does not regard it as indigenous either in India proper or along the North-West frontier. But even in some of the Siberian districts accepted as part of its original home, it has been noted as occurring near dwellings, and Gmelin (Fl. Sibir. Hist. Pl., 1768, iii., 104) seems to believe it to be wild simply because the Buriats and Krasnoiar Tatars do not actually sow it. The arguments against its being wild in Northern and Central Asia are thus almost as strong as in the case of Eastern and South-Eastern Asia. So far as India is concerned, the conclusion of the Hemp Drugs Commission is probably correct, namely that it is not indigenous.

Properties and Uses.—The hemp plant is known to yield three distinct products, or perhaps rather groups of products, separately dealt with in this work:—

A BAST FIBRE, largely employed in the manufacture of cordage ropes and coarse textiles.

An EDIBLE SEED, from which a useful fatty OIL is expressed. A NARCOTIC resinous substance that appears in trade in three chief

Vernacular Names.

Not Indigenous in India.

Habitat.

Products.
forms, known as *bhang*, *charas*, and *ganja*, and which chemically consists of a resin and a volatile oil.

The word *bhangra* is given in Nepal to a coarse cloth made from the nettle *Girardinia heterophylla* and in Sikkim a similar textile bears the name *gunna*, while in Burma the name *gun* or *gwon* denotes *Bohmeria nivea*, and in Bengal the fisherman’s nets made of *rhea* fibre are called *gangajalou*. A coarse cloth made in Mysore from *Crotalaria* is also named *gunj*. It is thus somewhat surprising that in India the best-known nettle fibres, including hemp, bear names that have the sound of *bhang* or *ganja* (though possibly quite unconnected). Christopher Acosta (Tract. de las Drogas, 1578, 359–61) figures and describes the “Bhangue,” Mandelslo (Travels, 1662, 37) speaks of “Bengi,” a drug made from hemp. Fryer (New Acc. E. Ind. and Pers., 1672–81, 126) mentions “a Fakier drunk with Bang” whom he saw in Surat. On the Himalaya, where *Cannabis sativa* is grown for its fibre, the male plant is called *phāl bhang* and the female *gūl—or gūr-bhāngā*. At Indore the male plant is *hari* and the female *bhāmgera*. Very nearly throughout the world wherever hemp is cultivated the larger and more prolific plant has been taken as the male (though as a matter of fact it is botanically the female). Prain informs me that he believes, with the Mongolian races, the sexes are not as a rule reversed. The names given to the two forms or sexes are therefore interesting. From Gardnrole (1636) we learn that in his time English writers spoke of the one plant as the “Male” and called it “Charle” or “Steele Hempe” (p. 1053), or “Winter Hempe,” and of the other as the “Female” (or, as he calls it, Femeline, botanically the male), the “Barren Hempe” or “Summer Hempe,” and by more recent writers “Fimble Hempe.” Gerarde makes an interesting observation in this connection:—“There is another, beeing the female Hempe, yet barren and without seed, contrarie unto the nature of that sex; which is very like to the other beeing the male, and one must be gathered before the other be ripe, else it will wither away and come to no good purpose.” The corresponding German names are *Fimmel* (male) and *Maschel* (female). It is, however, significant that in none of the prehistoric remains of Europe has hemp been found, though flax is frequent. [Cf. O. Schrader, Reallexicon, etc., 330–1.]

But Gerarde’s observation regarding the necessity to remove the male plants (the “females,” as he calls them) because otherwise the crop may come to no good, is curiously suggestive of the Bengal practice, that will presently be explained. As a matter of fact, however, it is the general custom in Europe to remove the male (or, as it is called, “female”) plants some 20 to 40 days before the female (male) is harvested, the reason being that after the dissemination of the pollen the male plants rapidly mature, so that long before the females have formed their seeds the fibre in the male stems has been ruined. Similarly, if the seeds be allowed to ripen, the fibre of the female plants will also be ruined. It accordingly is the custom to harvest the female crop when in a half-ripe condition, that is to say, the seeds have not been fully matured but they are at that stage rich in oil and thus afford a by-product of no small importance. Still further, it seems the custom, in some parts of Europe, to store the stems for a time before separating and cleaning the fibre. The fibre cleaned in winter is accordingly called Winter Hemp and that retted in spring and cleaned finally in summer is described as Summer Hemp. But like the names “male” and “female,” the terms “summer” and “winter” are often inverted. Lastly, the greatest possible confusion exists in the literature of this subject as to whether or not the botanically male plant yields a fibre, and if it does, its relative value to that of the female. [Cf. Crawford, Indist. of Russia, Agri. and Forest, 1893, 139–43; Wiesner, Die Rohst. des Pflanzenn., 1903, i., 520, ii., 300.] Wilson (Farm Crops, 1859, ii., 325–43) gives what is doubtless the complete statement when he observes that the plants flower in about twelve weeks after the date of sowing, “and then is seen the peculiarity of the cultivation of hemp as compared with other crops. If the crop be intended for fibre only, the harvesting generally takes place as soon as the process of flowering is completed, and both male and female plants are pulled at the same time and treated in the same manner. When, however, the double produce of fibre and seed are desired, a different method is pursued, by which the full produce of the crop is secured.” The male plants are pulled up by the roots, care being taken not to injure the female, which are left on the field for a further period. “The male plants are collected and tied in small sheaves, and either left standing in a convenient place till dry or at once taken to the retting vats.” Morris
ORIGIN OF NAME

(Cannab. Lec. Journ. Soc. Arts, 1895, 901) says the fibre of the male plant is tougher and better than that of the female. It is separated by reeling, breaking and scutching as in flax. [Cf. also Dodge, Cult. of Hemp and Jute, U.S. Dept. Agri. Fibre Invest. Rept., 1896, No. 8.] In New Jersey experiments were conducted to test the influence of environment on the relative production of male and female plants. On rich soils twice as many female as male plants spring from the seeds. So also seed collected late in the season was found to give more pistillate than staminate plants.

Turning now to the mistakes made by Gerardo and most of the early writers regarding plants supposed to be wild states of *Cannabis sativa*, it may be observed that in the classical literature of this subject in Europe, India and China, exactly parallel examples of error may be cited to those of the 13th to 18th century writers. In India from the time of the early Mughal Emperors, at least two, if not three fibre-yielding plants have been recognised as forms of hemp, viz. *bhangā* or *sana* (*Cannabis sativa*), *patan* (*Hibiscus cannabinus*), and *saen* (or *sunn*) (*Crotalaria juncea*). The first two are mentioned, for example, in the *Ain-i-Akbari* (1599, Blochmann, transal., i., 87) in such terms as to leave no doubt as to the palmate-leaved *saen* having been recognised as distinct from the yellow-flowered *sana* of another passage (Gladwin, transl., i., 101). But while *sana*—a fibre—occurs in the *Institutes of Mathur* (probably of date 100 to 500 A.D.) and in some of the later Sanskrit works, it apparently denotes *Crotalaria* rather than *Cannabis*. It would thus seem as if the word *sana* to denote the true hemp had been a comparatively modern usage.

**History.—** The names *schema* and *deeschoma* given to it, according to John Ammanus (Strip. Var. Imp. Rsth., 1739, 174), in Dahuria, are suggestive of the Chinese *ta-ma* (great-ma), *ni-ma* (male-ma), *tau* (sometimes written *chu*) *ma* (female and seed-bearing-ma). Bretschneider says "the character *ma*, which nowadays is a generic term for plants yielding textile fibres, was in ancient times applied exclusively to the common hemp plant *Cannabis sativa*, lnk. It would, in fact, seem fairly certain, if the plant be excluded by botanists from the position of being regarded as indigenous to China, it has been frequently mentioned in the *Rh-ya*, and special characters are employed to denote the fibre plant as distinct from the seed-bearing form. In fact it would seem that so very ancient is the character *ma* that it denotes conjointly fibre and oil (or food). Dr. Henry has pointed out to me that the character in question looks not unlike two plants within a partially protecting line. Whether or not the very character used to denote *ma* was intended to convey the idea of the two forms, the double property was certainly known from the most ancient times. [Cf. Kew Bull., 1891, 247-59.] Bretschneider accordingly observes:—"As hemp-seed was an article of food, hemp in ancient times was reckoned as one of the five, or nine, kinds of grain." The *Lu Shih* (Sung dynasty) relates a tradition according to which the Emperor Shen Nung (28th century b.c.) first taught the people to cultivate the *ma*.

Discussing the classic names associated with India, G. A. Grierson (Note on the References to the Hemp Plant occurring in Sanskrit and Hindi Literature, in H.D.C.R., iii., 240) mentions *bhanga*, *indrāpāna* and *viṣayā* or *jāyā*. "The name *bhanga* occurs in the *Atharvaveda* (say 1400 b.c.). The hemp plant is there mentioned simply as a sacred grass." It was one of the five herbs offered in oblations, viz. *soma*, *kuca*, *bhanga*, barley and *saha*. "The first mention of *bhanga* as a medicine which I have noted is in the work of *Suvarut* (before the 8th century a.d.), where it is called an antiphlegmatic. During the next four centuries *bhanga* (feminine) frequently occurs in Native Sanskrit dictionaries in the sense of hemp plant." "In the 10th century the intoxicating nature of *bhanga* seems to have been known: and the name *indragana*, Indra's food, first appears, so far as I know, in literature. Its intoxicating power was certainly known in the beginning of the 14th century." The synonym *viṣayā* (the giver of success) often has the alternative meaning of *haritaki* (*Terminalia*). Dutt (*Mat. Med. Hind.*, 1900, 235-41)—a great authority on the Sanskrit names of plants—says a mythological origin has been invented for this plant. It is reputed to have been produced in the shape of nectar while the gods were churning the ocean. In part confirmation of that view it may be mentioned that in the medical treatise that constitutes *The Bower Manuscript* (translated and annotated by Dr. A. F. Rudolf Hoernle) no mention is made of Indian hemp in any form. The MS. was found at Kucha, Khotan, which according to Stein was engulfed by sand towards the close of the 8th century. It is thus

251
THE HEMP PLANT

very possibly the oldest Indian MS. of a medical work extant. But in the Pharmacographia Indica the following occurs, "It is mentioned along with the Vedic plant-jañja, an herb which is described in the Atharva Veda (ix., 34, 35) as a protector." "The gods are said to have three times created the herb (oshadhi)." "The intoxicating properties which the plant possesses in its Eastern home appear not to have been discovered until a more recent date, but in the fifth chapter of Manu, Brahmins are prohibited from using it, and in the sacred books of the Parsis the use of bana for the purpose of procuring abortion is forbidden." It may, however, be pointed out that the authors of the Pharmacographia Indica would perhaps have been more correct had they stated that the magic plant was called sana not bhang and was spoken of as springing from the saps of husbandry—it was therefore a cultivated plant and one possibly of moist soils. On the other hand, Dr. Krishna Garde of Poona, in his evidence before the Hemp Drugs Commission (vii., 173-9), stated in the most emphatic manner that in the ancient classic literature of India there was not the slightest reference, direct or implied, to the narcotic properties of the plant." Panini, he continues, "refers to it as cultivated in fields (evidently for its fibre and seed). Manu and Kaushitaki Brahmana refer to it as a source of fibre. Later Sanskrit commentators and lexicographers interpret bhang as shana, the Bengal swn plant (Crotolaria juncea), which has been known in India from time immemorial as a plant-yielding fibre." There are no Sanskrit names for ganja or charas; all the words so used, according to Dr. Parker, have been recently coined. In the "Sahba Parva" of the Mahabharata, the Sakas (Scythians of Turkestan) are spoken of as bringing presents of thread spun by worms and patta. In that reference apparently the fibre of hemp may have been denoted, but it was not called sana but patta.

Grierson (in his communication to the Hemp Drugs Commission) observes that the first reference to ganja which he has noticed is about 1300 A.D. He then adds that a very old Hindu play written in the beginning of the 16th century Siva himself brought down the bhang plant from the Himalaya and gave it to mankind. Jogis are well-known consumers of bhang and ganja, and they are worshippers of Siva. In this connection also it may be explained that Grierson has permitted me to re-submit to him personally the controversy regarding the bhanga, ganja and sana of Sanskrit literature. While he diffidently urges that comparative philology is out of his line, he points out that if it be accepted that bhanga is an Aryan (not a Semitic word as Burton suggests), it is derived from bhanj—to break (transitive). In that sense it occurs not infrequently in names of plants other than Cannabis, such as gatra-bhangà (= body-breaking), katu-bhangà (= pungent bhanga); so also in certain combinations such as prishtha-bhangà (= back-breaking—a trick in wrestling). But if the derivation from bhanj be correct, then the "breaking" might refer to the sense and have the meaning of "weaving," as in the Persian bhang, the Avesta bangka (the word bhang) and the hemp. The Sanskrit bhanj is a common origin and the "bh" form is the original. The reverse is improbable if not impossible. The nearest certain common root is the Sanskrit bhanj already mentioned (suggestive of a hypothetical bhranj, and of frangere, brechen, break, etc.). [Cf. Hehn, Kulturpl. und Haust., 471-2.] The word bhanga has both a male and female form, a circumstance suggestive of the botanical male and female plants, and if so fact might be viewed as removing it from sana (which usually denotes Crotolaria juncea). Commenting on the word sana, Grierson says its origin is unknown to him but that the cerebral "n" suggests a previous "rn." It can have nothing to do with indra-asana (Indra's food). Prain, on the other hand (Cult. and Use of Ganja, 1883, 43), regards sana as the most interesting of the Sanskrit names for this plant. Prof. Rapson writes that it is quite possible the original form of the word was kowardus, hence the numerous Teutonic names like the English "hemp" and the early English "heneq". The Greek and Latin "k" often changes into "bh" and the "b" into "p" on passing into English. But if this be so, the final "b" was dropped off in Sanskrit—the sana may have been originally samb. The sound-changes involved are quite regular, namely the Sanskrit "b" [the palatal bilabial] passing into the Greek and Latin "k" sound, and then into the English "h." But O. Schrader (Realexlexion der ind. Veget., 1901, 331) observes that the bis or pis in the Graco-Thracian kwařis is suggestive of pis, pus, the (Finnic) Siryenian and Votiiak word for nettle, so that the original may have been kwařis and meant hemp-nettle.
CULTIVATED AND WILD

1. THE FIBRE HEMP. (Seed, pp. 256-7, and Narcotics, pp. 258-63.)

Cultivated and Wild States of the Plants.—The remarks already made regarding the male and female conditions of Cannabis sativa have indicated some of the chief opinions that prevail in Europe regarding methods of cultivation. It has moreover been incidentally implied that in India, hemp is grown for either of two main purposes: (a) the supply of the narcotic; (b) the production of fibre. It is, however, very generally admitted that in the plains of India, while the narcotic principle is readily developed, the fibre is as a rule but very imperfectly formed. In many reports it is affirmed that certain forms of hemp contain a stronger or a better flavoured narcotic than others, circumstances explained by some authorities as being consequent on more careful preparation. [Cf. Kotah State Mem., H.D.C.R., app. iii., 178.] Prain says, "Bhang is held in very different degrees of estimation according to the locality in which it is grown; that from the plains is valued more highly than that from the submontane tracts along the Himalaya." On the North-West Himalaya the plant is fairly extensively cultivated, however, as a source of fibre, the narcotic being but indifferently produced. In some localities ganja is said to be obtained, in others charas, in a third bhang. While in Sind it is reported that the plant affords a good fibre as well as a fair quality of bhang. These peculiarities are not, however, by recent opinion accepted as involving conditions that are even racial in value, but are viewed as the direct results of climatic and soil influences. Prain, moreover, remarks, "We must conclude that, having reached India as a fibre-yielding species, the plant developed the narcotic property for which it is now chiefly celebrated there." So also the H.D. Commissioners in their Report (i., 17) observe, "The function of the Commission is to test by the information they have collected the views therein expressed regarding the probable existence of races capable of yielding as a speciality the different products—fibre, ganja, charas and bhang. The only differences recognised in the plant by the people are between the wild and the cultivated plant, the male and the female and the varieties of the male and female plants already referred to." Summing up, the Commissioners, however, observe that "there is no evidence of racial speciality or differentiation of the decided sort suggested" by some writers. Similarly it may be pointed out that Roxburgh was apparently much impressed with the absence of distinctive varieties. "Few vegetables," he remarks, "so widely diffused over almost every part of the known world, and under the immediate management of man, have undergone less change." (Trans. Soc. Arts, London, 1804, xxii., 385). It is thus certain the plant has varied structurally to a far less extent than might have been anticipated. But racial characteristics are not necessarily botanical manifestations, and that the plant has changed is at once evident by the widely different products which it affords. It has not as yet, however, been critically examined and compared province by province on the
THE HEMP PLANT

field from the standpoint of the cultivator. Roxburgh was not aware, for example, that in Asia "the fibres of the bark have ever been employed for any purpose," so that he certainly had not studied all the racial forms that may have existed in India even in his time.

In the Report issued by the H.D. Commission (i., 32), reference is made to there being two forms of the plant in Kashmir: "The bhang, which grows on both banks of the Jhelum below the city of Srinagar, is known as kathiya bhang, is weak in narcotic and is used only for its fibre and for burning. The wild growth is very abundant. It supplies all the wants of the people, and there is consequently no cultivation." So again (i.e., i., 30), doubt is thrown on the existence of the plant in Burma. It is probably not so plentiful in that country as in India.

Pottinger and Prain, however (Note on the Botany of the Kachin Hills, etc., in Rec. Bot. Surv. Ind., i., 219), found it near the Kyeng-mo Kha, in the forests, and they add that the people appeared to have no knowledge of ganja and no idea that the plant possessed narcotic properties. But while Indian authorities thus throw doubt on the existence of cultivated forms of the plant, in Europe and America those engaged in the hemp industry have no hesitation in recognising many well-established races. Dodge, for example, says several varieties are recognised, such as that cultivated in Kentucky, having a hollow stem, the most common. Then there are the following forms: China, Smyrna, Common European, Bologna or Great hemp, the canapa piccola or small Italian, and lastly the Arabian. [Cf. Boyce, Treat. on Cult. of Hemp., etc., New York, 1900.]

Early Experiments.—On more than one occasion public interest has been aroused as to the possibility of India becoming a source of hemp fibre. That the plant was completely acclimatised over the greater part of the plains and fairly extensively cultivated on account of its narcotic, are circumstances that have been cited in support of the contention that apathy and indifference had to account for India's backwardness in hemp production. During the closing decade of the 18th century the East India Company made various experiments on an extended scale. Roxburgh, in a letter dated Calcutta, 24th December, 1799, expresses somewhat piquantly his astonishment on finding a Mr. Sinclair sent from England to "establish the cultivation of hemp, a thing I had begun some time before." Sinclair seems to have died shortly after his arrival in India, but the experiments were continued for a few years. Speaking of san hemp (Crotalaria juncea), Roxburgh wrote in his Plants of the Coast of Coromandel (1798, ii., 50, t. 193), "This useful plant yields the Hindoos their best hemp, for they have no idea of the superior quality of the bark of the common hemp-plant (Cannabis), which is indigenous in all parts of India; but of that plant they only use the leaves as an intoxicating drug. I have taken some trouble to teach the natives the use of a plant which hitherto they have only abused, by making some of their farmers witnesses to every part of the culture and preparation of the hemp, and which, on being compared with their tschanamoo hemp, they were perfectly convinced was infinitely better; at the same time the culture being equally easy, and the produce equally large, I have reason to think a few years will bring it into general use in these parts, and by degrees over India."

In the early experiments European seed and European cultivators were alike imported, and every effort made to ensure success. Cultivation
and manufacture were carried on at Rishra, Cassimpore, Maldah, Gorakhpur, Mhow, Rohilkund, Azimgarh, etc., etc. The results were everywhere unsatisfactory. Still, however, inquiry and experiment were re-instituted in 1871, especially with regard to the fibre of the rejected stems from ganja cultivation; but the result was again unfavourable. The area of possible cultivation of hemp fibre was admitted to be that where it has from time immemorial been produced, namely the slopes of the warm temperate Himalaya. But it may fairly well be affirmed that the Himalaya as a possible extended source of supply has not been fully exploited. Recent and future increased facilities of transport may be looked to as giving openings for developing the trade in Nepal, Kumaon, Simla, Kullu and Kashmir hemp fibre. Some years ago the East India Company made contracts for Himalayan hemp (H.D.C.R., app. iii., 26, 27, 231). For this purpose advances were made to the cultivators, and the fibre purchased at a fixed rate. The system worked well, and should a demand arise in the future, it might be resumed as the best mode of dealing with a community of very poor cultivators. [Cf. N.W. Provl. Gaz., x., 799-800.]

CULTIVATION AND CHIEF LOCALITIES.—Cannabis sativa is grown as a source of hemp fibre in two localities: (a) the North-West Himalaya, including Kashmir, and to a much smaller extent in (b) Sind. The wild or fully acclimatised plant is called jangli-bhang, or ganara-bhang. Whether the two conditions—the wild and the cultivated—can be separately recognised seems doubtful; still it is a fact that the wild is useless, or nearly so, for either fibre or drug.

(a) Garhwal.—The fibre-yielding plant grown in this district is met with on rich land having a north exposure. It is believed, moreover, that it would be impossible to give it too much manure. The small plots assigned to hemp are accordingly, as a rule, seen in immediate proximity to the cultivator's house, and are carefully protected. The crop does not succeed below 3,000, nor much above 7,000 feet in altitude. It is sown in May to June (about 60 lb. to the acre), and during growth the land is once or twice dressed, and where necessary the plants are thinned out so as to stand a few inches apart each way. By September to early in November the crop is ripe, and may then stand from 10 to 14 feet in height. The plants that bear seed are called sujungo or kalango, and those that do not are phulango. The stems are cut with a sickle and spread on the ground to dry for 24 hours. Those who desire to procure charas (i ganja) now rub the fruiting tops and young leaves between their hands and thus procure the drug. The leaves are as a rule regarded as useless, but a small quantity may be collected, dried, and employed as bhang. The seeds are gathered, and constitute the second valuable product of the plant. The kalango stems are exposed to dry, and are in due course retted and the fibre separated and cleaned, as with the male stems (see p. 50). From the fine fibres of both plants the teoka or sheet worn by the people in Garhwal is prepared. Nearly one-third of the population of that district are clad in hemp garments. While that is so, it is remarkable that a certain odium is associated with the cultivation of the hemp plant, and hence only the low-caste farmers (dôma), or the half-caste Rajputs (Khasia-Rajputs) will grow it. [Cf. H.D.C.R., v., 19, 20, 41-8, 76-8.]

(b) Kumaon.—A highly instructive account of the cultivation of hemp fibre in Kumaon will be found in the Gazetteer of N.W. Himalaya (1882, 790-7). The system pursued differs in no essential from that just detailed, and the objection to being classed as a "hemp-grower" also prevails. In the Hemp Drugs Report (lc., i., 93) mention is made of the manufactures produced, which it would appear are fairly extensively exported from Almora to the plains. Owing to the useffulness of the plant its cultivation is said to have recently been considerably extended. The manufacturers of hemp string and rope are reported to be a special class of people called boras or pajais.

(c) Nepal.—In this State the sowings are usually made a little earlier than in Kumaon and Garhwal—viz. from March to April, and the crop is accordingly
THE HEMP PLANT

THESE

Sativa

THE

Cannabis

Oil-seed

ready in August. It would appear to be specially abundant in the hills from
Maukamana to Redi, also in the Nepalese Terai. [Of. H.D.C.R., iii., 131;
Kirkpatrick, Acc. Kingdom of Nepal, 1811, 142-3; Buchanan-Hamilton, Acc.
Kingdom of Nepal, 1819, 226, 231-2.]

(d) Simla and Kangra.—A short notice of hemp fibre in Kotgarh will be
found in the Asiatic Researches (1825, xv., 474, 478). One of the most interesting
and useful accounts of the hemp cultivation of the Himalaya is that given by
Baden-Powell (Ph. Prod., 1868, 504-7). Stewart, in a correction on the text of
his Panjab Plants, has recorded his final opinion that Cannabis was wild in the
Panjab hills, and speaks of it as cultivated up to 10,000 feet in altitude
Coldstream says (H.D.C.R., v., 365) it is not cultivated in the Panjab for
the production of charas or ganja. Useful additional particulars will also
be found in the Kangra Gazetteer (1897, 78) and in Mr. Anderson’s statement

(e) Kashmir.—In 1799 Captain Thomas Hardwicke visited Srinagar, and
in the Asiatick Researches furnished an interesting narrative of his journey (vi.,
376). He there observes that Cannabis sativa “is cultivated in several parts
of the mountains for two purposes: one for the manufacture of a coarse thick
cloth, which the poor people wear, and the other in making an intoxicating drug
exported to the low countries.” Lawrence (Valley of Kashmir, 69) tells us that
about 600 maunds of fibre are annually produced in the country below Srinagar.
Further particulars on this subject will be found in the Hemp Drugs Report
(app. iii., 128). Many writers allude to the very superior paper that was formerly
made in Kashmir from bhang fibre (H.D.C.R., v., 438). Of Kyilang, the Rev.
Mr. Heyde (H.D.C.R., v., 487) informed the Commission that in British Lahul
all the zamindars cultivate a small piece of ground, if possible, close to their
houses, with hemp, solely in order to obtain fibre. This is made into strings,
with which the straw shoes (bula) are sewn together. Very few people smoke
bhang, and those who do, obtain their supplies from traders, who carry it from
Yarkand to Hindustan.

(f) Sind.—Wild hemp known as kohi bhang is said to grow on the hills.
The plant is cultivated on account of bhang (it does not yield ganja or charas) in
this province, but the stems are occasionally utilised as sources of fibre, hence
Sind being sometimes mentioned as producing the true hemp; at the same time
the seeds are collected and eaten, or oil is expressed from them. Sir H. E. M.
James, in his evidence submitted to the Hemp Drugs Commission (vii., 235),
stated that the charas used in Sind is imported chiefly from Kandahar. The
Deputy Collector of Naushabra (Witness, La. No. 4, 243) says, “In order to raise
a good crop of hemp, it is necessary that the land should be well ploughed, manured,
and copiously watered. The seed is sown in October or November, and the crop
is ripe in April. According to another witness (Seth Vishindas Nihalchand, 291)
the fibre is called sini. The stems are steeped in water for 15 days, after which
they are taken out and then yield their fibre. But it may be added—is it possible
that Crotalaria juncea is the hemp fibre of at least some of the Sind reports? In
South India, at all events, it would appear certain the fibre-yielding plant often
spoken of as Cannabis sativa (H.D.C.R., app. iii., 83) is in reality Crotalaria
Juncea.

Trade in Hemp.—Russia still holds the foremost position in the
world’s supply of this fibre. The exports of hemp from India are mainly
in san-hemp (Crotalaria), and the imports almost exclusively in Manila
hemp. Hemp is regarded as resembling flax, but as possessing a higher
tensile strength (30 to 35 as compared with 20 to 25 kilos per square mm.).
It resists retting, and on that account is much valued for ropes and sail-
cloth.

II. THE SEED AND OIL.

Edible Seeds.—Galen tells us that it was customary to give hemp-
seeds to guests as a promoter of hilarity (cum aliis tragematis). Garcia
de Orta speaks of the Indian seed being smaller and darker coloured than
that of Europe. There is little doubt that the tendency for the seeds
(fruits) to become agglutinated with the resinous narcotic is much greater
in India than in most other countries, and this would seem to account

256
for their being described as darker coloured. But it is no stretch of imagination to assume that it was the presence of the very minute particles of the narcotic that, in the story told by Herodotus, made the Scythians shout for joy while in their medicated vapour baths. Hove's description (1787) of the vapour given off by the preparation consumed by his followers at Surat having overpowered him, might in fact be cited as a commentary on the passage in Herodotus. O. Schrader, in fact, says the Scythians never washed in water but intoxicated themselves with the smoke of the seeds of hemp. In Persia the seeds are called Shahdanah, or Emperor's seeds. Tragus tells us that in Eastern France in his time (1539 A.D.) the seed was cooked daily among other foods such as barley, but he adds it was regarded as dangerous if partaken of too liberally or too frequently. Paludanus in a footnote to Linschoten's account of hemp refers (1598) to a mixture eaten in India called busa or bosa which, he says, consisted of the seeds of Lolium and of hemp (see Eleusine, p. 521; also Malt Liquors, p. 758). Mr. W. Coldstream, for example, informed the Commission that the edible preparation known as mira consists of hemp-seeds mixed with parched wheat or bathu (Amaranthus) or of rice. Pundit Gunga Datt Upreti spoke of the seeds being cooked in Almora along with vegetables. Mr. Dharma Nand Joshi remarked that they make all vegetables palatable and wholesome. Mr. Anderson spoke of the parched hemp being mixed with grain and eaten, although, he adds, the mixture sometimes affects the eyes in the fashion known of charas. Mr. R. C. Artal of Bijapur mentioned that the seeds are employed as an ingredient in chutney. Mr. Minniken observed that in Bashahr the ripe seed is mixed with spirit to make it more intoxicating, and Sir Walter Lawrence in his work on Kashmir informs us that "the hemp seeds yield an oil which like charas is used for intoxicating purposes." It may thus be concluded that if the fruits be used without being specially cleaned they may be, and in India apparently often are, so impregnated or agglutinated with narcotic that they are distinctly intoxicating. These fully substantiated facts seem to justify the inference that the Scythians of old, as do the African bushmen to-day (Burton, Arab. Nights, i., 65), became intoxicated by inhaling the volatile narcotic present on the seed-coats and adhering particles of the inflorescence, without for centuries thereafter the drug having been isolated or separately recognised.

Hemp-seed is employed as a food for birds, poultry, etc., and in India is specially commended as an occasional diet for milk-cows.

**Oil.**—Hemp-seed when expressed yields 15 to 25 per cent. of a pale limpid oil. This is at first of a greenish-yellow colour but gradually deepens when exposed to the air. The flavour is described as disagreeable, but the odour as mild. Its sp. gr. ranges from 0·925 to 0·931. It becomes turbid at a temperature of 15° C. It absorbs from 143 to 144 per cent. of its own weight of iodine. Its drying properties are good, but in England it is rarely used for paint, though in some parts of Europe, where procurable in abundance (especially in Russia), it is fairly extensively utilised. It is also largely employed as a lamp oil, but its best use is in the preparation of soft soap. It dissolves in boiling water, and in 30 parts of cold alcohol. It is sometimes difficult to get linseed oil absolutely free from adulteration with hemp-seed oil. The oilcake is used in feeding stock. In the United States hemp is said to yield from 20 to 40 bushels of seed to the acre. The plant requires to be harvested before becoming quite ripe, owing to liability to seeding. The seed loses its germinating power very quickly, hence the stock should be one season old only. It is said that Russia annually produces close on half a million tons.
THE INDIAN HEMP PLANT

III. THE NARCOTIC—INDIAN HEMP.

So much has already been indicated of the narcotic property of Indian hemp that the subject need hardly be further dealt with in this work. Moreover, it has been so thoroughly treated of, in the publications quoted in the opening preamble, that it seems only necessary to refer the reader, who may desire full particulars, to these most useful publications. As already explained, there are primarily three forms of Indian hemp, with, under each, local modifications, special preparations, adulterants and imitations. Chemically, all three are one and the same. They represent different methods of production, different degrees of purity and intensity, and are often so blended into each other that their isolation becomes impossible, or nearly so. They may, however, be indicated briefly, as follows:—

1. Bhang.—This is also known as siddhi, subji, or sabzi, thandai, patti, etc., and in Central India it is vijaya, buti, and sabzi. It consists of the specially dried leaves and flowering shoots of either or both the male and female plants, whether wild or cultivated. Lt.-Col. Prain dissents somewhat from this opinion, since he would appear to believe that the male plant is inferior to the female in value as bhang. “There is reason for thinking,” he says, “that from the best bhang male leaves are excluded.” The narcotic principle, though not present in the very young state, begins to form with the growth of the plants, and reaches its greatest abundance about the time the flowers appear. But it gradually diminishes as the leaves pass maturity, and is entirely absent (or nearly so) from leaves allowed to turn yellow and to be dried up while still attached to the plant. [Baden-Powell, Pb. Prod., i., 505; H.D.C.R., iii., app., 153; Prain, Cult. and Use of Ganja, 12.]

The dried leaves as met with in the Indian drug-shops usually consist of a powder known as siddhi, and this may be composed of fragmentary leaves only, or, as already stated, of the inflorescence as well, and even of the seeds. Sometimes this is called patti (the leaf), the word bhang, the most general of all, having more often a wider signification than the dried leaves. Siddhi is collected on the plains and lower hills, frequently from the wild plant, but here and there, all over the country, small plots may be seen near the homesteads in which the plant exists in the condition of semi-cultivation. When prepared for consumption the fragments of the plant are ground to a paste, and of this an emulsion is made which, after being filtered through a cloth, may be consurnfed in that form, or flavoured with sugar, spices, cardamoms, melon seeds or milk. The simple beverage goes by various names: bhang or siddhi in Bengal; siddhi or thandai in the United Provinces; ghota in the Central Provinces; and ghota, tadhal or panga in Sind. In Madras a similar liquid is called ramras or ramrasam, which in Upper India is sometimes called dudhia. In Poona a beer made with juar and bhang is called bhoja. Occasionally music or other perfumes are added to disguise the objectionable smell, while to make the beverage more intoxicating and poisonous, opium, dhatura seeds, arsenic, strychnine, aconite, oleander root, and the seeds of black henbane are used. The special employment of the roots of certain grasses such as rice and judr is frequently resorted to (see Sorghum vulgare, p. 1040). A preparation of Indian hemp and alcohol is called bukki, and a drink called mudra (used in Baluchistan and the Panjab) is said to contain hemp, opium, alcohol, and dhatura. Majum is a sweetmeat prepared from the emulsion; it is extensively eaten all over India. The Emperor Baber mentions in his Memoirs (1519) the number of times he had partaken of “majum.” John Lindsay (Journ. Captivity in Mysoor, 1781, iii., 293) tells of his soldiers having been obliged to eat a “majum.” The practice is, therefore, a fairly ancient one. Lastly, it may be pointed out that in Thomas de Quincey’s Confessions of an English Opium-eater, “madjoon” would seem to be spoken of (but quite incorrectly) as the Turkish name for opium.

Of all the forms of Indian hemp bhang is the least harmful, and, according to
the vast majority of the opinions recorded by the H.D. Commission, it is the beer or refreshing beverage—the occasional indulgences or luxury of the middle and better classes of India. A large percentage of the people use it, and apparently with less injurious consequences than the similar consumption of alcohol in Europe. It is not, however, a cheap beverage, since the flavouring and perfuming adjuncts are expensive. By the people in the localities where the plant is wild, however, it is often employed in the form of a simple infusion without any adjuncts, and then of course it may be had for the trouble of collection and preparation. It would seem satisfactorily proved that no form of Indian hemp possesses the property of establishing a craving for its continued and extended use. The total prohibition, even were that possible, would therefore be strongly opposed by the majority of the people, though the fiscal control established by the Government meets with their very general approval. Honigberger tells us that in his day, “not far from the outside of the Delhi gate at Lahore, near the road to Anari or close by my hospital, there was an establishment called Seed Gunge, where this beverage was delivered gratuitously.” Several witnesses reported to the H.D. Commissioners places where the beverage was daily given (even now) to all applicants free of charge. Dr. Ewens alludes to the seats (takiars) in Lahore, where men assemble to drink bhang. Moreover, the use of bhang is considered essential in certain religious observances by a large section of the Indian community, and its total prohibition (sometimes recommended by Europeans) would be regarded as an encroachment on religious liberty. The employment of bhang as a cattle medicine is so widespread that its discontinuance would be resented even by those who do not consume it themselves as a beverage.

2. Charas.—This may be defined as a resinous substance that appears spontaneously on the leaves, stems, inflorescences and fruits of the hemp plant when cultivated in cold and dry countries. It is practically the active principle, and consequently a more powerful drug than either bhang or ganja. It is spoken of as the special narcotic procured throughout the North-West Himalaya from Nepal, Kumaon, Kashmir, Afghanistan, Ladakh, Herat, Bokhara to Turkestan, and was very possibly the gelotophyllum (laughing leaf) which Pliny says came from Bactria. The resin appears shortly before the flowers begin to form, and is present over a larger proportion of the plant than is the case with the third form, ganja, presently to be described. According to most writers charas is not produced on the male plants, a circumstance probably due to their being removed on account of the fine fibres contained in their stems, before the time that the charas would naturally appear.

Prain speaks of charas as a greenish-brown moist, resinous mass that possesses the peculiar odour of the hemp plant. When kept for some time it hardens, becomes friable and brownish-grey in colour, but when that earthy condition is fully attained, the drug is found to be inert. The name charas is said to mean a “bag” or “skin,” and was given in India in allusion to “the bags” in which the drug is imported from Central Asia. The name charas would, therefore, point to this peculiar form of the drug having been originally recognised as foreign produce.

In a commentary on the celebrated Sanskrit grammar written by Panini (300 B.C.), tikakata, umakata and bhangakata occur, and the termination kata, it is explained, means rajas or dust of sesamum, of linseed and of hemp. The kata of bhang might have been at once viewed as the resinous powder now known as charas but for the difficulty of understanding what could have been the kata of the other plants—perhaps the pollen grains in all cases were therefore meant. In Turkestan (according to Aitchison) charas is called nasha, before it is made up into the skin packages ready for export to India. It is subsequently freely adulterated with linseed oil and a powder of the dried leaves of the plant. In passing it may be here pointed out that Stein (Ancient Khotan) makes no mention
THE INDIAN HEMP PLANT

of coming across, in the ruins explored by him, either samples of charas or of the hemp plant in any form, and further that in neither The Bower Manuscript nor the voluminous records found by Stein is there apparently any mention of the hemp drugs. This is the more significant since, while discussing the modern trade in charas, Stein (l.c. footnote, 133) observes that the heavy import duty now imposed by the Government of India has caused the traders of Turkestan to turn to Khotan silk as a substitute commodity to be conveyed to India and there disposed of in exchange for the return of Indian goods.

The line of separation between what should be called charas and what might be accepted as ganja is, however, a very narrow one indeed. It would seem highly probable, in fact, that on the moister southern slopes of the Himalaya the resinous substance produced by rubbing the fruiting panicles between the hands is more frequently ganja than charas. The definition that charas is the pure resin without any admixture of vegetable tissue is true no doubt, but is perhaps not the whole truth. If both articles were freed from foreign matter, the question might still have to be asked, in what respects do they differ? Physically more than chemically very possibly, and as the direct consequence of production in a cold-dry or warm-damp atmosphere. [Cf. Marshall, Contrib. to Pharm. of Cannabis Ind., 1899; Holmes, Mus. Rept. Pharm. Soc., 1903, 47.]

Sir Walter Lawrence (Valley of Kashmir, 67) has expressed astonishment that the drug produced in Kashmir is in trade called charas, whereas "recent inquiries show that in the south of the valley the drug known as gard bhang or churu charas, is extracted from the female plant, and Indians who consume it declare that it is real ganja and utterly distinct from the Yarkandi charras, which is also procurable in Srinagar." "If the-Kashmiri drug is ganja and not charas it is somewhat surprising, and I have taken some pains to verify the statement more by the official, who investigated the subject of hemp drugs. He and the men employed in the trade maintain that the drug made in Kashmir is ganja." Lawrence then adds that contrary to the experience in Bengal, Kashmir ganja is produced from plants that are allowed to mature seeds, the oil from which is also intoxicating. It is thus highly probable that the true charas is a foreign article exclusively derived from Central Asia, and, as it came to India through Kashmir, was in ancient times called Kashmiri. Formerly it came also via Nepal, but at the present day the chief emporium is Hoshiarpur, the supply coming both via Kashmir and Kullu. It would thus seem highly probable that we do not even now possess an accurate account of the production of this substance, nor all the information desirable of the condition under which the dry resin charas or the moist adhesive ganja is produced. Pain holds that the former being comparatively permanent once on the surface, it is not affected by the subsequent fecundation and development of the subject of hemp drugs.

It may be here observed that there is at least one important difference between the South Himalayan so-called charas and that from Central Asia, namely the former is taken from the green plant before it is reaped, and the latter from the dried plant. The possibility of adulteration with actual dust and with fragments of the plant is very great with the Central Asiatic charas, and this circumstance may account for the higher price often paid for the purer qualities of the Indian so-called charas. For methods of collection consult the Dictionary (ii., 115-7); and Baden-Powell (Ph. Prod., 1868, 293, etc.).

Charas is almost exclusively used in smoking, though some of the finer qualities are employed for medicinal purposes. It is admitted on all hands to be a more pernicious drug than either bhang or ganja.

3. Ganja.—This is the dried flowering tops of the cultivated female plants, which become coated with a resinous exudation from glandular hairs, very largely, it would seem, in consequence of being deprived of the opportunity of setting seed. To secure this result, therefore, the male plants are deliberately removed from the field at an early date, by an expert known as the poddar. (Compare this with the account above of the removal of the males from the fibre-yielding crop.) One or two visits are paid by the poddar, with the result that every male plant is uprooted. As the female plants begin to form ganja, all the large leaves on their
stems and branches are also removed. The smaller leaves and bracts of the inflorescence become agglutinated and the manufactured article is valued very largely by its freedom from leaf. The colour and smell are features of merit, but as a rule the ganja which has the least leaf is regarded as the best.

Ganja is cultivated in several localities such as in North Bengal, on the Malabar Coast of Western India, and in the Tributary Mahals of Orissa (the Gourja ganja). These may be regarded as the chief centres, but it is also produced in the Central Provinces (Nimar), in Indore, Gwalior, Kishengarh, Mysore, Hyderabad, and in some districts of the Bombay Presidency. It may suffice to give a few practical facts regarding the Bengal cultivation and manufacture. It is grown in a very compact tract of country with a radius of about sixteen miles, and which lies in three districts, viz. Dinajpur, Rajshahi and Bogra. It is for administrative purposes placed under the Collector of Rajshahi, the sub-divisional officer of Naogaon being in immediate charge of this, the so-called Ganja Mahal. Seed-beds are formed on high land above inundation, and consist of a light sandy loam. The beds are richly manured and ploughed once a week from the middle of May forward, and are sown in August. Meantime the land on which the crop is to be ultimately raised is being also richly manured and top-dressed from the ditches and ploughed and harrowed once a month. By the middle of September the seedlings are transplanted to the ridges formed in the field. A month later a careful weeding is given, and in November the ridges are hoed down and the plants trimmed by the removal of the lower branches. This admits of a further ploughing between the furrows and of a top dressing with powdered cow-dung and oilcake, after which the ridges are again built up.

At this stage the first visit of the "ganja doctor"—the poddar—is made. Prain, in his paper (Morphol., Teratol., etc., l.c.), explains that the poddar's guide is the early appearance "of the often abortive, solitary female flowers that so frequently, in the Indian male hemp plant, take the place that theoretically should be occupied by the lowest pairs of paniculate male inflorescences." These abnormally placed female flowers, it would seem, are visible long before the inflorescence of male flowers could for certain be recognised. The poddar in consequence breaks the stems of the plants that manifest this peculiarity and the cultivator following behind uproots them, and fills up the vacant places by fresh transplantations from the purposely reserved surplus in the seed-beds. A second or a third visit of the poddar suffices for the complete extirpation of the male plants. But abnormal male flowers are not unusual on the female plants, and these the cultivator keeps a sharp outlook for and removes. By January the flowers begin to appear, harvest is general in February, and by the middle of March is completed.

There are three forms of ganja produced:—

(a) Flat Ganja.—The stems are cut with a sickle about 6 inches above ground, tied together by their ends, placed across a bamboo and carried to the selected place of manufacture. The inflorescences are then one by one placed on the ground, and trodden underfoot so as to cause the agglutinated flower-tops and smaller leaves to become compacted into flat masses (chápta ganja). These heads are then baled as "large flat" or "twig flat," according to the size of heads and length of stalks.

(b) Round Ganja.—Instead of being trodden, the heads are rolled underfoot so that they are less firmly compacted, and are in the form of rounded or sausage-shaped masses. Round ganja is never baled, but is tied up into bundles (goli ganja).

(c) Chur (Powder) Ganja or Rora.—Broken fragments or flower-tops detached from the twigs, whether of flat or round ganja, constitute chur. These are very largely produced through trimming, especially that of the round form.

Bengal Ganja is in other provinces of India usually designated as
THE INDIAN HEMP PLANT

CANNABIS SATIVA
Narcotic

"Baluchar," from the name of a village where it is supposed to have been originally procured. The ganja of Upper India, such as that of Gwalior and the Central Provinces, is called "Pathar." The refuse from the manufacture of ganja is often sold as bhang.

Medicinal and Chemical Properties.—The action of the drug in causing insanity has, by the Report of the Hemp Drugs Commission, been viewed as a greatly overstated belief. The moderate use of the drug is attended with no evil physical effects. If pure and taken in moderation it has little or no tendency to originate insanity. But when mixed with the poisonous substances sometimes employed it becomes most pernicious. Excessive use of hemp in any form, however, indicates and intensifies mental instability. It tends to weaken the mind, and may even lead to insanity. But in the year of the Hemp Drugs Commission only 7-3 per cent. of lunatics admitted to all the Asylums in India were said to be those in which hemp could reasonably be regarded as having been a factor of importance. [Cf. Gibbon, Med. Jurisprudence for Ind.; Walsh, in Journ. Mental Science, 1894.] Moreover, the insanity produced, as a rule readily gives way to treatment, and since the drug creates no craving its discontinuance is possible, and the restoration of the mental faculties almost instant. So much has, however, been written on these subjects that it is impossible to do more than refer the reader to some of the standard works that may with advantage be consulted.

Trade and Fiscal Administration.—In India the cultivation of this plant, where intended for the production of ganja, can alone be undertaken under license; moreover, the cultivation is periodically inspected, and the yield approximately ascertained. While no restrictions are placed on the sales to the trade, the produce when disposed of by the cultivator is stored either in Government warehouses for the purpose, or in approved godowns under double keys, one retained by the owner, the other by a Government official. Removals pay the fixed duty, and are recorded in such a way as to show the relation to the cultivator's estimated production and deed of sale. Both wholesale and retail traders have to obtain licenses. The traffic in ganja is thus under complete control through every stage. With regard to charas, a minimum duty of Rs. 80 per maund is levied on all imports. The drug is stored in approved warehouses and a further duty paid on removal, while inter-provincial adjustments are conducted on permits to carry from one province to another. Bhang, where found possible, is also taxed, but, the plant being wild in many localities, no interference is made with the domestic supplies of the people, the regulations having effect only on actual sales and regular trade. The sale of the narcotic in any form by persons not licensed to cultivate or sell these drugs, is a criminal offence.

Separate licenses have to be taken out for the traffic in each of the three kinds of the drug, and the retail vendor is prohibited from supplying
 TRADE AND ADMINISTRATION

children or insane persons with any. A limit is at the same time fixed on the amount that may be either sold to, or possessed by, a private person at one time. It is universally believed by both traders and consumers that all forms of the drug deteriorate with age. This is just the opposite opinion to that held with regard to opium. It accordingly follows that every effort is made to dispose of the produce year by year, and not to store it. It is perhaps on this account that such indifferent results have been obtained with Indian hemp as a medicine in Europe as compared with India. Long years ago Honigerberger (l.c. 157) deplored this fact. To ensure fresh stuff it has accordingly been recommended by Prain that all purchases by the European dealers should be made direct through the Government official in joint charge of the warehouses.

Area and Revenue.—In 1895, when the Government of India published their Resolution on the Report of the H.D. Commission, the total area in all India under regular cultivation of the plant was estimated at under 6,000 acres. In 1900-1 the Agricultural Statistics of India show the extent of cultivation to have been only 4,096 acres; in 1901-2 it would appear to have stood at 2,496 acres; in 1902-3 at 1,940 acres; in 1903-4 at 2,637 acres; and in 1905-6 at 2,645 acres, with, over and above, 419 acres in the Native States. If these figures denote an actual curtailment of area, not merely more accurate returns, they have curiously enough been coincident with increasing revenue. In the Excise Administration Reports, the Hemp Drugs are shown to have realised a total revenue of £201,344 in 1900-1, of £213,224 in 1901-2, and of £225,352 in 1902-3—later figures are not available. It would therefore seem that official returns may be accepted as exemplifying the continued careful control and restriction pursued by the Government.

Prices and Duty.—The prices of the various forms of Indian hemp vary so greatly that it seems hardly worth while to give a quotation of the figures usually recorded. The price depends upon a multitude of circumstances, such as the quality, method of preparation, degree of taxation, and the like. The Government of India, in their Resolution on the H.D. Commissioners’ Report, placed before the various Indian Administrations a table of retail prices per seer (2 lb.), which was commended to their attention with a view to gradually securing a greater uniformity. To manifest the extremes exhibited in that table the following may be abstracted:—GANJA in Assam sells at Rs. 15 lowest price and Rs. 40 highest price; while in Bombay it is sold, lowest price 6 annas and highest Rs. 5. CHARAS in Panjáb, lowest price Rs. 4, highest Rs. 15; while in Bengal its lowest price is Rs. 35 and its highest Rs. 40. BHANG in Panjáb sells at lowest price 2 annas and highest 8 annas, while in Bengal its lowest price is Rs. 1 and the highest Rs. 6 per seer. These variations to a large extent are the direct expression of the varying incidence of taxation, but there can be little or no doubt that there is a considerable variability in intrinsic merit, not only between the produce of one province and another but even between the different districts of the same province.

For the rates of duty and all other particulars regarding the traffic in hemp narcotics, the reader should consult the provincial Reports of Excise Administration in India. Some of these annual volumes (especially those published by the Government of Bengal) will be found to contain the fullest possible details.
CAPSICUM
Chillies.

D.E.P.,
i., 133.
Caper.

CAPPARIS SPINOSA, Linn.; Fl. Br. Ind., i., 173; Cooke, Fl. Pres. Bomb., i., 44; Pharmacogn. Ind., i., 135; CAPPARIDEÆ. The Edible Caper of Europe and the kabarra, kaour, kari, etc., of India.

A small prostrate shrub found on hilly and rocky ground in Upper India. It is distributed to Afghanistan, West Asia, Europe, N. Africa, Australia and the Sandwich Islands. There are a considerable number of species of CAPPARIS, no less than 30 being mentioned in the Flora of British India, but only two or three besides C. spinosa are of any great importance. These are C. aphyllya, Roth., the kard, nepi, etc.—a dense much-branched shrub found abundantly in the drier parts of the Panjab, Gujerat, Rajputana, Deccan and S. Karnaták, and C. porydta, Linn., f., the ardanda, kavilla, etc., found in the Gangetic valley, etc., as far north as Saharanpur, in the Western Peninsula, also in Chitta-
gong, Pegu and Ceylon. It is also distributed to Java and the Philippines. Besides these C. grandis, the pachunda, guli, etc., is found in the Deccan, Karnaták and Ceylon.

Oils.

Several species are known to yield OILS. C. grandis affords an oil used in medicine and for burning, while C. spinosa yields a volatile oil which has the properties of garlic oil (Pharmacog. Ind., i.e.). The caper is mentioned by Greek and Latin writers, and through them doubtless the medicinal properties of the root were made known to the Arabs. It was very generally employed in affections of the liver and spleen, and also in amenorrhoea. In India all parts of the plant are regarded as stimulating and astringent, when externally applied. The young flower-buds and fruits of C. aphyllya, as also of C. spinosa, are eaten in India. The former species is the more important; the buds are pickled and the fruits eaten both when green and when fully ripe. C. spinosa is met with in the Panjab, but it has never assumed the position of importance assigned to it in Europe, where the pickled buds form the "Capers" of commerce. Gerarde (1596) and Miller (1748) mention that the caper had been successfully grown in England in the open air, but it is usually regarded as requiring protection in winter. The Wood of C. aphyllya is employed in India for making combs, small beams and rafters, for the knees of boats, etc., and is valuable because of its not being attacked by white ants. [Cf. Tallej Shereef (Playfair, transl.), 1833, 120.]

History.

History.—There would seem to be little doubt that the entire series of plants constituting the genus CAPSICUM are natives of tropical America. Peter Martyr was perhaps the first person who described this kind of pepper. In an epistle dated 1493 (the year following the discovery of the West Indies), he says that Columbus had brought to Spain "pepper more pungent than that from the Caucasus." In 1494 Chanco, the physician who accompanied Columbus on his second voyage, addressed a letter to the Chapter of Seville on the same subject. In that he calls this pepper by its West Indian name, aì—-a word that has since been rendered as oìhi or aqi, and has survived in Spanish to this day. Although some of the 16th century authors maintain that the soliquastrum of Pliny is the Pod Pepper (CAPSICUM) of modern trade, the more strictly botanical writers are very nearly unanimous in the opinion that capsicum was not known in Europe prior to the discovery of America. In passing it may further be observed that all the older authors speak of soliquastrum as coming from Calicut, from which circumstance it may be inferred to have been the cardamom—a spice which to this day is almost exclusively derived from that port and which has been associated with the Malabar Coast of India from the remotest antiquity. At all events Amatus on Dioscorides (pub. 1154) describes capsicum with the cardamom. Fuchs (Comment. de l'Hist. des Pl., 1542-9, ch. 281; also Hist. Stirip., 1555, 797) gives an account of "Siliquastrum or Piperita," which by some is called "Indian or Chalechut Pepper," "Cardamom," "Spanish Pepper," etc., and which Avicenna speaks of under the name of "Zingiber cananim.

264
Matthiolius (New Kreuterb., 1563, 216) gives a good plate of Capsicum and calls it "Callicut pepper." He says it is a foreign plant lately introduced into gardens in Germany, and subsequently (Med. Compend., 1571, 322) he remarks that it is an obvious mistake to confuse Capsicum with Cardamomum. Clusius (Stirp. Adv. Nova, 1570, 134) observes that within his memory this plant (of which he gives a good plate) has been brought from Goa and the shores of Callicut. There can be no doubt, therefore, that the Portuguese had very early introduced Capsicum into Goa, and very possibly commenced to export it, in competition with the true pepper, hence Clusius as an after-thought may have associated Callicut with the new emporium Goa. Clusius (review of Garcia de Orta) in the Aromaticum, published in 1574, makes no mention of Capsicum; so that it may be inferred the plant had not been seen by Garcia de Orta in India. A little later, however, Clusius (Hist. Exot. Pl., 1605, 340) under Capsicum brasiliannum or wild pepper, observes that Spanish or American pepper was brought from the Spanish West Indies and carried to India by the Portuguese under the name of Pernambuco Pepper. Jacobus Bontius (Hist. Nat. et Med. Ind. Or., in Piso, Ind. Utire Nat. et Med., 1658, 130–1), who wrote in 1629, describes this pepper under the names of Lada Chili and Brazilian RICINUS, a fact that led some authors to confuse it with RICINUS COMMUNIS—the Castor Oil. [Cf. Paulus Aegineta (Adam. transl., iii., 171).] Rheede (Hort. Mat., 1679, ii., 109, pl. 56, in a note by John Common) remarks that the capo-molago or Indian pepper described by him was in reality Brazilian pepper, the prefix capo or capro denoting its introduction by the Arab traders; his plate is a typical example of Capsicum frutescens. It is practically the same plant which Rochefort calls aisi or carive; which Recchius (Hist. Nat. New Spain) describes as chilli or Mexican pepper; possibly also that which Piso calls by its Brazilian name quiya; which Elizabeth Blackwell figures and describes in her Curious Herbal (1739, i., pl. 161); and which Hernandus (Hist. Pl. Nov. Hisp., 1790, i., 277–82) discusses and illustrates most fully as one of the forms of Capsicum.

With a history so full and so pertinent (many other authors might be cited), it is indeed surprising that one of the greatest of Eastern botanical authors, nearly a hundred years after the appearance of Rheede's Hortus Malabaricus, should have affirmed in the most emphatic manner possible his belief that at least certain forms of Capsicum had not only been cultivated in India from the most ancient times, but that it was the eikouanum of Pliny and Capsicum ornatum of Rumphius (Herb. Amb., 1750, v., 247–52, pl. 88, ff. 1–4) advanced those opinions without observing that many of the passages in his own most admirable and detailed account contradicted his main contention. For example, while commenting on Rheede's Malabar name molago, he deprecatingly observes that no mention is made of its daily and well-known use as a condiment. It never seems to have occurred to Rumphius that Rheede's silence on that point, as also the fact that Marco Polo (1286–90) and Garcia de Orta (1563) made no reference at all to capsicum (though they discuss ordinary pepper and the cardamom), might be accounted for by the belief that the capsicums were unknown to the Natives of India in the time of Marco Polo, and even so late as that of Garcia de Orta, while they were but imperfectly understood in Rheede's time. Rumphius describes three main forms of Capsicum, which he calls (a) the great red capsicum, the riteje of the Dutch and recche of the Portuguese in India, the tschili bear or tschili-ayer of the Natives; (b) the lesser red capsicum—a fruitaceous plant called tschili-nura; and (c) the yellow Capsicum known as tschili-cuning. Rumphius then adds that the Portuguese write the West Indian name aisi as achi, hence comes the Indian name achar, which the Dutch render aetsjar—a word which has the same meaning as reccheado, namely pickles. It will thus be seen that practically the entire series of vernacular names mentioned by Rumphius, far from their establishing an ancient knowledge in India, would seem to prove that the introduction of the plant may have taken place somewhere about the middle of the 17th century. The names in use in India to-day are clearly of foreign or modern origin, such as chillies, lat-marcha (= red pepper), goa-mircha and the like. There are, in fact, no ancient

Modern Names.
names for the capsicums in Chinese, Sanskrit, Arabic, Persian, Hebrew, Greek, or Latin. No Indian botanist has ever recorded having found a species of *Capsicum* in a wild condition. But the rapidity with which the species and races of this pepper became disseminated throughout the tropical and warm temperate tracts of the globe, following closely on the discovery of the West Indies and America, is one of the many examples of the marvellous powers of adaptability and endurance possessed by the plant-cohorts from the New World on their invading the Old.

The following statement is derived mainly from Mr. H. C. Irish's admirable review of the varieties and cultivated races of this species:—

(a) Var. *abbreviatum*, Fingerh.: the Celestial, Etna, Kaleidoscope, Red Wrinkled Princess of Wales, etc.

(b) Var. *acuminatum*, Fingerh.: the best examples are the erect-fruited Chilli and the pendent-fruited Long Cayenne, Long Yellow Cayenne, Nepal Chilli and the Yellow Nepal Chilli. It includes, in fact, most if not all the long, pointed, pendent forms common as field crops. Recently Mr. H. M. Leake performed some interesting experiments with capsicums at Dalhing Sarai. He selected seeds carefully and sowed them in order to watch the tendencies to variation. Nearly half the erect podded stock had pendent pods. Every plant was, however, consistent, either having all its pods erect or all suspended. He further found that chillies will grow on *usar* land if sown early. Very possibly most of Leake's plants belonged to this variety, but as I have not seen any of his specimens I cannot say for certain.

This would appear to be the *Capsicum minus flavum* of Rumphius (lc. 248). Mr. Irish remarks that the seed of the Nepal Chilli had been supplied by the Superintendent of Saharanpur Botanic Gardens, and on being cultivated proved different from other plants seen by him. In the Report of the Saharanpur Botanic Gardens (1894-5, 10) it is stated that the Superintendent had received seed direct from Col. H. Wylie, British Resident in Nepal. The plants grew freely, but the pods produced possessed none of the peculiar flavour and pungency of the pods imported from Nepal. The Superintendent then adds, "In the letter which accompanied the seeds Col. Wylie informed me that that would prove to be the case, as the variety so much in request is the product of a peculiar kind of soil, only found in certain localities, and that in Nepal itself the true Nepal chilli when not grown on the right soil, scarcely differs from the common long red chilli of Indian bazars."

(c) Var. *cerasiforme*, Miller: Roxzb., Fl. Ind., i., 574.—Cherry-pepper is often alluded to by the early authors, such as Miller, Gerarde, Parkinson, Tournefort, etc. This includes the Little Gem, Prince of Wales, Cherry, Yellow Cherry Oxheart, Yellow Oxheart, etc.

(d) Var. *conoides*, Miller: the best-known races are the Coral Gem, Tobasco, Cayenne, Orange-Red Cluster, etc.

(e) Var. *fasciculatum*, Sturt.: the better known races are Red Cluster, Yellow Cluster, etc.

(f) Var. *glossum*, Sendt.: Roxzb., Lc.—This is the kaffree-murich; often alluded to and figured by the early European writers such as Miller, Parkinson, Fousch, Gregorius, Baubin, Morison, Rheede, etc. Under this form have to be placed—the Emperor, Monstrous, Sweet Spanish, Bell, Ruby King, Golden King, Brazilian Upright, Squash, Yellow Squash. In India the races of this variety may be said to exist mainly as garden plants, though large inflated yellow fruits of this form have recently begun to appear in the markets as a regular article of trade.

(g) Var. *longum*, Sendt.: *C. annuum* and *purpureum*, Roxzb., Fl. Ind., i., 573; *C. bicolor*, Bot. Mag., 43, n. 1835.—This is the plant most frequently described by the early European authors. The best-known races are Black Nubian, Long Red, Country Fair, Cardinal, Long Yellow, Elephant's Trunk, Ivory Trunk, etc. Roxburgh tells us that he found a single plant of *C. purpureum* in the Botanic Gardens, Calcutta, in 1706 but could not learn whence it came, though he adds, "most likely from the Malacca Islands." Irish assorts all these together as forms in which the calyx rarely embraces the base of the fruit. It seems probable that most of the plants hitherto regarded by writers on Indian garden plants as forms of *C. frutescens* should be relegated to this position.
FIELD AND GARDEN CULTIVATION

This is often called "Bird Pepper." According to the _Pharmacographia Indica_ (ii., 563), _C. minimum_ exists as a weed of cultivation in most parts of India. This I personally have never observed, and hesitate to accept. Owing to the large size of the plant it is the _gach-marich_ of most Indian writers.

_Var. baccatum_, Linn.: _C. minus rubrum_, Rumph., l.c. 248, t. 88, f. 2; _C. Brasili-anum_, Clusius, Hist. Exot. Pl., 340, etc.

Rheede and Rumphius figure and describe forms of _C. frutescens_, but say remarkably little about the capsicums most prevalently cultivated at the present day. And a thoughtful perusal of the passages used by Roxburgh, in his _Flora of India_, leaves the impression that, even in his day, the cultivation of no capsicum assumed the magnitude of a regular field crop, such as may be seen to-day in almost every province of India, especially in Bengal, Orissa, Madras and the Deccan. But _C. frutescens_, far from having become the most abundant form, is usually met with as solitary plants in the grounds around temples and in the flower gardens of the well-to-do classes, but is hardly if ever a regular crop. It is nearly always distinguished as the _gach-marich_ or "long ka marich," as it is called by Buchanan-Hamilton (_Stat. Acc. Dinaj.,_ 187–8). In India the most extensively cultivated are the following forms of _C. annuum_ :—var. _acuminata_ followed by _longa_, and next _cerasiformis._

_Cultivation._—It is impossible to furnish any statistics of the areas under these plants since they are most frequently raised as borders to fields, or as lines through fields. In Eastern and Northern Bengal, however, capsicum becomes a regular field crop, thriving best on a light sandy loam. The form most frequently seen is a long, narrow, pointed, pendulous red fruit. The seed is sown broadcast, and in Bogra, for example, capsicum assumes the condition of an exceedingly important cold-season crop. In the _Settlement Report for Nagpur, Central Provinces_, some useful particulars are afforded regarding chillies. The seed is sown about June and the seedlings are transplanted about August. In September the earth has to be banked up against the stems. Irrigation is necessary during the cold weather, and the crop comes into season from January to March. Its value is from Rs. 120 to Rs. 150 per acre. Dry chillies are only about one quarter the weight when green. Very little information exists regarding the red pepper of Assam or of Burma. Of the Kyauke district of the latter province we read that the lowest estimated yield would be 365 lb. (=100 viss), valued at Rs. 15 an acre, the highest about Rs. 350. Of Sagaing it is said the seed is sown in August, planted out in September and October and the crop ripens from January to March, the green fruit a month earlier. A long and highly instructive account will be found in the _Settlement Report for Meik-tila_ (1896–8, 8, 28, 69), which shows the high-class cultivation pursued, the labour entailed, and the risks through failure of rains. The crop usually comes into bearing by the middle of December. The trade is entirely in the hands of the Chinese, who rule the market and export all they can purchase. In Myingyan the sowings are not made till September, and the plants come into season about March. Chillies have been recommended as a catch crop among young tea for Assam.
In the Bombay Presidency chillies are rotated with ordinary market-garden produce. On the black soil of the Deccan (Krishna Valley) is produced a fairly large proportion of the red pepper conveyed to Bombay. But the most important areas of production in Western India are Dharwar, Belgaum, Khandesh, Satara, Poona and Sholapur. Capsicums are usually sown in the rains, but if the land be irrigated they become a rabi crop. Usually they are raised in a nursery and transplanted, and in about three months the first crop may be gathered. [Cf. Mollison, Textbook Ind. Agri., 1901, iii., 206-9.] Speaking of the Panjáb, Dr. Stewart tells us that when grown on the hills, chillies become more pungent, hence no doubt the special merit of the so-called Nepal Cayenne. In the Lahore Gazetteer (1893-4, 164) will be found useful particulars of this crop. It is planted out in June and begins to come into season by October. Thirty maunds an acre for wet and 8 for dry are considered a fair outturn. The cultivators sell it wet at 30 seers or one maund the rupee. In the Gazetteer for Montgomery District (1898-9, 142) it is stated that the crop is sown in January—February; the ground dug about the roots in February—March; watered every fifteen days; and the pods collected May, June and July. White ants and parrots prey on it.

Uses.—It is needless to mention the varied uses of capsicum. The dried fruit reduced to powder forms the Red Pepper or Cayenne of commerce. But cayenne is, as a rule, prepared from the small, very pungent fruited forms only. It is an ingredient in all curries and many other food preparations, and is used throughout India and by every class of the community, so that while of comparatively modern introduction, the consumption of red pepper has now become all but universal. There are various brands of pepper sauce, which are produced as decoctions of the fruits in salt water or vinegar (see p. 1110). Tabasco and Paprika are special European sauces. In Bengal an extract of the consistence of treacle is regularly prepared and sold. The green fruits are pickled or cooked fresh with special dishes or even eaten raw. As a medicine capsicum is stomachic, stimulant and astringent; cayenne pepper is a valued adjunct to gargles, and an ingredient in most medicines that are intended to alleviate toothache. As a rubefacient and counter-irritant, the bruised fruits, in the form of a poultice, act energetically, and added to mustard are often highly beneficial. For the medicinal uses and chemical properties the reader should consult the Pharmacographia Indica and other such works.

Trade in Capsicum.—During the five years ending 1900-1 the foreign exports rose from 8,126,175 lb. valued at Rs. 7,20,925, to 9,485,820 lb. valued at Rs. 12,47,349. These figures represent an increase of 16.7 per cent. on the quantity, and as much as 73.0 per cent. on the value. In 1906-7 the corresponding figures were 11,007,929 lb. and Rs. 14,37,635. During that year Madras contributed 7,677,763 lb., Burma 1,386,739 lb., Bengal 1,567,162 lb., and Bombay 363,060 lb. The most important receiving countries were Ceylon, which took 8,419,713 lb., the Straits Settlements 1,872,738 lb., Mauritius 287,027 lb., Aden 104,356 lb., the United Kingdom 85,428 lb., and other countries the balance of the total. These figures are, therefore, representative of the normal and present condition of the traffic, and they also denote its thriving condition. This is confirmed by the account of the Trade carried by Rail and River in India during 1906-7. During the five years previous the recorded transactions under the statement of imports were 832,648 cwt. in 1902-3; 760,611
A USEFUL FOREST TREE

cwt. in 1903-4; 763,106 cwt. in 1904-5; 977,801 cwt. in 1905-6; and 888,069 cwt. in 1906-7. But of these very large amounts only about one-third was received by the port towns as the supplies to meet local demands and foreign exports. Turning to the corresponding returns for exports, it is seen that Madras is by far the largest producing province of India proper (that is, excluding Burma, not shown in the returns of rail and river traffic), followed ordinarily by Bengal and the Panjáb. All the rest of India (including the Native States) exports usually about the same amount as Bengal, which is commonly only about half that of Madras.

CAREYA ARBOREA, Roxb. ; Fl. Br. Ind., ii., 511; Gamble, Man. Ind. Timbs., 364; Cooke, Fl. Pres. Bomb., i., 497; Duthie, Fl. Upper Gang. Plain, 344-5; Brandis, Ind. Trees, 332; MYRTACEÆ. The kumbi, ayna, arjana, putai-tanni-maram, kumbir, buda-durmi, kaval, gavulda, banbue, etc. A large deciduous tree of rapid growth, frequent in the Sub-Himalayan tracts from the Jumma eastward and in Bengal, Burma, Central and South West India, according to 5,000 feet, also met with in the moist regions of Ceylon. Bhandarkar (Des. Acc. Assam, 1841, 43) described it as a "tree of immense size." The wood . . . well adapted for the stocks of match-locks." It is much subject to the defoliating lymantrid moth, Dasychira thwaitesi, Moore. The leaves turn red in the cold season.

It appears to yield a Gum, and a good FIBRE for coarse cordage and sacks is made from the bark, the latter part being also employed in TANNING and as a DYE. Tasar silkworms feed on the leaves. The bark is also used as an astringent MEDICINE; when moistened it gives out much mucilage and is utilised in the preparation of emollient embrocations. The flowers are given as a tonic after child-birth, and the dried calyces (vakumbhā) of the flowers are sold in the market as a demulcent in coughs and colds. The fruit, known as khīni, is eaten in the Panjáb and is also given to cattle. According to Innes (Jungle Products, 1898, 10) the bark is ground into a kind of flour in Oudh during famine. The seeds are said to be more or less poisonous. The Tīmber, which is very durable and fairly hard, is used for agricultural implements, gunstocks, houseposts, cabinet-work, etc., but Kurz says it is too heavy for such purposes (43 to 60 lb. per cubic ft.). It stands well under water, and is much admired for axles. "This is an important tree with a fine wood, which is too much neglected." (Gamble). The fibrous bark is used as a slow-match in Mysore, and has been successfully tried by the Ordnance Department as a substitute for English beech in fuses. In Ganjam it serves for the scanty clothing of Hindus affecting sanctity. Rheedoe (Hort. Mal., iii., 36) says that wild pigs are very fond of the bark, and that it is used by hunters to attract them.

CARICA PAPAYA, Linn. ; Fl. Br. Ind., ii., 599; Cooke, Fl. Pres. Bomb., i., 524; PASSIFLOREÆ. Most of the vernacular names, papeya, papaya, papia, bappayi, popai, etc., are obviously derived from the Carib ababā, which is still further corrupted into the English Papaw. The Burmese name himbawthi means fruit brought by sea-going vessels, and the Panjábi name khārba ṭu is Castor-oil-Melon.

History.—A subherbaceous almost branchless tree, commonly cultivated in gardens throughout India and in various localities more or less naturalised. The fruit is not mentioned in the Ain-i-Akbari as having been known to Akbar. It was sent to Chusius from Brazil in 1611 (Hist. Exot. Pl., app. 42), who gives good drawings of the male and female plants. George Marcgraf (Hist. Pl., in Piso, De Med. Bras., 1648, 103) furnishes an account of the plant, and a short description, with a figure, is given by Jacobus Bontius (Hist. Nat. et Med. Ind. Or., in Piso, Ind. Utri. re Nat. et Med., 1658, 95). It was figured and described admirably by Boyom in 1656 as an Indian plant introduced into China (Fl. Sin., pl. A), so that it must be regarded as another instance of the rapid dispersion of new plants after the discovery of America. Rheedoe (Hort. Mal., i., 21, f. 15), 1686, and Rumphius (Herb. Amb., i., t. 50), 1750, also figure and describe both male and female plants, the former observing that the Malabar
THE PAPAW FRUIT

Pharmacopoeia did not include the drug. Hughes (Hist. Barbados, 1750, 181, tt. 14, 15) gives a couple of splendid plates prepared by Ehret, while Labat (Noves. Voy. aux Isles de l’Ameriq., 1724, ii., 308) contributes a useful account of the plant. Dr. Dymock believes that a fibre from the stem is utilised in America and Africa, but the principal value of the tree lies in the fruit, which is both eaten and employed as a Medicine. An account of its medicinal properties may here be summarised from The Agricultural Ledger (1896, No. 31). The digestive juice of the tree was probably known in the West Indies at a very early date, and appears to have been communicated to the inhabitants of this country upon the introduction of the tree by the Portuguese. It has long been the custom in India to render meat tender by rubbing it with the juice of the fruit or by wrapping it in papaw leaves. In 1877 the milky juice began to attract attention in Europe as a digestive ferment, and Herr Wittmaek of Berlin in 1878 made a careful examination of its properties (Pharm. Journ., Nov. 30, 1878). On the evidence of medical, physiological, and chemical experiments made with papaya, the active principle has been separated and given the name of papain or papayatin. It was first separated by Peckolt. This may now be considered almost an article of medical commerce in Europe, and has in fact been extensively used in France and Germany, as well as in England, being given with good results even to children. Notwithstanding all the experiments made with this vegetable pepsin, it has not as yet been introduced into the British Pharmacopoeia, though four preparations of it are given in the “Extra.-Pharmacopoeia.” Papain is even held by some to compare very unfavourably with pepsin when tested with egg albumen. Mr. J. C. Umney, reporting on a sample of 12 oz. of dried Carica powder, wrote:—“There is no doubt that by repeated precipitation by alcohol a highly active digestive product might be obtained from this crude concentrated papaw juice, valuable for use under those circumstances where pepsin is unavailable.” [Cf. Agri. Ledg., l.c. 310; Bouehut and Wurtz, Comptes Rendus, 1889, 425; 1890, 1379; Bouehut, 617; Wurtz, 1891, 787; also Dict. de Chem., suppl., ii; Pharm. Journ., ser. 3, x., 343, 383; Chem. and Drugg., 1904, 185.]

A question of importance to be settled is the most serviceable form of commercial papain. And since prolonged moisture is deleterious, the juice should be dried as soon as possible; but heat is said to destroy its activity, hence it should be dried at a low temperature. A preparation of this kind is sold in commerce under the name of “Finkler’s Papain.” The best method to prepare papain is to collect the juice of the unripe fruit, mix it with twice its own volume of rectified spirit, let the mixture stand for a few hours, and then filter off the insoluble matter and dry in vacuo or over calcium chloride at the ordinary temperature of the atmosphere. After being powdered it should be kept in well-stoppered bottles ready for use. In view of a possible trade either in India or in Europe, manufacturers are recommended to observe carefully the precautions just enumerated. On account of caste difficulties, it might not prove possible to introduce animal pepsin very largely into use in India, but a good vegetable substitute might be of much value and find a ready sale.

The ripe fruit is eaten by all classes and esteemed innocent and wholesome. A wonderful range in quality is observable. In some localities, such as Hazaribagh in Chota Nagpur and Gauhati in Assam, the fruit is large and very sweet; in others it is small, coarse and hardly edible. The opinion generally prevails that to obtain good fruit it is necessary to remove the majority of the male trees. The better qualities of the ripe fruit are eaten with a little sugar and fresh lemon juice, and by some people with pepper and salt. The use of papaw juice in softening tasar cocoons and thus facilitating their being reeled, has recently received some attention.

A dichotomously branched bush cultivated for its fruit in most parts of India and said to be wild in Oudh, Bengal, S. India, the Konkan and Kanara; distributed to Burma and Ceylon. The tree yields Lac in the Panjáb (Agric. Ledy., 1901, No. 9, 211). The fruit is ripe in July to August. It is mentioned in the Ain-i-Akbari (Bloehmann, transl., 1590, i., 67) as sub-acid, and as sold at 1 dam per seer, i.e. 40 seers for Rs. 1. It is said to be used as an auxiliary in dyeing and tanning; an adhesive fluid exudes from wounds on the stem. When unripe the fruit is astringent, and when ripe – cooling, acid and useful in bilious complaints and as an antiscorbutic. The root is acrid and is made up as a paste with lime-juice and camphor, and used to keep off flies and relieve itch. Just before it ripens, the fruit is made into pickles and also employed in tarts and puddings. When fully ripe it makes a jelly equal to red currant, for which purpose it is grown in European gardens. The Natives universally eat it fresh and do not cook it, except as a preserve in curry or chutney. The timber is hard, smooth and close-grained, and is used both as fuel and for making spoons and combs, especially at Udayagiri in Nellore. The shrub makes exceedingly strong fences, and its number of sharp spreading thorns render such hedges almost impassable.

Carpsinum, A. DC.; a small thorny evergreen shrub, wild in most parts of India, especially in the drier zones. The small fruit is eaten and the timber used for much the same purposes as that of C. Caramus. It is an important element in reforestation, since it persists on the poorest and rockiest soils in spite of being greedily eaten by sheep and goats. Rumphius (Herb. Amb. [Bauhin], 1533, vii., 57) describes C. Caramus, the cultivated plant, whose fruits he says are made into pickles when half ripe. His plate (t. xxv.) is, however, such that its determination is impossible.

History.—Considerations of space forbid any attempt to discuss the carpet Industry of India in detail. As pointing possibly to their essentially foreign nature, carpets are in India often designated as alcatis (katīf = a carpet with long pile, in Arabic). They are mentioned by Pinto (1540 A.D.); Tenreiro (1569); by Linschoten (1598); and by Pyrard (1608)—the last author gives details of the luxurious habits of the Portuguese ladies of Goa, sitting on costly alcatis. There may be said to be two chief kinds of carpets in India:—(a) Pile Stitch (the kalīnā or galīkās), and (b) the Plain Stitch (the darī and sharīnā). The reader will find a fairly comprehensive sketch of pile Carpets in Indian Art at Delhi, 1903, and with much advantage might consult the special monographs mentioned above as also the article in the Dictionary, while the series of admirable plates given in the Journal of Indian Art (1905) will fully elucidate the subject. In passing it may be said that there is no certain knowledge that the manufacture in India of high-class pile carpets dates farther back than the reign of the Emperor Akbar, of whom we read that in the year 1590 he “extensively encouraged” carpet weaving in Agra, Fatehpūr and Lahore, and again that “all kinds of carpet-weavers have settled here (Agra) and drive a flourishing trade.” [Cf. Ain-i-Akbari (Bloehmann, transl.), i., 55; (Gladvins, transl.) ii., 30, 41–2; also (Jarrett, transl.) iii., 9.] One of the earliest and best-known carpets from the Imperial factory at Lahore is that presented in 1634 by Mr. R. Bell to the Girdlers’ Company of London, and which may be seen in the Com-
CARPETS AND RUGS

Pile Stitch

Company's hall. It bears the Company's arms and is Persian in design. It is quiteprobable, however, that India possessed a carpet industry of its own, thoughvery possibly not in pile carpets, long anterior to the advent of Persian influence(see under Multan, also Ellore). But it would be difficult if not impossible toprove either that India possessed an indigenous art of pile-carpet weaving beforethe date named, or that the introduced industry made much progress for manyyears subsequently. It, however, survived and in time absorbed so manylocal conceptions as to justify the description "Indian Carpets." It has beensaid that the modern jail-made pile carpets have debased and degraded a systemof manufacture that had been "literally and figuratively interwoven with thelife of the people." But if the pile-carpet industry was only introduced andfostered by Akbar and practised by his co-religionists, and if it be the fact thatit has not to the present day been taken up by any recognised Indian caste,itis difficult to see how it could be described as having become "interwovenwith the life of the people." — It is much more likely that the modern jail-manufacture preserved from extinction the foreign art, than that it debased anddegraded it. Milburn (Or. Comm., 1813, i., 136) says that carpets were formerlyan article of trade, but through "the improved state of our own manufacturesand the heavy duty on Persian carpets, they are now seldom imported." Itwould thus seem fairly certain that by the beginning of the 19th century theIndian carpet trade (such as it had been previously), like that of Persia, hadsuffered greatly through the rise of British manufacturing enterprise. Thecraftsmen in all countries produce the standard of goods demanded of them;it would therefore be most interesting to obtain any sort of indication of theclass of goods in demand immediately prior to the modern jail-made artists.

Native Demand.

So far as Indian records are concerned there is nothing to show that the Nativesof India to any material extent ever used, and certainly to-day they do not use,Indian pile carpets. Pyrrard (Voy. E. Ind., 1601–10 (Engl. transl.), ii., 248)observes that "They make carpets of the fashion of those of Persia and Ormus,but not so fine or so dear, for they use the rouger and longer wool; the patternsare however the same; they also make cotton carpets with bands of manycolours." So long ago as 1655, Terry in his Voyage to East India (ed. 1777, 129)pointed out that the Eastern artists were essentially imitative. He speaks oftheir cotton and silk carpets, but makes no reference to woollen carpets. Thus,then, for the degradation of Indian art not the Government nor the Nativesare responsible, but the people of Europe and America, who ask for andtherefore get cheap inartistic productions. And this has possibly been confirmeddefinitely by an invention recently announced that will enable Oriental carpets tobe produced by new and special machinery at a price far below that of thehand-loom weaver.

For the purpose of easy reference the classification employed in Indian Art at Delhi may be pursued in this review:—

I. Pile Carpets:—

1. Panjáb.—The chief centres of the carpet industry in this provinceare Amritsar, Kashmir, Lahore, Multan, Hoshiarpur, Batala, Bahawalpur,Kohat and Bannu, and they have been named in their order of importance.But Peshawar has also to be added, since it is the great emporium of the Trans-frontier traffic in carpets brought from Afghanistan, Turkestan and Persia.

Lahore.—It has already been suggested that the manufacture of carpets at Lahore, established very possibly by the Emperor Akbar, soon decayed, andin support of that view it may be pointed out that in Honigberger's Thirty-five Years in the East (a work that deals specially with Lahore prior to 1852) thereis no mention of an indigenous carpet industry. In this connection also it maybe observed that the Ain-i-Akbari makes frequent reference to the Persiancarpets as regularly imported into India (Blochmann, transl., 55). And it wouldseem probable that most of the Lahore carpets mentioned in the Records of theEast India Co., and elsewhere, refer to that Trans-frontier trade and not toIndian woven carpets. A letter to the East India Co., for example, of the year1617 (Foster, E.I.C. Letters, vi., 250) mentions that "carpets to be wellchosen would require a long time: those which are true Lahore carpets arenot suddenly to be gotten." It is possible that this may point to the survivalof the Muhammadan carpet-weaving industry (introduced by the Emperor some30 or 40 years previously), or it may simply denote the uncertain Trans-frontiersupply, the carpets being picked up in the bazars, not ordered from the weavers.

At the present day, at any rate, the most prized carpets in Lahore Museum are
AMRITSAR AND KASHMIR

those discovered at Peshawar, and, with the exception of a few looms in the jails, there is no local industry. A beautiful carpet, the property of Mr. G. Saltis, is figured in the Journal of Indian Art for April 1905, and said to have come from a Lahore factory in the 17th century.

Amritsar—This is probably the most important carpet-weaving centre in India, although the industry would appear to be quite modern. I have not been able to find any references to it, either in the East India Co.’s Letters or in the older books of travel. It may be said to be mainly in the hands of Hindus who employ European supervision, and Muhammadan weavers who work (for the most part) on the contract system. It is affirmed that the utmost care is taken in securing the oldest and choicest patterns and in selecting the wool and the vegetable dyes. Pashm (the fine shawl-wool) and camel’s hair are used for the best descriptions, and, as with all Indian carpets, the work is done entirely by hand. There are several factories, some of which possess as many as 300 looms, others not more than eight or ten. The industries of Kasur and Batala may be taken as off-shoots of the carpet-weaving of Amritsar.

In Kashmir there are several factories which turn out extremely beautiful work. The trade is in Srinagar, and the factories are practically all owned by Europeans, and were originated to find labour for the shawl-weavers who were thrown out of employment through the decline in the demand for their hereditary craft manufactures. The plates in the Journal of Indian Art (1905), July and October (six in number), fully exemplify this style. The fine old carpets preserved in the Asar Mahal of Bijapur are believed to date from 1657 and to have come from Kashmir. If this be correct the Delhi Emperors may have established a factory in the “Happy Valley” 250 years ago. The carpets in question are fully representative of the styles usually designated Mughal. [Cf. Journ. Ind. Art., t.c. Jan.]

Multan is often spoken of as having an indigenous carpet industry, or at all events one which dates prior to the introduction of the Persian craft. It thus seems probable that the so-called Multan conceptions were modelled on rugs brought long ago from Turkestan, in consequence of the Pawindah trade. The narrow shape, bold yet not clear detail, and vivid colouring are characteristics of both Multan and Turkestan carpets. On the other hand, Mr. Latimer speaks of the household industry of Multan as characterised by names of tools, designs, and methods of weaving that are clearly of Persian origin. Examples of Multan and Dera Ismail Khan carpets are to be seen in the Journal of Indian Art (1905), July and October numbers. Bahawalpur carpets differ but little from those of Multan. In passing, mention may be made of a recent attempt to utilise in the local carpet industry the vast supplies of the floss of Colocynthis gigantea (p. 207).

Peshawar is, as has already been observed, the emporium for Trans-frontier rug weaving, notably Turkoman or Tekke (formerly called Bokhara) rugs and the expensive Herat and Yarkand carpets. In Kohat and Bannu and a few other places along the North-West Frontier a peculiar form of rug is produced called aghai, in which loops of the weft threads are made to protrude an inch or so between each pair of the warp strands. The designs are usually in purple or crimson with black, yellow, and sometimes green. The result is crude but not inartistic.

2. Rajputana and Central India.—From the jail-looms of Jaipur excellent rugs and carpets are produced. Some of the most historic of pile carpets are, it is said, in the possession of His Highness the Maharaja. In the Journal of Indian Art is given a coloured illustration of one of the gems of that series. Bikanir produces the best carpet-wool in India, and is thus eminently suited to become a great weaving centre. The Central Jail has for some years taken a high place for the quality and artistic merit of its carpets. The patterns followed are mostly those of the famous book on Oriental Carpets published by the Imperial and Royal Austrian Commercial Museum, and the carpets produced have attained a position of great merit, through the enlightened interest taken in the subject by His Highness the Maharaja. Ajmir jail also produces many excellent carpets and beautiful rugs.

3. Sind and Baluchistan.—The carpets manufactured in Sind closely resemble those made in Multan. They are said to be the cheapest, coarsest, and least durable of all Indian carpets. The Baluchistan rugs are in design Turkoman, not Persian. They arrive by camel-caravan at Quetta (and Peshawar also) from Afghanistan, mainly Seistan. They are made mostly of goat’s hair, which gives

them their singularly beautiful lustre. But the Baluchistan carpets and rugs have deteriorated sadly from their pristine beauty and excellence.

4. United Provinces.—Several centres are noted for their carpets, such as Agra, Mirzapore, Jhansi, Jubbulpur and Allahabad. Agra is one of the three centres at which the Emperor Akbar endeavoured to establish a carpet industry. In the Journal of Indian Art (Oct. 1905) two plates are given of carpets turned out at this centre. To this day the superior designs of its jail-made carpets are a striking refutation of the charge brought against the jails of having degraded the carpet industry. Recently a factory has been established under European management, to utilise the skilled labour outside the Central Jail. It appears from the E.I.Co.'s letters that Agra was an important distributing centre for other than locally made carpets. Thus the Company's servants of Surat purchased Lahore carpets at Agra (E.I.C. Letters, 4c. 250), and the Portuguese merchants of Goa took various carpets from Agra in exchange for jewellery.

5. South India.—The carpets exported from Masulipatam and Cocanada were those that first attracted attention in Europe as being specifically Indian, and doubtless a century ago they were made at much the same centres as to-day. At Ellore, where the weavers are Muhammadans but very poor, the business is done by advances. Three classes of carpets were shown to me during a visit made by the Delhi Exhibition:—(a) carpets of foreign design, mostly Persian, and defective in every direction; (b) carpets collectively known as Ram Chandra design. In the Journal of Indian Art will be seen (July and October numbers) examples of these carpets, especially those from Vellore. The same journal (viii., pl. 50) shows a Coromandel carpet which doubtless belongs also to the Ram Chandra group. These, as a rule, were good, the colours being well chosen but the quality very low, not more than 5 or 6 threads to the inch; (c) the third type represented by an old rug which was so woven (by what the weavers call the "velvet method") as to simulate the fine texture of the old grass-mats. This was probably the original style of Rajamundry and Ellore. Masulipatam once turned out some of the finest carpets in India, but foreign exporters are said to have degraded the industry by supplying cheap and bad material. At the writer's suggestion the Madras School of Arts reproduced for the Delhi Exhibition two fine Ram Chandra carpets, the originals of which are preserved in the Madras Central Museum. The prevailing features are the rich deep brown-red of the field and the quaint border of rosettes of flowers. Malabar is said to have formerly produced the only pile carpets of pure Hindu design made in India. They are apparently not now manufactured. In the account of Sir George Birdwood—his Life and Work—as given in the Journal of Indian Art (viii., pl. 50), a corner of a beautiful Malabar carpet is shown. The jail in Bangalore in Mysore State has for long been noted for the good quality of its carpets. One shown at Delhi was distinctly a Hindu design with a Ram Chandra border.

6. The Deccan.—Hyderabad formerly produced the wonderfully fine silk rugs known as Warangals. The Journal of Indian Art (Jan. and July, 1905) shows three carpets of this school. This charming textile has the property of changing colour according to the point of view. The carpets at present produced, while possessing certain features of their own, are far inferior to the old work. The scheme of colour is scarlet, yellow and white. In the work just quoted will also be found highly characteristic examples of Hyderabad carpets.

7. Western India.—It is probable that the Persian traders very early established themselves along the western coast of India, and there produced carpets under the patronage of the Khorasan. In 1684, the people of that

274
DARIS AND SHATRANJIS

City made "alcatifas" (that is, long-pile carpets), "but they are neither so fine nor so good as those that are brought toOrmuz out of Persia." Alcatif, according to Crooke (Hobson-Johnson, 11), was a name much used in India for carpets during the 16th century. Bombay, except in the School of Art, does not produce carpets. Ahmedabad is mentioned very frequently in the E.I.C.'s letters and records as a centre in the carpet industry. At present there are only one or two very small factories, and the carpets turned out are sent chiefly to America. In Poona, the Yeroda Jail has produced some excellent work, mostly copies of the old carpets in the possession of the Asar Mahal and Jamai Musjid of Bijapur. Thus it may safely be affirmed that the Poona jail, instead of exercising a debasing influence on the carpet industry, has conserved what might otherwise have been lost.

II. Cotton and Woollen Carpets in other than Pile Stitch.—The daris, shatranjis, etc. Just as the pile carpets referred to above (the kalins, kalichas or galichas) are usually in wool but sometimes in cotton, so the daris and shatranjis are mostly in cotton though sometimes in wool.

As already suggested, it is probable that the Indian carpets, prior to the Muhammadan invasion, belonged almost exclusively to the description here indicated. Stein (Ancient Khotan, 1907, xxiv., 337, 398) describes and illustrates a fragment of a woollen carpet found by him in the ruins of the Niya site, which were engulfed by sand about the year 250 A.D. This appears to be in plain stitch, and recalls in design the embroidered rugs of Hissar and Srinagar. So also another rug found at the Niya site is described as of the regular Indian designs, and seems to have been woven by the weavers of the Northern parts of India, perhaps in the area of the ancient Manshia or Antiqua (now the Yarkand). It is said to have been a present from the Emperor Auranzeb in 1626 to the Jamai Mosque of Bijapur. This has a rich Indian red field with, suspended from the top of each jainamaz section, a lamp symbolical of the faith. It would appear to have been woven more like tapestry than an ordinary dadi, and to have had the patterns separately made and interwoven in their places on the loom. These and such-like give a lesson that might well be learned by the manufacturers of cotton carpets throughout India, namely, that if they would abandon the striped forms and produce richer and more varied designs, such as those of the Poona Jail daris, a larger market might be found in India itself, and in foreign countries as well, than has as yet been secured. There can be little doubt that neatly and substantially woven cotton carpets would be more acceptable to the inhabitants of tropical countries than woolen ones, because cheaper, cooler, cleaner and (under a tropical climate) more durable. Further, cotton plain carpets would doubtless be preferable to cotton pile carpets.

Much, therefore, remains to be done in the direction of developing the Indian trade in cotton carpets and rugs. [Cf. Monographs, Cotton Industries: Banerjë, Bengal, 1898, 33-4; Silberrad, N.W. Prov., 1898, 24-6, f. 36; Enthoven, Bombay, 1897-9, 11, 33, etc.; Thurston, Madras, 1897, 7-11; Latimer, Monog. Carpet-making Pb., 1907, 1-3]

Woollen Daris and Shatranjis, though not met with very abundantly in India, are still made and much admired. The Bhutias of Darjeeling and the people of Nepal and Eastern Tibet weave strips of woollen thick cloth in various designs, which, when sewn together into sheets, closely resemble Kurdish rhiibs. Mention has already been made of a fragment of a rug found by Stein in the ruins of Niya, Khotan, as recalling the Bhutia woollen rugs. The people of Darjeeling proper also weave thick chadars of white and blue
CARTHAMUS TINCTORIUS

THE SAFFLOWER PLANT

that are very beautiful and find a distinct place among the art treasures of the residents in the eastern side of India, but are only rarely seen elsewhere. In Bikanir, plain-stitch rugs are regularly woven in wool, but in the same form as the cotton *dorai*. The pattern most often employed recalls the barbaric cross-stitch embroideries of Hissar and Sirsa. In Quetta, rugs and camel saddlecloths are largely woven in wool and richly ornamented with shells. They are in stripes with patterns worked within, and to all intents and purposes should be classed as *khillims*.

Trade in Carpets and Rugs.—The only available details concerning the export trade in Indian-made carpets and rugs refer to (a) Mats and Matting of vegetable fibre: (b) Carpets and Rugs of wool. A summary of available statistics on the former subject will be found on page 778, so that it is only necessary to give here such particulars as are available regarding the woollen carpets. The quantities are always estimated by pound weight, not number. The total weight exported from India to foreign countries in 1899–1900 was 1,691,577 lb., valued at Rs. 23,73,289; in 1903–4, 1,878,202 lb., Rs. 26,04,576; and in 1906–7, 1,603,330 lb., Rs. 20,89,516. In the last year, goods to the value of 11 lakhs of rupees went from Bengal, 6 lakhs from Bombay, and 2 lakhs from Madras. The increase in the total quantity and value of carpets, etc., exported in 1903–4 was due to an improvement in the trade in these articles with the United Kingdom. The latter took in 1899–1900, 1,180,779 lb., Rs. 17,21,987; and in 1903–4, 1,549,658 lb., Rs. 19,54,560; but in 1906–7 the quantity fell again to 1,346,144 lb., Rs. 15,66,113. The exports to Ceylon fell from 235,070 lb. in 1899–1900 to 2,980 lb. in 1903–4; and in 1906–7 rose to 4,303 lb. The United States took quantities varying from 223,551 lb. in 1899–1900 to 401,340 lb. in 1901–2; 266,526 lb. in 1903–4; and 174,727 lb. in 1906–7. There is also a fairly extensive import trade in Carpets and Rugs, chiefly to Burma and Bombay, from the United Kingdom and Germany. It amounted in 1899–1900 to 842,716 lb., Rs. 8,46,013; in 1903–4 to 887,192 lb., Rs. 8,96,738; and in 1906–7 to 1,016,055 lb., Rs. 10,56,679.

Wild Safflower. (The *kusubrai, khârese*, of the Trans-Indus and karar, *poliyan, polî, kantiário, kandîário, mian kaloî*, etc., of the Panjâb) is a native of the drier arid tracts of North India. In Peshawar district it is peculiarly prevalent, the spinose clumps constituting an objectionable feature of the grassy tracts. Where met with in fair abundance the seeds (or to be more correct, fruits) are collected on account of the large quantity of oil which they contain. This oil is the chief ingredient in the Afridi wax-cloth presently to be described, and may also be used as a glass cement.

276
have originated the botanical name *Carthamus*. The most prevalent Indian vernacular name *kusum* comes direct from the Sanskrit *kusumba*.

**History.**—"This plant is the *kusumba* of Sanskrit writers, who describe the seeds as purgative, and mention a medicated oil" (*Pharmacog. Ind.*, ii., 208). That is the commonly accepted opinion, but on the other hand Dutt (*Mat. Med. Hind.*, 307) makes no mention of the special knowledge possessed by the Sanskrit medical writers, and it may be added the medical treatise which constitutes The Bower Manuscript (Hoernle, transl.) is silent both as to the *kusumba* plant and its oil. The Greek *cnicus* (Paulus Egineta (Adams, transl.), iii., 178) by most authors is identified with the Bastard Saffron. The early Greek authors speak of *cnicus* as a spinose plant, but Dioscorides (iv., 187 (ed. Sprengel), 1829, i., 650) mentions that it was a pot-herb and purgative medicine. Galen, Avicenna, Serapion, Rhases, etc., follow Dioscorides, but most Arab writers add the additional property that it is aloeipharmic. Mesua, who lived at Bagdad in the 10th century, wrote a great work on the Medicine of the Greeks and Arabs. He opens his account of *cnicus* (Marinus, transl., 1562, 74) by observing that the plant is both wild and cultivated, but that the so-called Indian *cnicus* is not *cnicus* at all. He then observes that the seed is the most valuable, especially the large white kind. The figure given by Marinus is an excellent representation of *C. tinctorius*. Carthamus was retained in European pharmacy down to comparatively recent times. De Candolle (*Orig. Cult. Plants* (Engl. transl.), 164,) following Targioni-Tozzetti (*Cenni Storici, Intro. di Varie Piante*, 1853, 88), thinks the determination of the Greek *cnicus* with Carthamus very doubtful. Pliny distinctly says the oil was used in Egypt in place of castor-oil, but he adds the plant was not known to the Romans. It may be added that Pliny writes it *tinoccus* and Columella *cnicas*.

The grave-cloths of the ancient Egyptian mummies are dyed with safflower, and fragments of the plant and the seeds have been found in tombs. [Cf. Rawlinson, *Hist. Egypt*, 1881, i., 02–3; Hehn, *Kulturpl. und Haus*. (ed. 6), 261; Wiesner, *Die Rohst. des Pflanzenw.*, ii., 678–54.] The Sanskrit authors describe the *kuumbha* oil as purgative, so that identical properties were assigned to it in Egypt, Africa and India. An Abyssinian so-called wild species (*C. linnatus*, in Schweinfurth, *Fl. Eth.*, 1867, 143) has by some writers been accepted as the original stock of the cultivated plant; so also, and with equal if not greater force, *C. Oxyacantha*, the Indian wild species, has been advanced as the source of the cultivated plant. De Candolle accordingly came to the opinion that since an undoubted ancient cultivation had been established for both India and Africa it was probable the true *Carthamus tinctorius* might be found wild in the intermediate country Arabia. He accordingly cites in part support of that suggestion the circumstance that an author quoted by Ibn Balthar (the Arab, Abu Anifa) mentions both a wild and cultivated form as met with in that very country. In China there would seem little doubt safflower (*hung-hua* or red-flower) was introduced about the 2nd century B.C. [Cf. Breitschneider, *Europ. Bot. Disc. in China*, 1898, 4; also *Value Chinese Botanical Works*, 1870, 15.] Japan received it from China, but according to Rein (*Indust. Japan*, 176–7) it can hardly be regarded as more than a botanical curiosity in that country—the cosmetic *beni* being manufactured from foreign (mostly Indian) supplies of safflower. [Cf. Milburn, *Or. Comm.*, 1813, ii., 238–9; Buchanan-Hamilton, *Stat. Acc. Dinaj.*, 205; Lacaia, in *Maw, Genus Crocus*, ap. v.; *Der Tropenflanzer*, viii., 511; Joret, *Les Pl. dans L’Antiq.*, 1904, ii., 272.]

**Cultivated Indian Races.**—There are two main conditions, one grown purely and simply for its flowers—the safflower dye of commerce, the other for its oil-yielding seeds, the *kusum* or *carthamus* oil of trade. The former is fairly extensively produced in Bengal, the United Provinces and the Panjab, while the latter is chiefly met with in the Central Provinces and Bombay. But while these two conditions or properties seem well understood agriculturally, dried specimens of the plant grown for the one or the other purpose are indistinguishable. Moreover several races occur under each of these states, such as with small, very hard spinose leaves (much as in *C. Oxyacantha*) or with large, soft, almost non-spinose edible leaves. Some have narrow, hard and sharply spinose bracts, others broad almost entire bracts. Still, however, most of these...

conditions recur again and again with the oil-yielding and the dye-yielding races, so that no set of characters can be given, to separate the groups that belong to the one or the other. Speaking broadly, however, the oil-yielding forms are more spinose than the dye-yielding, and have usually yellow-coloured flowers, the dye forms being orange or even yellow tinged with scarlet. The dye-yielding plants require a rich soil and humid atmosphere, hence the loss of spines may be due to high cultivation and protection. In the young state the smooth-leaved spineless forms are edible, and in some parts of the country, notably Burma, they are mainly, if not exclusively, grown as pot-herbs. But within each of the great centres of production there may be both smooth and spinose forms. Thus in Bengal a spinose dye-plant is known as kuthi or kutela and a spineless dye-state called murdi, murilla (=shaved), bhuili. In the United Provinces the spineless kusum affords both dye and oil, while the spineless form distinguished as kasar, kasur, is grown for its oil-seeds only. In Berar (Sule, Monog. Dyes and Dyeing, 1895–6, 1) the spiny katti kardi yields an inferior dye and good oil, while spineless bodki gives a superior dye. In Bombay two great centres of production exist, viz. on the rich alluvial loams of Kaira and Ahmedabad, in Gujarat, where the spineless red-flowered dye-yielding kusumbjachi or kusumba prevails, and the Deccan, with its spiny sadhi or kardai, an oil-yielding crop. [Cf. Fawcett, Monog. Dyes and Dyeing, Bomb., 1896, 25–9.] Briefly Bengal is (or rather was) the source of kusum dye, and the Deccan of the safflower oil. These products may therefore be dealt with separately:—

1. THE DYE—Safflower or Carthamine.—So much has been written regarding the cultivation and utilisation of safflower that a brief review of the modern results seems all that is called for. But it may be explained that the various provincial Governments of India issued, in 1896, monographs on “Dyes and Dyeing,” and that these will be found to have special chapters on safflower. So also The Agricultural Ledger (1904, No. 11) may be described as a compilation of the more important passages from modern writers, and it thus amplifies the particulars recorded in the Dictionary. The remarks that follow will accordingly be restricted as far as possible to facts calculated to assist the merchant or cultivator, but will abstain from republishing technical details, especially methods of dyeing. But in this connection it may be observed that safflower has preserved its position in spite of foreign dyes, mainly through the colour being viewed as more or less sacred for wedding garments.

Cultivation.—Safflower, though by no means so important a crop as in former years, is still grown to a fair extent in the Dacca Division of Bengal, and here and there throughout the Province. Taylor (Topog. and Stat. Dacca, 1840, 133–5) gives an interesting account of the production during the prosperity of the industry. The best quality was grown in the vicinity of Patteggotta. Safflower is also met with in the Surma Valley and in Manipur, but not in the Assam Valley proper. In the Central Provinces it used to be extensively produced in Raipur and Chhindwara, but the area in recent years has been greatly curtailed. In the United Provinces of Agra and Oudh, though met with now and again, it assumes importance in Meerut only. In the Panjab it is to be seen in most districts, but Hoshiarpur and Amballa are perhaps most spoken of, and the safflower of the hills, especially that of Kabul, has the best reputation. The wild
PREPARATION OF CAKES

CARTHAMUS TINCTORIUS

Dye

Safflower is also a product of considerable value. In Berar safflower is regularly cultivated, though by no means to the extent formerly witnessed. In Madras it may be seen here and there, and in Burma it is more grown as a vegetable than as a dye. But in Bombay there are two centres of production. The cultivation for dye is not extensive, and is confined to Gujarat and the Karnátk, Kaira being perhaps the most important district. Dr. Hove (1787) refers to the dye of *Carthamus* being then used in Gujarat to dye *pagra*. But the Bombay dye is regarded as much inferior to that of Dacca in Bengal.

Methods.—The systems of cultivation pursued are so very similar throughout India that the subject may be treated collectively, the remark being made that it differs province by province, according to the amount of attention given and the local value of the crop. It is sown along with other *rabi* crops such as gram, wheat, barley, tobacco, opium, chillies, carrots, etc., from about the middle of October to the end of November, or in Chittagong as late as January. It requires a light sandy soil, and one which possesses a fair amount of moisture. In the better cultivation the land is lightly manured and ploughed repeatedly from May or June till sowing time. It is either sown broadcast or drilled, the latter in Bombay, 3 drills 18 to 22 inches apart of safflower alternating with the subsidiary crop. In the less important cultivation it forms single drills or surrounds other crops, its spiny character serving the purpose of a protecting hedge. On the central flowering head appearing, this is nipped off in order to cause lateral shoots and a more copious flowering. The prunings and thinnings are eaten as a pot-herb. The crop comes into season in January to April, or even May, and is plucked every second or third day. Delay in collecting the flushings of florets causes loss in dye. Rain during the flowering is also very injurious. The florets being picked after fecundation, the seed ripens and yields a supplementary crop. The average yield of dried florets is in Bengal about 80 lb. (according to Mollison *l.c.* 100) from 100 to 120 lb. in Bombay), per acre, and of oil-yielding seeds (fruits) 400 to 600 lb. The first and the last pickings of florets are by most writers considered inferior in dye merit to those in mid-season.

Manufacture.—The day’s collection is carried to the homestead and partially dried in the shade. It is then rubbed between the hands, placed on an arrangement of basket filters, and pure stream (or slightly acidulated) water poured over. This removes the most soluble of the useless yellow dye, but care must be taken that the water is not alkaline, or the red dye also may be washed out and the florets rendered useless. When the water passes through clear the washings are regarded as complete. The florets are then partially dried and pressed into the small characteristic cakes met with in trade; then the drying is completed. According to Taylor the florets in his time were saturated with water in the evening and next morning trodden underfoot, and this was repeated for four or five days until the water ran off clear.

In centres where little attention is given to the crop the florets are not washed, and instead of being made into cakes, are formed into balls or sold as loose powder. The presence of the yellow dye lowers the value and increases the weight. In Bombay a curious sytem prevails which consists in rubbing into the florets a certain amount of *til* oil (a tola weight to a pound of the florets). Mollison observes that this is the practice in Gujarat, but it is known to produce loss of colour. This very possibly
accounts for the lower price of Gujarat safflower as compared with that of Dacca. Apparently also the yellow dye is not removed until a later stage, and the oil would thus seem to serve no useful purpose. It recalls, however, the practice described by Rumphius (L.c. 217), where the people of the Malay are spoken of as adding the bruised oil-yielding seeds of *Aleurites trifolia* to prevent the florets from crumbling to dust.

Safflower-dye cakes (Gujarat) are sold in Bombay at 2 to 2½ lb. per rupee. The value is estimated according to the colour that a given weight will impart to a pound of cotton.

*Trade in Safflower Dye.*—Madder in Europe and Safflower in India are the dyes that felt immediately the effect of the discovery of chemical colours. This, in the case of the Indian product, may be exemplified very briefly. Half a century or so ago, safflower became a fairly important commodity. It is curious, however, that none of the early travellers in India mention the dye. The first botanist who describes its cultivation in the East would appear to be Rumphius. Milburn records the exports in 1804 as having been 247 cwt., valued at £1.460, or £5 18s. 5d. a cwt. Four years later the exports were 1,070 cwt., valued at £4,532, or £4 4s. 8d. a cwt. An import duty at British ports was levied of 7s. 4d. a cwt. In 1824–5 the exports from India appear to have been 6,185 cwt., and in 1837 they stood at 7,962 cwt. Passing over a period of close on forty years, we next learn that the Indian traffic had become (1874–5) 10,157 cwt., valued at Rs. 6.50,827 (or expressed at the rate of exchange that then prevailed, approximately £60,000); but a sudden change took place, for the very next year the traffic fell to 2,914 cwt., valued at Rs. 1,63,528, and ten years still later (1884–5) had become 1,459 cwt., valued at Rs. 53,083. Within the past six years a revival in quantity seems to have set in, since the exports were in 1899–1900, 1,993 cwt., valued at Rs. 34,572, and in 1903–4 the corresponding figures were 4,313 cwt. and Rs. 67,506. They have since fallen, however, to 3,670 cwt., Rs. 50,389, in 1906–7. A remarkable feature of the traffic thus briefly outlined may be said to be the decline in the prices realised—viz. from £5 18s. 5d. a cwt. to the price in 1901–2, viz. Rs. 20 or £1 6s. 8d. a cwt. Even twenty years previously (1881–2) the price realised was nearly double the rates that rule to-day. It is not, therefore, to be wondered at that safflower has ceased to be an important crop, and that but for the local markets the dye might by now have disappeared from India as completely as has the madder from Europe.

The exports from India go mainly to Hongkong, but a recent demand from Japan has been viewed as a favourable prognostication for the future. The local market continues fairly large in spite of foreign mineral dyes, owing to the fact that safflower is associated with the social customs and religious feelings of the people. The varying quality would seem to depend first of all upon the climate and soil of the locality where produced; next, the care pursued in collection, and the method of preparation followed. With all the finer samples the yellow dye has been washed out and the florets purified. This has naturally the effect of lowering the weight and concentrating the dye. Washed safflower must accordingly fetch a higher price than the impure and adulterated dye. In further purification of the dye a second yellow colour is precipitated and removed by means of acetate of lead. *Carthamin*, the valuable red colour, may then be extracted in a pure form by making use of its
IMPORTANT OIL-SEED IN BOMBAY

solubility in alkaline solutions, and insolubility in pure or acidulated water. In India the alkali used is almost invariably that prepared by incinerating bajra (Pennisetum) stems or chir chira (Achyranthes, see p. 49), but crude natural carbonate of soda known as sajji-matti is also employed. It would seem probable that the isolation and utilisation of carthamin is in India a comparatively recent discovery.

II. THE OIL.—The seeds from the dye-yielding plant are collected and form a supplementary return, but, as already stated, in some parts of the country, notably Bombay, an oil-yielding crop is specially grown. Mollison (l.c. 98) says, “Safflower is the most important oil-seed crop in the Bombay Presidency. The area is usually from 500,000 to 600,000 acres annually. The chief centres of cultivation are in the black-soil rabi lands of Ahmednagar, Poona, Sátára, Bijápur, Dhárwár, and Belgaum.” It is subordinate to the crops with which it is associated such as puár, wheat or gram. “It therefore participates in the general cultivation given to these crops.” “Usually three consecutive rows of safflower alternate with 9 or 15 or 21 consecutive rows of the principal crop.” In the Central Provinces the area of special oil cultivation has recently been greatly curtailed, so that the Deccan production may be accepted as alone of importance, though of course the oil of the dye crop must not be entirely ignored.

Manufacture.—It has been customary to find Baden-Powell’s statement (Pb. Prod., 421) that two oil-yielding forms of this plant exist—the wild and the cultivated—repeated by Indian writers without its being observed that an admission was being thereby made to which only the most cursory attention had been subsequently paid. But in addition to there being two distinct sources of the oil there are also two widely different methods of preparation. In the one the seeds (fruits) are simply subjected to cold-dry pressure either before or after they have been husked. The yield is said to range from 20 to 30 per cent., but both the quality of the oil and the value of the cake depends upon the seed being husked. The second process is a hot-dry extraction, or rather a crude downward distillation. The seeds are placed within an earthen pot, and this is inverted over the mouth of a similar pot placed within the ground, the two pots being separated by a perforated plate. Over and around the inverted pot is piled some fuel, and on this being ignited, the seeds are partly roasted; the oil in consequence drains from them and accumulates in the lower or submerged pot.

The cold-drawn oil has a clear straw colour, with a sp. gr. of 0.9224 at 15° C. According to Hooper (Agri. Ledg., 1904, No. 11, 160), it “possesses pronounced drying properties. It readily saponifies with alkalis, forming a fairly good soap, and the free fatty acids have some of the characteristics of the linoleic acid obtained from linseed. The oilcake retains 11·55 per cent. of the natural oil, and is not contaminated with earthy impurity. The nitrogen amounts to 3·19 per cent., which is equivalent to 19·94 per cent. of albuminoids.” It is an oil extensively used for culinary purposes, and to adulterate ghi or til. Moreover, safflower, earthnut, and til are often mixed together and the oil expressed; this constitutes the sweet-oil of Bombay. Safflower oil is also said to be an ingredient in Macassar hair-oil. Inferior qualities are used for illumination. The hot-extraction oil is about one-fourth larger than the cold, but is useless both for burning purposes or for food. It has, in fact, acquired a

281
new property, and been converted into a substance very serviceable for greasing well-ropes, leather well-buckets, etc., purposes for which the cold-drawn oil is quite unsuited. In other words, the oil has been converted into what is known as roghan—a substance employed to prevent leather from hardening on its being exposed to the action of water or of a damp atmosphere.

Oil of Wild Safflower.—In the Northern Panjáb, more especially Peshawar, a very different process is adopted from that just detailed for the manufacture of roghan. The polí (the oil of C. Oxyacantha) expressed by the cold process is placed in earthen vessels and boiled continuously for twelve hours. The vessels are so placed that it is not possible for a flame to reach the boiling liquid, and the temperature is kept low and uniform. In time it emits volumes of white pungent vapour, so exceedingly disagreeable that the manufacturers are compelled to conduct their industry under special license and in a place assigned to them remote from human dwellings. On the oil being cooked to the required extent, and while still boiling hot, it is thrown into large shallow trays containing cold water. It swells up into a jelly-like substance, the roghan of Northern India. This is stored in tin cans and sold to the manufacturers of the so-called Afridi wax-cloth.

Wax-cloth.—It would occupy too much space to repeat the accounts published in The Agricultural Ledger (1901, No. 12, 393-414) and Indian Art at Delhi, 1903 (229-34), regarding this curious little industry. The facts made known in these publications prove that we have been incorrect in affirming that the Natives of India were unaware of the drying property of certain oils in the manufacture of paint with mineral pigments. But in the Afridi wax-cloth the paint is not applied by a brush but by means of an iron style. The rapidity and accuracy with which the pattern is elaborated by threads of plastic and coloured roghan has to be seen to be appreciated or understood. The skilled artist can work from right to left or left to right with equal ease, and, just as in penmanship, the thick downward strokes and the fine upward hair-lines are each made to occur in their proper places in the elaboration of the pattern with which the fabric is being covered. Where two or more colours have to be given, the operator usually applies all the patches or lines of one colour before he proceeds to use the second or the third shade. The half-finished table-cloth or fire-screen may in consequence often appear a bewildering production, since it may be impossible to discover the actual pattern in the operator’s mind.

In passing it may here be added that in Baroda, castor-oil, and in Kach, linseed-oil, are similarly made into the roghan used in the fabrication of the wax-cloths of these localities. Experiments conducted in the Industrial Museum, Calcutta, have revealed the fact that the oil of the wild safflower possesses no special properties over those of the cultivated plant. It would further seem that in the Afridi wax-cloth India possesses the nucleus of a possible large new craft, that of producing wax-cloth, waterproofing materials and linoleum, from local materials and possibly by means of the expert craftsmen who from time immemorial have turned out the goods here indicated. The jute mills of Calcutta prepare and export the cloth required by the wax-cloth and linoleum manufacturers of Europe and America. India, moreover, will be seen to import a by no means insignificant amount of the specially prepared wax-cloth and linoleum (oil-cloth and floor-cloth) made on the jute textiles exported from India.
BLACK CARAWAY

CARUM BULBOCASTANUM

for that purpose. In 1876–7 these imports were valued at only Rs. 17,620; in 1901–2 they came to Rs. 5,74,306; in 1903–4 to Rs. 4,17,788; and in 1906–7 to Rs. 6,20,305. Surely the effort to participate in so prosperous a traffic is worthy of attention.

Edible Seed and Cake.—Curthamnus seeds, especially after being roasted, are eaten, but are most valued as a food for poultry, though, as already observed, the tender shoots are prized as a pot-herb or salad. Mollison makes the remark that cattle have to be educated to eat the cake, but that it has the advantage of keeping well and does not get mouldy. It is highly valued as a manure.

[ Cf. Leaether, Agri. Ledg., 1897, No. 5, 159; Duthie and Fuller, Field and Garden Crops, i., 51–4, pl. xiii.; Monographs, Dyes and Dyeing.—Banerjee, Bengal, 73.; Duncan, Assema, 17–8; Russell, Cent. CARUM BULBOCASTANUM, Koch.; Fl. Br. Ind., ii., 681; Bumium Bulbocastanum, Linn.; Carum nigrum, Royle, Illust. Him. Bot., 229; Rec. Bot. Surv. Ind., i., 154; Paulus Ægíneta (Adams, transl.), iii., 74; Umbelli feræ. Black Caraway, siyāh, šíā, saţïra, shah-zerah, siyāh zireh (zerah), zīdū sīah, etc., also called guniyun in Kashmir and umbhu in Ladakh. These names seem for the most part to be modern adaptations, since the true kālā-żira is the Black Cumin (Nigella sativa, see pp. 442, 811).

Black Caraway is a native of Baluchistan, Afghanistan, Kashmir, Laha ul, Chumba, etc., eastward to Garhwal and Kumaon, and westward to Quetta. It is mainly a weed of cultivated land, but is liable to prove dangerous in fields owing to the fondness of pigs for the root. It also exists purely wild on grassy slopes (at alt. 6,000 to 11,000 feet), whence the shepherds collect it as a valuable source of income; but it is nowhere cultivated. It is probably the krishna-żiraka, which Royle maintained was well known to the Hindus before the introduction of the European Caraway (C. carvi). [ Cf. Lawrence, Valley of Kashmir, 67; Aitchison, Bot. Afghan. Delimit. Comm., in Trans. Linn. Soc., iii., 1.]

An inquiry instituted by the Reporter on Economic Products in response to a question put by the Indian Chambers of Commerce, resulted in the collection of specimens of zira (zi r a) from the chief towns of India as well as of the fruits (seeds) and plants from all known areas of supply. The fruits in every instance were found to be C. Bulbocastanum and not C. carvi (except when stated to be a foreign or imported drug). The examination showed, however, that other seeds are often used as adulterants or substitutes for black caraway. The adulterants are similar in shape, size and markings, but quite destitute of the characteristic aroma. For example, Mr. L. G. Smith, Forest Divisional Officer of Sambulpur, sent four samples from the local bazars which were subsequently identified as (1) the true Caraway (mita zera h), most probably imported; (2) C. Bulbocast anum, sau- or shah-za rah; (3) Vernonia anthelmintica, parbat-zera h; and (4) Nigella sativa, kala-zerah. The sample of black caraway was, however, not pure. Pure parcels were received from Yasin in Gilgit and from Hazara. From Kulu and Bashahr were furnished two qualities called "zi ra" and " singhu." The latter was stated to be an adulterant. "Zira" proved to be C. Bulbocastanum; and ultimately, through the assistance of Mr. J. H. Lace, then Assistant Inspector-General of Forests, the adulterant was recognised as Bupleurum falcatum. Mr. Lace found the people gathering the seeds in Chamba; he secured a sample and corresponding botanical specimen, so that his material became an authentic type with which to compare the adulterants of commercial parcels. It was in consequence found that the Bupleurum was identical with the adulterant sent from most parts of India. Is this the pseudo- bunsium alluded to by Paulus Ægíneta which Adams suggested might be Pimpinella lenus? Mr. Lace says that Bupleurum is known locally as
CARUM
CARUI
Caraway

Use.

banchak or bankok, and that before it is mixed with the carum the fruits are coloured with a decoction of walnut bark. It is sold at 9 seers to the rupee, the true article being very much more expensive—say 3 seers to the rupee. Usually 5 seers of banchak are mixed with one seer of zira. The black caraway and its adulterant are therefore respectively the “zira” and “singhu” mentioned in the Panjab Forest Administration Reports from 1894–1900 as obtained from the Kulu forests and sold, the former at Rs. 15 to Rs. 27½ per maund, the latter at Rs. 8. Sir Walter Lawrence says that the seeds of Daucus Carota are also used as an adulterant, but this cannot be done to any great extent since carrot-seed is not abundant and is also easily distinguishable from caraway, while the dyed Bupleurum can with difficulty be separated.

THE TRUE CARAWAY

Uses.
The uses of this caraway, so far as can be ascertained, seem identical with those of C. Carui. From Bashahr large quantities of black caraway are conveyed annually to Rampur and thence distributed vid Amritsar all over India. Amritsar also receives the Kashmir, Afghanistan and N. Himalayan supplies. Other emporia are Karachi and Cawnpore; the former obtains its supplies from Hazara and Baluchistan, the latter from Garhwal and Kumaon.

Price.
The price at Cawnpore varies according to quality from Rs. 25 to Rs. 44 per maund of 53½ seers, but the consumption is very limited and the sales are usually in small parcels of ½ to 2 maunds. In addition to an Indian supply, Bombay imports from Persia. The wholesale price is said to be Rs. 8 per 37½ lb. (= Surat maund), and the retail price for cleaned fruit 8 annas per lb. [Cf. Pharmacog. Ind., ii., 120; Kaye, Settl. Rept. Baltistan Dist., Kashmir, 1889, 16; Rivett, Assess. Rept. Muzaffarabad, Kashmir, 1889, 10, 12, 50, app. xxxv.; For. Admin. Repts. Ph., 1894–5 to 1901–2; Rev. Working Plans, Pangi For., Chamba, 1901, 2; Rept. Cent. Indig. Drugs Comm., 1901, i, 119; etc., etc.]

C. Carui, Linn.; Fl. Br. Ind., ii., 680. The European Caraway, Carve, Kümml, zira, karoya, karuveya. The vernacular names are in the main, of course, those given under the foregoing species, though sometimes to the name zera is prefixed a description, as mitha (sweet), vilayati (foreign), or safed (white).

As met with in India the fruits are mainly imported, but the plant is probably occasionally cultivated in gardens on the plains as a cold-season crop. The repeated though vague statements of its existence in India "wild and cultivated" seem likely to be due mainly to confusion with C. Bulbocastanum. There is, however, a fairly large import trade in the spice and it may be well to epitomise here a few of the chief uses of caraway, always premising that when such uses can be attributed to the Indian-grown caraway, the reference is in all probability to C. Bulbocastanum. The seed is employed both powdered and entire. In the former condition it is an important ingredient in curry powders; in the latter it is put into cakes, biscuits, etc. As a Medicine it is stimulant, carminative and astringent. But it is frequently used in flavouring cordials and certain preparations of Indian hemp (bhang). A valuable essential Oil, obtained from the fruits, is employed in medicine and as a perfume for soaps. The distilled oil is first mentioned in the price ordinances of Berlin for 1574 and in the Dispensatorium Noricium (1659). The two valuable constituents in the oil are carvone (formerly, carvol), which is the essential and odour-bearing body and possesses all the qualities of the drug in a pure form; and carvone or limonene, a by-product, not suitable for liqueurs but "can be satisfactorily employed instead of caraway oil in medium and cheap soaps" (Schimmel & Co., Semi-Ann. Rept., April 1892, 12). The percentage of oil varies apparently according to cultivation and country of origin. Of the European sorts the Bavarian wild plant yields the highest percentage, 8:5 to 7, whilst the Russian stock yields only 3:2 per cent. The sp. gr. lies between 0:907 and 0:915; oils of lower sp. gr. rarely occur, and are less valuable as they contain less carvone. [Cf. Gildemeister and Hoffmann, Volatile Oils, 550–8.] A case of poisoning by caraway-seed presented symptoms similar to those induced by other essential oils. [Cf. Ind. Med. Gaz., 1896, 1:45.] It may be added that caraway from which the oil has been expressed is dried in special apparatus and used as a CATTLE FOOD, being prized for its high percentage of crude protein (20 to 23:5 per cent.) and fat (14 to 16 per cent.). [Cf. Paulus Aegineta (Adams, transl.), iii., 168; E.I.C. First Letter Book, 201, 480; Bentham, Comment. on Targioni-Tozzetti, in Journ. Hort. Soc., ix., 145; Wiesner, Die Rohst. des Pflanzern., ii., 794.]

The Fibre.—The plant is mentioned by almost all the pre-Linnean
THE INDIAN SAGO-PALM

CARYOTA

URENS

Sago and Sugar

authors from Varro (116 B.C.) downwards. The chief commercial value
of the palm lies in the fibrous cords or fibro-vascular bundles found
at the base of the leaf-sheath and within the petioles, flowering stalks and
even the stems as well. These constitute the strong kittul fibre of Ceylon
and the salopa of Orissa, a fibre which also comes from Burma and Bombay.
It is made into ropes, brushes, brooms, baskets, etc. As a brush fibre it
was described in the Treasury of Botany (1866) and has been shipped from
Ceylon to England since about 1860. Five or more strands, fastened
一起 by special machinery, have moreover been found to make an
excellent substitue for whalebone in corsets. Since the discovery that
kittul fibre was not only equal but even superior to, because less brittle
than, the Bahia piassava (the fibre of Attalea funifera), several
brush factories in India, it is believed, have begun to use it instead
of bristles in hair-brushes, clothes-brushes, horse-brushes, etc. [Cf.
Hooper, Rept. Labor. Ind. Mus., 1903–4, 29.] In this they are following
the lead of European makers: Hannan (Text. Fibres Comm., 1902, 155),
for example, says that kittul is now in much request in Europe for
brush-making and that some of the finest qualities have been adopted
as substitutes for bristles. Jackson (Comm. Bot. XIXth Cent., 1890, 142)
observes that as much as forty (now fifty) years ago kittul fibre was ex-
ported to England for admixture with horse-hair (may it not have been
Chamærops humilis?). In the brush trade it is steeped in linseed-oil
and thus made so pliable that it can be used either with or without
bristles in making soft, long-handled brooms which are extremely durable
and can be sold at about a third the price of ordinary hair-brooms.
Dodge (Useful Fibre Plants of the World, 112–3) says it is also made
up into machine brushes for polishing linen and cotton yarns, for cleaning
scutched flax, brushing velvets, etc. Both in India and Ceylon fishing-
lines are made from kittul fibre (Drury, U. Prov. Ind.) and strong wiry
ropes capable of holding wild elephants are constructed of the fibre.
while in Australia the leaves apparently are regarded as a good paper
material. Lastly, the woolly substance or scurf scraped from the leaf-
stalks is used in Burma for caulking boats. The quotations in London
on April 20, 1901, were for long quality, 8½d. to 9d. per lb.; for No. 1,
6½d. to 7d.; No. 2, 2½d. to 3½d.; and No. 3, 1d.; Ide & Christie (Monthly
Circ., Oct. 15, 1907) give the following returns of present date:—Long,
8d. to 9½d.; No. 1, 6d. to 7½d.; No. 2, 2½d. to 3½d.; No. 3, 1d. to 1½d.
Mr. J. C. Willis tells us (Admin. Repts. Bot. Gard.) that the exports from
Ceylon have never exceeded those returned for the year 1898, viz.
3,794 cwt. The exports from India are unimportant.

Sago:

Sugar.

Food.

Cabbage.

The Sago and Sugar.—Besides its fibres, Caryota yields from
the inferior of the stem a sago which is mentioned by Roxburgh (1832), by
Robinson (Desc. Acc. Assam, 1841, 56) and by other writers as almost equal
in quality to the best sago of commerce. As a matter of fact it would seem
to be an inferior article, though quite wholesome (Yearbook of Pharmacy,
1903, 328). On the Malabar Coast and elsewhere it is made into bread or
gruel and thus constitutes an important article of food with the poorer
classes. The “cabbage” or terminal bud is edible, like that of most
palms. Commelinus (Rheelee, Hort. Mal., i., 16, n.) remarks that, ac-
gording to authors, the pulp of the fruit is bitter and irritates the tongue
—a circumstance which doubtless suggested the specific name urens.
The fruit is certainly very pungent and insipid, but I cannot recollect

828
PURGING FISTULA

Having observed the tingling property just mentioned, though I have eaten it. Finally a toddy or juice is collected by "training" and "tapping" the spathe. This juice is either fermented and distilled into an alcoholic liquor or boiled down into a dark syrup which solidifies into jaggery or palm-sugar—an important product, especially in Bombay and Ceylon. Mr. A. M. Sawyer, writing of the "training" and "tapping" processes in North Travancore (Ind. For., 1896, xxii., 134–8), says that at the end of the first five days of tapping the yield is about 4 quarts per day, increasing by degrees to 6, 8, and 12 quarts. In strong, healthy individuals even 18 or 20 quarts may be obtained at the end of the course. Sometimes, in an unusually prolific palm, three or even four spathe may be seen tapped at the same time, while others, in spite of the most careful training, yield no toddy whatever. An average-sized spathe is tapped in about four months, and all the spathe of one palm are exhausted in about two years. According to Roxburgh the best trees give as much as 100 pints in twenty-four hours. Further details may be found by reference to Borassus (pp. 170–1).

The Timber is strong and durable, being much used for agricultural purposes, water-conducts, and for beams and rafters. Not infrequently it is cut into walking-sticks. The seeds are used as beads by the Muhammadans. [Cf. Rhodes, Hort. Mat., i, t. 11; Buchanan-Hamilton, Stat. Acc. Dinaj., 150; Morris, Comm. Fibres, Cantor Lect., 1895, 34; Lushington, in Ind. For., 1899, xxv., 54–6; Sadebeck, Kulturgew. der Deut. Kolon., 1899, 313; Junelle, Les Cult. Colon. (Aliment.), 1901, 25–7; Wiesner, Die Rohst. des Pflanzenr., 1903, ii., 208, 411–2.]

A genus of herbs, shrubs or trees that contains in all about 380 species, mostly tropical, a few only being extra-tropical. India possesses some 18 indigenous species with three or four fairly plentiful introduced forms. They have all showy flowers but are mainly of value as medicines or as tans:

C. Absus, Linn.: chàkôô, chínmar or chinôl, bonar, etc., a herb found fairly plentifully throughout India. The seeds are used in the treatment of ophthalmia and as a cathartic.

C. alata, Linn.: the dádmardan (= ringworm-killer), or vilayati- (or shinnai) agdi (the foreign Sesbania grandiflora), is a small shrub found in gardens throughout India and supposed to have been introduced from the West Indies. The leaves rubbed up into a thin paste and mixed with vaseline constitute an effectual remedy for ringworm. [Cf. Fleming, Ind. Med. Pl. and Drugs, As. Res., 1870, xi., 103; Bennett, Wanderings N.-S. Wales, 1834, i., 123.]

C. Fistula, Linn.; the Indian Laburnum, the Purging Fistula, or amaltôs, alash, sundâti, sonîl, bähâvâ, gûrmâla, konrâk-kî, etc. A moderate-sized tree of the Sub-Himalayan tracts ascending to 3,000 feet and common throughout the plains of India and Burma.

The bark is to some extent used both as a tanning material and a drug. The pulp of the fruit is regarded as a safe and useful purgative—one of the commonest of domestic medicines in India—but has the objection of not keeping well. Adams (Comment. in Paulus Œgineta, iii., 429–31) mentions that it was known to Serapion, Rhases, Mesua, Ebn Baithar, etc.—in fact to most of the early Arab writers, who speak of it as a purgative drug procured from India, Arabia and Egypt. It is also largely used in smoking mixtures to flavour the tobacco used by the Natives, especially in Bengal. [Cf. Mosua, Op. (ed. Marinus), 1562, 52; García de Orta, Coll., xiv.; also Clusiuss, Hist. Arom., 1567, 130; also Comment. by Ball, in Proc. Roy. Ir. Acad., 3rd ser., i., 400; Linschoten, Voy. E.
CASSIA ANGUSTIFOLIA  

THE TINNEVELLY SENNA

C. obovata, Collot.; sometimes called Country Senna, Jamaica Senna, Italian Senna. This is the bhui-tarwar, a plant common in many parts of India and occasionally to be seen in the bazaars as an inferior quality of Senna. [Cf. Greenish, Pharm. Journ., 4th ser., ix., 470-1.]

C. occidentalis, Linn.; the Negro Coffee or kásöndá, kásündá, hikal, kálkashundá, etc. An under-shrub abundant on waste land and roadsides throughout India, though probably originally introduced from America. The leaves, roots, and seeds are medicinal. The seeds dried, then ground to powder, are used as a good substitute for coffee, and since they are antibilious are said to be often beneficial. [Cf. Kew Bull., 1881, 34-5; Yearbook of Pharmacy, 1887, 175-6; Pharmaceut. Journ., 1900, lxv., 439; Ridley, Mal. Pl. Names, 116; Rev. des Cult. Colon., 1902, x., 63.]

C. Sophora, Linn.: the káli-kasondá, jangli-takla, kál-kanzandá, banar—(the kásamarda or cough-destroyer)—a closely allied and often much confused plant with C. occidentalis. It is cosmopolitan in the tropics and common throughout India. The bark, leaves and seeds are cathartic and the juice of the leaves viewed as a specific for ringworm. [Cf. Prosper Alpinus, i.c. 35.]

C. Torá, Linn.; the Foestd Cassia or chákundu, panévr, panévár, taróvá, kóvarí, kóvarí, a gregarious annual under-shrub found everywhere in Bengal and throughout tropical India. This is in Sanskrit called chákramarda (= ringworm-destroyer), once more confirming the all but universal reputation of the species of Sennas. But in this particular plant a more or less new property has been attributed to the seeds, in that they are largely used along with indigo. For this purpose they are regularly sold to the dyers. They are also roasted, ground to a powder, and used in place of coffee. Mr. William Elborne of Owens College chemically investigated these seeds and came to the conclusion that their activity was due to “emodin, a substance closely allied to chrysophanic acid, in chemical characteristics, and considering the purpose for which the Natives of India use the plant, evidently in medicinal properties.” Adams (Comment. in Paulus Egineta, iii., 466) identifies this plant with the kelkel of the Arabs—a drug mentioned by Avicenna, Serapion, Rhases, etc. etc.

C. angustifolia, Vahl.; the Tinnevelly Senna of Indian commerce, perhaps best known by the following names:—sanna-mukhi, seni-makhí, Hindi-sanna, nilavviri, etc.

Adams (Comment. in Paulus Egineta, iii., 431-3) gives a most interesting sketch of the early knowledge in Senna. He says Serapion was undoubtedly the first author who describes the drug as an article of the Materia Medica. He, however, quotes still other writers, such as Isaac Ebn Amram and Abix. All the Arab physicians, in fact, extol the merits of senna in purging black or yellow bile and in acting as a cordial when mixed with suitable drugs, such as violets. The present species, as also the Alexandrian (C. acutifolia, Delile), were introduced to both Indian and European pharmacy through the Arabs. The former species (the only one grown in India) is fairly extensively produced in Tinnevelly, and recently its cultivation has been extended to Madura and Trichinopoly, districts of South India, and to Poona in Bombay. It is sown on red or black clay loams, fairly liberally ploughed and manured, the sowing being in May. Weeding has to be attended to, but irrigation is hardly if ever necessary. The season for collecting the leaves is June to December. The yield is said to be 1,000 lb. (2 caddies) an acre, which allows a handsome margin for profit.

Indian senna is either exported coastwise to Bombay and thence to foreign countries, or is consigned direct from Tuticorin. The drug is also imported by India from Arabia, where it is collected from the wild plant and

Cultivation.
MADRAS TANNED SKINS

CASSIA AURICULATA Tanner’s Bark

Aden Senna.

Exports.

D.E.P.,

C. auriculata, Linn.; the Tanner’s Cassia, tarwar, tarota, tangedu, tangheddi, tangadi, avala, avari, etc. A tall shrub found plentifully in Central and South India as far north as Rajputana and also in some parts of Burma. It is common on dry stony hills and on black soils.

The bark is largely used in tanning and gives a buff-coloured leather. It has been remarked that Madras is favoured in the possession of this tanning material. But it is feared the discovery of the method of chrome tanning has even already given a totally new turn to the subject of Madras tanned or dressed skins and rendered the special advantage mentioned of comparatively little avail. (See Hides—Chrome Process, p. 637.) It has always, however, been contended that the raw skins of Madras are naturally well fitted for a high-class tannage. They possess some special properties much liked by the curriers into whose hands they eventually pass to be transformed into the morocco leather used for book-binding, furniture, carriage lining, and many other such purposes. Experts have, moreover, reported that the colour of leather prepared with this bark alone changes into murky brown, further that compared to its merits the price is too high (Rs. 20 a candy of 500 lb.). With a view to ascertaining more precise particulars as to supply, price, and property of this tanning bark, the Reporter on Economic Products to the Government of India issued a circular letter to Forest and other officers of India in which samples of the bark and full particulars were called for. The result was rather disappointing, and has been reviewed in The Agricultural Ledger (1896, No. 9). The Scientific Staff of the Imperial Institute also published some of their investigations with the bark (reprinted by Dunstan, Imp. Inst. Tech. Repts., 1903, 184–5), from which it would appear that the samples examined gave extreme variations in amount of astringent principle and therefore of commercial value. Some time subsequently Hooper (Agri. Ledg., 1902, No. 1, 27) pointed out that one source of diversity was in the age of the plant from which the bark had been collected. In young plants he found the bark to contain only 11.92 of tannin and 22.35 extract, while in old plants the corresponding figures were 20.12 of the former and 29.0 of the latter. In another part of his report (l.c. 3) he places
CEDRELA
TOONA

THE TOON WOOD

cassia bark as the fourth most valuable in a series exhibited by him, the cassia having 23 per cent. of tanning matter. Prof. Hummel, Yorkshire College, Leeds, found the tannin to be 20-5 per cent. On the other hand, Leather mentions only 15-5 per cent. of tannin, but a high accompaniment of soluble non-tannings. So also Prof. Procter (Rept. Soc. Arts, 1904), who places this bark as one of the Catechols, speaks of the "thoroughly unsatisfactory character of the turwar tannage, for the use of book-binding and upholstery," and asks whether there may not be other more desirable materials. These modern results and opinions would thus seem to assign a much lower position to the Tanner's Cassia than seems to be the belief in South India. By way of conclusion it may be mentioned that in the Northern Division of Madras the bark (tanghedi) or some babul gum is added to sesamum seed when it is to be pressed for its oil. It is said that this practice enhances the value of the cake (see p. 986).

The seeds, like those of C. Absus, are valued as a local application in purulent ophthalmia. An infusion of the leaves is esteemed as a cooling medicine and as a substitute for tea. The leaves are also eaten as a green vegetable in times of famine. The shoots are largely utilised as Native tooth-brushes, and the root is spoken of as of great value in tempering iron metal (see Acacia, p. 5; and cf. Wiener, Die Rohst. des Pflanzenr., i., 716).

CEDRELA TOONA, Roxb. ; Fl. Br. Ind., i., 508-9; Gamble, Man. Ind. Timbs., 157-9; Cooke, Fl. Pres. Bomb., i., 217; Duthie, Fl. Upper Gang. Plain, i., 153; Brandis, Ind. Trees, 145; MELIACEÆ. The Toon or Indian Mahogany, Moulinein Cedar, tūn, lim, lidā, dāvī, pomā, tunā, thīt-kado, etc. A large, rapidly growing, deciduous tree, 50 to 60 or even 80 feet high and sometimes as much as 20 feet in girth. It is met with chiefly near streams in the tropical Sub-Himalayan tracts, from the Indus eastwards to Sikkim and Assam; also at low elevations throughout Western and Southern India: less common in Eastern Bengal and Burmania.

This important Indian timber tree is extensively cultivated and often self-sown. It would appear to have first been described, so far as India is concerned, by Jones (As. Res., 1795, iv., 251; also Fleming, As. Res., 1810, xi., 183). The roots are surface-feeders, so that it ought not to be grown on the borders of fields. In the plains of the Panjāb the young plant must be protected against frost. The Timber is durable, not eaten by white ants, and not liable to warp. It is therefore much in demand for furniture and carvings, especially in Saharanpur (Indian Art at Delhi, 1903, 111), and in Bengal and Assam is constantly used for tea-boxes, hence its having become scarce. In Assam it was formerly much employed for boats and canoes, and in South India is very largely converted into cigar-boxes. It is exported from Burma as "Moulinein Cedar," and known under that name on the English market. Col. Seaton gives the cost of cutting and delivery as Rs. 44 per ton. Specimens sent to London from Dehra Dun in 1883 realised 4½d. per superficial foot, and in Malabar in 1902, ½-inch planking fetched Rs. 2 per cubic foot, ¾-inch planking was sold at Rs. 1-14-0, and 1-inch at Rs. 12-0. [Cf. Ind. For., 1883, ix., 427; Capital, July 24, 1902, 115.]

The bark is used, especially along with a powder of the nuts (seeds) of Cevatopsis Bondacolla, as a tonic and antiperiodic in Native Medicine. The flowers afford a red and yellow Dye. [Cf. Tāleef Shereef (Playfair, transl.), 1833, 61.] The seeds, young shoots, and leaves are given as FODDER to cattle.

There are several other Indian forms, the properties of which are similar to those just detailed. The most important are C. microcarpa, C. DC., and C. serrata, hojie (the dāl, dawri, soni, etc.). The latter is particularly abundant below Simla and elsewhere in the N.W. Himalaya, where the timber is in considerable local demand, being employed for beams and sleepers, on

N.W. Himalayan Form.
THE HIMALAYAN CEDAR

CEDRUS LIBANI, Barret., var. Deodara, Hook. f.; Fl. Br. Ind., v., 653; Ribbentrop, Deodar, in Ind. For., 1899, xxv., app.; Gamble, Man. Ind. Timbs., 710-6; Collet, Fl. Sim., 487; Brandis, Ind. Trees, 1906, 691; Confere. The Himalayan Cedar, deodar, dedwar, diir, keu, keori, kelon, kilar, giam, paludar, nakhtar, etc. Dutt (Mat. Med. Ind., 1900, 247, 296) gives it the Sanskrit name of deevādāra.

A very large evergreen tree (often 250 feet) of the Western Himalaya, extending westwards to the mountains of Afghanistan and eastwards to the Dauli river in Kumaon: most common at 6,000 to 8,000 feet, but in the more eastern section of its area it ascends to 10,000 feet in altitude. Said to have been introduced into Great Britain about 1831, and is now cultivated to a considerable extent both in Europe and America. The closely allied species, the Cedar of Lebanon proper, was introduced, so Miller says (Gard. Dict., 1731), into the Physic Garden of Chelsea about 1683, but it is now believed that it was actually being grown in England a few years before that date (1662-70). According to Bonham (Notes on Tartagioni-Tossetti, Journ. Hort. Soc., ix., 175), that cedar, although apparently well known to the Ancients as a valuable tree, had never been grown in Italy until carried from England to Pisa in 1787.

The Deodar is usually though not always monocious, and is roughly distinguishable from the Lebanon and Atlas cedars by its drooping branches and longer needles. Though gregarious it rarely forms pure forests, being found with blue pine, spruce, silver fir, oak, yew, poplar, horse-chestnut, etc. Gamble says that good seed years come about once in four or five years, and in suitable localities, where the seeds can get through the grass, weeds and moss of the surface covering, natural reproduction is very prolific. Artificial propagation also is not difficult, deodar being easily grown in nurseries, and with care successfully transplanted. Young plants suffer from waterlogging, and it is therefore best to transplant them from April to May. Deodar is probably at its best in good localities when about 12 feet in girth, but it can reach a much greater size, trees of 30 to 45 feet in girth, and 100 to 240 feet in height. It prefers a light soil and gneiss, granite or even limestone sub-soil; in the Himalaya it seeks the northern and western slopes, thus avoiding the rain, and in cultivation does not succeed either at Darjeeling or on the Nilgiri hills, where there is too much clay and too much rain.

This is the chief timber of Northern India. It is light yellowish-brown, scented and moderately hard. When well seasoned its weight rarely exceeds 35 lb. per cubic foot. It is very durable as well as immune from white ants, hence is extensively used for railway sleepers. It is believed that the deodar timber of certain buildings in Kashmir and Kanawar may be 600 to 800 years old. Accordingly it is held in considerable esteem for bridge-work and house-building (though its scent is by some regarded as too strong for interior fittings). It is rather brittle, however, and does not take paint nor varnish freely. In woodcarving, especially that of the Panjāb and Kashmir, deodar is of course pre-eminent. The Muhammadan and Sikh work are directly adapted to it, and the characteristic feature of old Kashmir wood-work may be said to have been the bold and effective pinjra or lattice panellings made of this wood. Further details as well as illustrations of deodar-carving may be found in Indian Art at Delhi, 1903 (103 and seq.), and the reader should also consult Lawrence's Valley of Kashmir (1895, 79-80) for further interesting details.

An Orr. (kelon-ka-tel), which resembles crude turpentine, is obtained from the wood, and is used in veterinary practice. [Cf. Gildemeister and Hoffmann, Volatile Oils, 1900, 279.] It is also employed by the men who float deodar logs down the rivers, to coat the inflated skins by the help of which they pass the rapids. In connection with the arrangements for the Delhi Durbar Exhibition, I observed that certain metallic objects kept in a box of deodar wood were beautifully varnished. On inquiry, I found this was due to the action of the oil. It would seem probable that this property may prove of much value. It should certainly be investigated. The aromatic wood (bhadra-kashtha) is employed in Native

OLEUM NIGRUM

**Trade in Cedar.** — It is next to impossible to give a definite statement of the annual supply of this timber. It is floated down the rivers in the form of logs, sleepers, or scantlings. The oil which it contains prevents it getting waterlogged, so that comparatively speaking few pieces get irretrievably lost; nevertheless the obstacle that bars an extended use is the cost of transit from the forests to the markets. The Forest Administration Reports of the Panjáb, of the North-West Frontier Province, and of the United Provinces give particulars of the deodár removals from the forests owned or leased by Government, as also of the imports of that timber from Native States or foreign territory. The Statistical Department of the Government of India also gives particulars of the Trans-frontier traffic in which certain facts are given of imported timber. Comparing and analysing all these and such-like returns it may be affirmed that the annual supply obtained by the plains of India comes to approximately from 3 to 4 million cubic feet of this timber. The supplies come mainly from the forests of the Panjáb proper (Chamba, Kullú, Kangra, Bashahr, etc.), of Kashmir and Afghanistan, of Hazara, Kagan eastward to Jaunsar—the Tonse, Jumna, Bhagirathi, etc. [Cf. Paulus Aegineta (Adams, Comment.), iii., 450; Taleef Shereef (Playfair, transl.), 1833, 83; McDonell, Ind. For., 1885, xi., 213-20; Mián Motí Singh, Ind. For., 1882, viii., 268; 1893, xix., 168-74; Ind. For., 1898, xxiv., 61; Pharmacog. Ind., iii., 380-2; Wiesner, Die Rohst. des Pflanzenn., 1903, ii., 147, etc.; McIntire, Ann. Rep’s. For. Dept. Working Plans Pb. For., 1895; etc., etc.]

**Celastrus Paniculata, Willd.; Fl. Br. Ind., i., 617; Pharmacog. Ind., i., 343-5; Gamble, Man. Ind. Timbs., 1902, 175-6; Brandis, Ind. Trees, 1906, 162; Celastrinæ.** The Black-oil plant, māł-kangni, māl-kungi, sankhū, kujāri, jiotish-mati, etc. A scandent shrub of the outer Hímalaya from the Jhelum to Assam, ascending to 4,000 feet, also of Eastern Bengal, Bihar, South India, Burma and Ceylon. The seeds yield by expression a deep scarlet or yellow Oil, which is used in Medicines for external application. It is also burnt in lamps and employed in certain religious ceremonies, but its chief interest lies in the fact that by destructive distillation along with benzoin, cloves, nutmegs and mace is obtained the oleum nigrum of pharmacy, an empyreumatic fluid usefully employed, according to Dr. Herklot, in the treatment of heri-beri. In doses of 10 to 15 drops, black-oil is powerfully stimulant and diaphoretic. It is chiefly manufactured in the Northern Circars, the best quality being that of Vizagapatam and Eilore. The price of the seed is said to be about 2 annas per lb., and the oil about Rs. 20 per cwt. Moodeen Sheriff (Mat. Med. Mad., 1891, 106-8), the Taleef Shereef (Playfair, transl., 1833, 148) and other writers say that the seeds are supposed to have the property of stimulating the intellect. The red seeds and the leaves are also employed in Native medicine. [Cf. Gamble, Man. Ind. Timbs., 175-6; Cooke, Fl. Pres. Bomb., i., 251; Dutthis, Fl. Upper Gang. Plain, i., 158-9; Brandis, Ind. Trees, 102; etc.]

**Cements and materials used.** — *Agri. Legd.,* 1902, No. 5, 142-4; *Ind. Art at Delhi,* 1903, 95-6, 215; Papers relating to Magnesia Cement (a reprint of reports, letters, etc., dating from 1826 to 1837), issued by Madras Government. Cements are commonly distinguished under five groups:—(a) calcareous; (b) gelatinous; (c) glutinous; (d) resinous; and (e) various materials. Since nearly all cements contain lime, the reader is referred to the article on that
THE MANGROVE

CHENOPODIUM

subject (pp. 685, 713). The following are the chief vegetable and animal substances employed as constituents in special cements, and mostly along with lime.

Adenanthera pavonina, Linn.; seeds (see p. 25).

Agave; sap (see p. 35).

Allium sativum, Linn.; fresh juice (see p. 58).

Borassus flabellifer, Linn.; juice (see p. 171).

Cathamus oxyacantha, Bieb.; oil (see p. 278; also cf. Agri. Ledg., 1904, No. 11).

Cocos nucifera, Linn.; jaggery and milk (see pp. 361, 929).

Commiphora agarbetta, Engl.; the gum-resin (see p. 400).

Gelatinous Cements; see Isinglass (p. 695).

Melanorrhiza usitata, Wall.; oleo-resin (see p. 779).

Oryza (glutinous rice); (see p. 826).

Sugar; gur or jaggery used in chandam (see p. 956).

Triticum; gluten of wheat-flour (see p. 1088).

Typha angustata, Chaub and Bory.; the down from ripe fruits (see p. 777).

The vernacular name gordan or gordan applies to both these plants, and in fact they are not economically distinguished. The former is a small evergreen tree of the muddy shores and tidal creeks of India, especially common in Sind; and the latter a large shrub of similar conditions in the Sundarbans and the coast of Chittagong down to Tenasserim. The barks of both trees yield an important TAN. A sample of tannin-extract prepared in the Sundarbans and examined in England in 1900 was not, however, much valued because of its dark colour. Prof. Trimbole of the Philadelphia College of Pharmacy found 23.97 per cent. of tannin in the dry bark of a sample of C. Candolleana sent from Singapore, and 31.56 per cent. in a Bengal sample. Other Bengal specimens were found to yield on the dry bark 30-20 per cent. and 18-30 per cent. (Hooper); 17-77 per cent., 21-54 per cent., 13-23 per cent. (Dunstan). [For further details cf. Imp. Inst. Tech. Repts., 1903, 186-90; Agri. Ledg., Lc.] About ten to twelve thousand maunds of Mangrove Bark are sold annually for tan in the Calcutta market at about 10 annas per maund of dry bark. The extract is also used as a Dye to give a brownish-red colour to cloth, but especially a good black and purple in conjunction with indigo. In the Malay the cloth is first dyed in Mangrove-extract, then dried, and subsequently dipped in indigo. [Cf. Kew Bull., 1897, 91-2.] The whole plant is astringent: a decoction of the bark is applied to stop haemorrhage, and on the African coast the young shoots are employed in the preparation of a substitute for quinine. The Timber of most of the species is hard and that of C. Candolleana is used for knees of boats. It is a superior fuel, and makes excellent charcoal.

CHENOPODIUM ALBUM, Linn.; Fl. Br. Ind., v., 3; Duthie and Fuller, Field and Garden Crops, iii., 21; Cooke, Fl. Pres. Bomb., ii., 501; CHENOPODIACEAE. The White-goose-foot, bathú-sag, chandan-betū, lāmak, etc.

There are various cultivated and wild forms of this ubiquitous plant, e.g. album proper (chandan-betū), viride (betti-shak), purpurascens (lat-beti), etc. From the point of view of the present work the interest lies in the fairly extensive cultivation in the higher Western Himalaya as a food-grain and pot-herb. A sample of the seed sent from the Panjāb and examined at the Imperial Institute gave the following results:—water 8.3 per cent., albuminoids 18.4 per cent., starch 19.2 per cent., oil 21.1 per cent. The nutrient ratio was 1:377 and the nutrient value 86. Church (Food-Grains of Ind., suppl., 8) says that "analysis amply confirms the Indian opinion of its highly nutritious character." The wild plant is regularly collected as a pot-herb and green vegetable. The leaves are rich in potash-salts. A decoction of the plant is used as an adjunct in indigo-dyeing and the seeds are employed medicinally (see Vinegar, Medicine, p. 1110). [Cf. Buchanan-Hamilton, Stat. Acc. Dīnāy, 169, 194.]

293
**CHLOROXYLON SWietenia, DC.; Fl. Br. Ind., i., 569;**

The Satin-wood, *bhera, bhera, billa, biltu, biltu, madu, sengel, jirhal, salt, bhangal, halda,* etc. A moderate-sized tree of Central and South India, also Ceylon. Is met with in the dry forests of the Cérears, Konkan, Deccan and Kárnátak, on especially poor soils, such as sand and laterite; common on the Satpuras and the sandstone formations of Káladgi and Belgaum. Its most useful product is its *Timber,* the Satin-wood of commerce, which is largely exported from Ceylon and S. India (*"Tamil Satin-wood"). It is in much demand for cabinet-work, the backs of brushes, picture frames, turnery (makes good stethoscopes), furniture, etc., and locally is utilised in house-building, carts and agricultural implements, but is not a good firewood, as it smokes too much. The tree also yields an amber-coloured *Gum* (of which little is known), a *Dye,* a wood-Orl and an astringent *Bark,* sometimes used medicinally, as also a paste made from the roots. Trees often destroyed on account of leaves being given as *Fodder.* [Cf. Forsyth, *Highlands Cent. Ind.,* 464; Pharmacog. Ind., 1890, i., 338–9; Basu, *Agri. Lohardaga,* 134; Biscoe, *List Hyderabad Trees,* 1895, 5; *Ind. For.,* 1897, xxiii., 52; 1899, 181; *Cat. des Pl. Econ. Colon, "L'Hort. Colon,* Brussels, 1900, 52; Wiesner, *Die Rosh. des Pflanzenr.,* ii., 983; *Imp. Inst. Tech. Repts.,* 1903, 248.]

This cultivated little herb is of interest mainly because of the fact that from Dinajpur and Rangpur in Bengal, north-east to Assam, it is extensively eaten, and is number 15 in Buchanan-Hamilton's list of *ságs* or pot-herbs. This fact seems to have escaped observation until re-discovered by myself while investigating the areas of successful cultivation of *Bohemnia nivea.—Chinesegrass.* In my report on that subject, published in *The Agricultural Ledger* (1898, No. 15, 517–8), I pointed out that plants of the pea family become scarce, but that a peculiar series of pot-herbs take their places. Among these *C. coronarium* was found to hold a foremost position, being known as *babir* in North Bengal, *babui* in Assam, and *jalymin* in the Hāsia hills. It may now be added that after an inspection of the collections preserved in the Royal Herbarium, Kew, I am able to add that only one collector would appear to have previously recorded that observation of this plant being eaten. Speaking of Formosa, Walters calls it *tan-ëi-tsai* and adds that it is a "herb much used by the Chinese as an article of food." Bretschneider (Bot. Sin., 1892, pt. ii., 76) makes mention of two species of *Chrysanthemum* as known to the Chinese classics, the leaves of one of which are boiled into soup. This would appear to be called *tsi' ū huā kū,* but in another part Bretschneider adds that he does not know...
THE BENGAL GRAM

CICER ARIETINUM

the edible Chrysanthemum. It is, however, remarkable that not a few of the special vegetables of the rhea fibre area of India should be more Chinese than Indian plants. For the medicinal and other uses of this plant the reader should consult the works cited in the opening sentence above.

CICER ARIETINUM, Linn. ; Fl. Br. Ind., ii., 176; Duthie and Fuller, Field and Garden Crops, 1882, i., 33-6, pl. 8; Agri. Ledg., 1895, No. 3, 37, 42; Mollison, Textbook Ind. Agri., 1901, iii., 73-8; Prain, Beng. Plants, 1903, 365-6; Duthie, Fl. Upper Ganj. Plain, 1903, 256; Cooke, Fl. Pres. Bomb., i., 408; LEGUMINOSÆ. The Common or Bengal Gram; Chick-pea; cicer (Latin); erebinthos, orobos, krios (Greek); ceci (It.); ziser, kirchen, ziser, kucherebs (Germ.); ciceren (Belg.); ciche, pois ciche, pois peechu, garvanse (Fr.); gravancos, garbancos (Castilian); cicerchas (Sp.).

History.—Most of the modern European names, like the English chick-pea or chiche, have doubtless come from the same root as the Latin cicer. Others may be viewed as derived from the Greek name, erebinthos, or are descriptive of the shape of the seed (krios—the ram’s head). Hehn (Kulturpf. und Hauat. 1894, 210 et seq.) identified cicer with the Greek krios (Dioscorides, ii., ch. 126). Apparently the earliest mention of the pulse in the literature of Europe occurs in Homer (IIiad, bk. 13, 589). Some centuries later Theophrastus (about 350 B.C.) assigned the word erebinthos definitely to the modern gram. Parched gram is mentioned by Horace as an article of food with the poor. Cicero took his cognomen from this pulse, as Fabius did from faba, also Piso and Lentulus from the pea and the lentil. Gram must, therefore, have been a common article of food with the poorer Greeks and Romans long before the Empire. The name “gram” comes from the Portuguese grao (i.e. grain), and was apparently a special appropriation made in India, because of its being in that country the most general grain given to horses. It is, of course, a pulse, not a grain, in the strict sense, but in South India, where cicer is but little cultivated, the name “horse gram” is given to Dolichos biflorus, just in the same way that “green gram” denotes Phaseolus Mungo. These pulses, cicer more especially, are frequently articles of cattle food, hence the expression “gram-fed” applied to the animals reared on them. Nikitin, a Russian traveller, who visited Western and Southern India in 1468, was impressed with the fact that in India horses were fed on peas. The old English words calavances, garvances, garvancos and garbances are derived from the Spanish garbanzos, and were apparently given (and to some extent still are given) to several peas or beans largely used by mariners in place of fresh vegetables, hence very possibly the refrain of the mariners who “live on yellow peas.” And those names survived till the beginning of the 19th century, for they occur in Act 54 of George III. (1814, ch. xxxvi.). For further particulars the reader should consult the article Cajanus (p. 199), also Dolichos (pp. 503-10) and Vigna (pp. 1107-8). [Cf. Cocks, Diary, 1620, ii., 311; Herbert, Travels, 1677, 333, 337; Fryer, New Acc. E. Ind. and Pers., 1675, 21; Shelvocke, Voyage, 1719, 62; Hamilton, New Acc. E. Ind., 1727, i., 393; Shaw, Travels, 1757, 140; Joret, Les Pl. dans L’Antiq., 1904, i., 249.]

In Sanskrit this pulse is known as chanaka or chennuka, and in the vernaculars of India—chan, chounna, chenna, chahna, chano, channa, sanna-galu or sanagalu, senagalu, chola, etc. Occasionally other names are given to it, such as bid, bido, harbara, kadit, kadaol, karanun-dhakum, kudoly kempa, kadale, kalerai, etc. The first series are most frequently used in Northern, Central and Western India (down to Gujrat), while the second are specially prevalent in Eastern and Southern India from Bengal, Assam, Burma and west to the Maratha country, thence to the extreme south. In Arabic it is kumuz, in Kabyl hammes; in Egyptian homos or omos and in Persian nakhid. Aitchison says that in Khorasan it is known as nakhn. De Candolle observes that south of the Caucasus it is known in Georgian as nakhoda; in Turkish and Armenian as nachius or nachunt—names which De Candolle asks whether they may not be connected with the Sanskrit chennuka. In India the Arabic and Persian names are often used by Muhammadan writers. Thus in the Ain-i-Akbari, written 1590 (Blochmann, transl., i., 62), mention is made of nakhid dal as a pulse, the price of which is given, and it is expressly stated not to be met with in Kashmir (Jarrett,
THE BENGAL GRAM

transl., ii., 350). It is curious, however, that no mention is made of gram in the Memoirs of Baber (written about 1519 A.D.), so that it may fairly be inferred gram was not an important article of food with the army under the first great Mughal conqueror of India. Baber’s silence regarding it may, however, have been a pure omission, or a consequence of its not having been a pulse new to him on his arrival in India, for it seems certain it was known to the people of India from a fairly remote period. By Hindu it is invariably described under its Sanskrit name, or some derivation from that. Susruta (Auyur Veda (Hessler, transl.), bk. i., ch. xx., 49), for example, alludes to it under the name of hariman t’kata as one of the specially wholesome articles of food. The name hariman-dkakam is very largely given to it by the present Tamil-speaking races. It is mentioned in the Puranas but apparently not in the Institutes of Manu. The vinegar made from the dew found on the leaves is referred to under the name chana-kámâ by most of the Sanskrit medical writers.

Varieties.—While it is quite correct to say of it to-day, as it was when the Ain-i-Akbari was written, that Bengal gram is not cultivated to any extent in Kashmir, still there is a special form of the plant fairly extensively produced in the western temperate and alpine regions, between 9,000 and 15,000 feet in altitude, such as in Piti, Lehul, Kumaon and Tibet. This has been described by botanists as a distinct species under the name of C. soongargicum, Steph. It bears the following vernacular names:—tisnu, fawâne, banyarts, sâbri or sârri—names apparently unconnected with those given to C. arietinum; and since C. soongargicum is only met with in alpine Central Asia, it may be assumed to be there indigenous.

So also a very special variety or distinct species is known as khabli gram. This has been much talked of recently, and even experimentally grown in India, but with indifferent results. It is apparently a form peculiar to the country indicated by its name, though it is specially mentioned by Buchanan-Hamilton as met with by him in Dinaipur about 1809. It is thus a form that has been experimentally grown in India for a century or more. It is a much more robust plant than the ordinary gram, and has large white seeds. But in addition to these special Trans-frontier varieties, India itself has also several fairly distinct cultivated forms indicated by the colour of the pea, viz. red to yellow, brown, creamy white and almost black. But in no part of India or of its mountainous frontier has any botanist recorded the existence of wild or even naturalised representatives of any form of gram. They all exist purely and simply as cultivated plants, and on the plains are usually rabi crops. It seems highly probable, however, that the forms of chick-pea originated in the tract of country between the Caucasus and the Himalaya. And if that opinion be accepted they can be regarded as having been carried into Southern Europe, Persia and India in very ancient times. But it seems probable that at least one of the forms may have originated in Persia, so that the chick-pea may have been also indigenous to that country.

CULTIVATION.—Area.—During the five years ending March 1905, the average area shown in the volume of Agricultural Statistics for British India as devoted to this crop, comes to almost 11 million acres, and for the Native States a little under 2 million acres, so that an estimate of 12 million acres for the whole of India would be under rather than over the mark. The most important producing province is that of Agra, which during the period named possessed an average of 3½ million acres, or say one-third of the Indian area. This is followed by Oudh (with 1½ million acres), by the Panjâb (which fluctuates very greatly, the area in 1899–1900 having been only 658,468 acres, and the very next year 3,405,121); by Bengal (with approximately one million acres); by Bombay, the Central Provinces and Mysore (with each normally a little under a million acres); by Gwalior (which has as a rule ½ million acres); by Berar, Madras and the North-West Frontier Province (with each about 150,000 acres); by Sind, Upper Burma, Alwar, Bharatpur and Kotah (with each about 70,000 to 100,000 acres); and lastly by all the other Provinces and Native States (which have each much smaller areas). It may thus be accepted that the upper basins of the Ganges and the Indus (which correspond with
Upper Bengal, the United Provinces and the Panjáb, also the adjacent portions of the Central Provinces, Central India and Rajputana) constitute the great gram-producing area of India. It has been repeatedly pointed out that a line drawn from Bombay to Patna would approximately divide India into two sections, the northern being the great gram area and the southern that in which gram is a very subordinate crop.

Production and Yield.—The yield of gram to the acre is annually reported by the various Governments and Administrations. It is shown to vary greatly according to suitability of soil and climate; the highest returns are in the provinces of chief production. In Bihar (the upper division of Bengal) the yield comes to 855 lb. per acre, for land not irrigated; in the United Provinces, 800 lb.; in the Panjáb, 634 lb.; while in Bombay, under similar conditions, the yield is only 410 lb. and in the North-West Frontier Province still less—406 lb. But irrigated land gives a higher yield than unirrigated: in Bombay as much as 1,200 lb. have been recorded; 950 lb. in the United Provinces; 835 lb. in the Panjáb, and 632 lb. in the North-West Frontier Province. Taking the nine chief producing provinces and accepting for a calculation of total production the mean of the published returns for 1901–2, on unirrigated cultivation, we arrive at the figure of 600 lb. as a possible safe average for all India. This, worked out to 10 million acres, or considerably under the present area, would show a total production of 53 million cwt. But that very large amount would in all probability be under rather than over India's actual supply, since this pulse is largely grown as a mixed crop and also as a garden vegetable, tracts not likely to be fully covered by its recorded acreage as a field crop.

It may be useful to take up the provinces one by one and exhibit the features of their gram-cultivation etc., that may be of interest:

Bengal.—Gram requires the same land as wheat, barley, linseed and peas. It cannot be grown on sandy soils but requires a moderately heavy clay-loam. Five or six ploughings are given, commencing towards the close of the rains. About the latter half of October to the first week in November it is sown, and the crop ripens in February to March. The quantity of seed required ranges from 27 to 36 seers, more being needed when "broadcasted" than when "drill" sown. The plants are pulled up by the roots, made up into loads, and carried to the threshing-floor. The straw and the husks of the pods form excellent fodder. The yield is stated to be about 9-7 maunds (or, say, approximately 800 lb.). The cost of cultivation (according to the Report of the Dumraon Experimental Farm for 1902–3) has been put at Rs. 15-1–8, and the money value of the crop at Rs. 44–12–3 an acre. [Cf. Buchanan-Hamilton, Stat. Acc. Dinaj., 1833, 174, 184; Basu, Agri. Lohardaga, 1890, 34; Barclay, Fungal Disease, Agri. Ledg., 1895, No. 20, 381.]

Burma.—Cultivation is important only in the upper districts. In Meiktita (Settl. Rept., 1896–8, 10) it is said the land is prepared in October and the seed sown in November after having been soaked in water for a day and then sown broadcast. The crop ripens in February. The plants are tied up in bundles, dried in the sun, and threshed out either by sticks or by being trodden under foot by cattle. The harvest-time, all over the province, is from February to April. One basket of seed to the acre—the yield being 15 to 20 baskets. There are three groups of districts according to date of sowing, viz.:—(1) September to October: Lower

297
CICER ARRIETINUM
Chick-pea

Chindwin; (2) November: Shwebo, Sagaing, Mandalay, Pakokku, Myingyan, Melktiha, Magwe and Yamethin; (3) January: Minbu and Thayetmyo. The district with the greatest area appears to be Pakokku, followed by Minbu and Sagaing.

C. Prov. Central Provinces.—In these provinces a rotation of gram, massur (Lens) or butana (Pisum) with wheat is much valued since the soil is thereby so improved that it does not require manure. This has been specially investigated at the Experimental Farm of Nagpur. [Cf. Rept. 1900-1, 10, 12; 1901-2, 9-10, 13; 1902-3, 8-9; 1903-4, 7, 8, 9; Voeleker, Improv. Ind. Agr., 1893, 26-7, 234-6.] Gram is sown in October-November and harvested March-April. Two forms are mentioned as specially valued, a grey and a white. It suffers very much from falls in temperature or by hail-storms. In Narsinghpur, Hoshangabad, Betul and Raipur the crop is of special importance, and of Sambalpur it might be said gram is not cultivated. In a "Note on the Outturn of Land Under the Principal Crops," Sir J. B. Fuller has shown that the average outturn ranges from 377 to 860 lb. an acre, and that the standard there accepted was accordingly 600 lb.

U. Prov. United Provinces.—Very little of importance has appeared regarding the gram of these provinces subsequent to the publication of the Dictionary. Duthie and Fuller observe that there are two main varieties grown—a large- and a small-grained plant. The former is reddish and the latter light-brown coloured. A black variety is not uncommon and there is also a very large white-grained form known as the Kabuli, which is, however, raised mainly as a curiosity. It resembles the Spanish form spoken of as garbanzos. Gram is largely grown as a mixed crop with wheat or barley. This would appear to have been the practice in Europe in classic times. Thus, for example, in the Geoponica (a work attributed to the Emperor Constantine, A.D. 300) there occurs an interesting passage to the effect that cicer seeds should be soaked in warm water the day before they are sown, and "some add nitre." Then follows the observation that if an early crop be wanted it should be sown together with barley. The Indian practice is thus apparently a very ancient one.

The seasons of sowing and reaping are those already mentioned, viz. September to October and March to April or May. It is a dry crop mainly, and will grow on soils too poor for wheat. The outturn is on an average said to be 12 maunds (984 lb.), valued at Rs. 30, and the cost of cultivation Rs. 12 to 13. Within recent years the area under this crop has in many districts apparently been greatly expanded and at the expense evidently of wheat. It may be grown on a heavy clay to a rich loam, preferably the former. The tops of the shoots are nipped off with a view to make the plants bushy and thus increase the outturn.

Expansion. Rajputana and Central India.—The seasons of sowing and reaping are those already mentioned. Of Bharatpur it is estimated that the cost of cultivation comes to Rs. 6 to 10, the produce Rs. 20 to 10, and the net profit per acre would therefore be Rs. 14. It is said that the average yield in Ajmir is 300 lb. and in Merwara 446 lb. an acre.

Panjáb.—This pulse is by Baden-Powell, Stewart and Aitchison spoken of as largely cultivated throughout the province. Numerous passages regarding the methods of cultivation, seasons, yield, etc., will be found in the Settlement Reports and Gazettes. One feature of interest may be specially noted, namely that the plant grown is said to succeed fairly
well on the sandy soils of many tracts of the province, especially as a mixed crop with wheat. Of Montgomery district it is observed there are both spring and autumn crops. It is not grown in the hill districts, a fact accounted for by some through the curious belief that the crop has a special affinity for lightning and is in consequence often destroyed by it. In most of the Panjab districts, on the other hand, it is believed that manure is harmful to gram. It is sown in October and reaped in March and April. Christmas rains are beneficial, but if heavy rains fall in spring the crop is believed to be much injured. As a rule gram is not preceded by an autumn crop. The plants are “topped” by hand in order to cause them to branch. But like other rabi crops it is ordinarily not weeded. The chief districts are Ferozepore, Ludhiana and Hoshiarpur.

[Cf. Rept. Exp. Farm, Lyallpur, 1901-2, 17-8.]

Bombay and Sind.—Mollison (l.c. iii., 73–8) gives a useful account of this pulse as cultivated in Bombay Presidency. He mentions four forms distinguished by the colour of the seed, namely black, dark red to brown, yellow to yellowish-red, and white to creamy. He remarks that the first three are often grown mixed but that the yellow of Gujarat is larger than that of the Deccan and when sold pure commands a higher price than the mixed pulse. The white is met with in Ahmednagar and may, Mollison thinks, be the Kabul gram already repeatedly mentioned. The area of production depends on the extent of the rain that falls in September and October—when abundant, the area is increased. It is grown on the same class of soils as wheat, and the two crops are often interchangeable. Gram is a fairly important crop in the Deccan and Karnatak. It is grown in three ways: (a) as a dry crop in deep black soil, and is then usually the sole crop of the year; (b) as a dry second crop following rice, and occasionally (as in the Panch Mahals) as an ordinary dry crop after kharif maize; and (c) as an irrigated crop liberally manured and regularly watered. In Bombay gram is rarely grown as a mixed crop with wheat or barley, though it is often lined with linseed or safflower. It is everywhere recognised as a valuable rotation, and in addition to nitrating the soil it forms such a dense surface herbage as to kill weeds and in that way improves the soil. The usual seed rate is about 40 to 50 lb. an acre. [Cf. Crop Exper. Bomb., 1895-6, 6.] It is sown in October and November and ripens in February to March and April. Experiments performed at Poona Experimental Farm (1895, 10–11) confirmed the reputation of the advantage in nipping off the early green buds. But too frequent cultivation of gram on the same land causes liability to disease. Cold is harmful, frost fatal. Cloudy weather and heavy rains during the setting of the fruits are alike harmful. Many experiments have been performed (reported under Crop Experiments) to ascertain the cost of production and incidence of assessment. In 1896–7 two fields irrigated were tested and gave the total value of produce as Rs. 17–12–0 for the one and Rs. 15–13–9 for the other, the assessment showing an incidence of 12°67 per cent. in the one and 16°45 in the other. These fairly represent the average of all results, though no calculation could be applicable to the whole Presidency since the conditions and necessities vary so greatly. [The Experimental Farm Reports teem with interesting particulars regarding this crop, and should be consulted.]

Berar.—There is nothing of any material importance to add regarding this province to the particulars already recorded under the
THE BENGAL GRAM

Central Provinces and Bombay. It occupies about 24 per cent. of the area devoted to cold-weather crops and is most abundant in Basim, Buldana and Wun.

Madras.—Bengal gram is an unimportant crop in Madras Presidency, its place being taken by the horse-gram (*Dalichos biflorus*). The manuals of North Arcot and Coimbatore districts contain, however, brief paragraphs regarding it.

Mysore.—The *Gazetteer* of this State will be found to give some useful particulars in connection with gram cultivation. It is grown on black soil, and as a second crop following *raqi*.

**USES OF GRAM.**—It would be beyond the scope of this article to afford details of every economic property of gram. The seed is extensively eaten both by men and cattle in every part of India except Madras. [Cf. Elliot, *Farinaceous Grains*, 1862, 294–5.] The pea is often parched and used in that form as diet, especially when cooking may be difficult or impossible. It is in this sense frequently of exceptional value to the Indian Army. The seeds are also steeped in water to remove the husks, then mashed up and boiled alone or with onions, etc. (and thus made into a thick soup), or the split peas may be cooked along with rice. Ground into flour gram is used in various ways, such as in the preparation of sweetmeats or biscuits. Although it is by far the most extensively consumed of all cattle foods in India, the results of the effort to introduce it into Europe as an article of horse food have not been encouraging. It would seem that when given in large quantity to animals not accustomed to it, poisonous effects have been observed. It has not, however, been placed beyond dispute that the grain used in Europe was pure gram. If adulterated with the pulse *Lathyrus sativus* the effects attributed to gram could be easily understood. [Consult the observations on this subject in the *D.E.P.*, ii., 279.]

The young tops are largely collected and eaten as a *pot-herb*. Moreover when sun-dried they may be preserved and used as required. As a *fodder*, gram-straw has the reputation of being inferior to that of other pulses owing to the amount of acid liquid (which contains oxalic, acetic and malic acids) found on the dew-besprinkled leaves. Still the stems, leaves and husks constitute important articles of Indian cattle food. They are specially valued for milch-cows, and are cut up and mixed with common straw.

The property of the green plant inaffording an acrid liquid often called a *vinegar* has been known from the remotest antiquity. It is systematically collected by spreading clean cotton cloths over the growing plants at night and collecting from these the vinegar with which they have become charged. This is used both medically and in diet. One of the earliest European travellers who described this vinegar-dew was Dr. Hove, who explored the agriculture of Gujarat in 1787. [Cf. with Birdwood, Baden-Powell, Mooden Sheriff, etc.; see also *Vinegar*, p. 1109.]

**Chemistry.**—Church (*Food-Grains of Ind.*, 1886, 128; suppl., 1901, 12) gives the results of his examination of the husked peas:—The nutrient ratio he found to be as 1:3.3 and the nutrient value 84. Similarly *C. spongicium* gave a nutrient ratio of 1:2.8 and the coagulable albuminoids amounted to 19.8 per cent., so that this form of the pulse is rather richer in albuminoids and in oil than are the seeds of the common gram. Leath has critically examined numerous samples of gram from all parts of India and has published in *The Agricultural Ledger* (1901, No. 10, 358–9; 1903,
PRICES IN CHIEF CENTRES

No. 7, 151, 155, 163) the results of his chemical investigations. Mr. Moreland has investigated the question of the extent to which gram may be used in the reclamation of upland usar soils. [Cf. Agric. Ledg., 1901, No. 13, 424.]

INDIAN TRADE IN GRAM.—In a previous paragraph the area has been accepted as approximately 12,000,000 acres and the yield something like 53,000,000 cwt. Gram is consumed very largely locally, so that the returns of foreign trade are comparatively of little value. Gram and millets are very much more the staples of Indian diet than are wheat, barley or rice. A study of the rise and fall in the prices of these grains affords, therefore, a surer indication of the cost of living and of the abundance or scarcity of food than can be learned from almost any other commodity (except perhaps the imports of copper metal). Were it possible to prepare a complete statement of the internal traffic in gram, it would be seen to what extent the resources of one province are drawn upon to supply the necessities of another. Unfortunately the record of internal transactions is very much less complete than the returns of articles received from or delivered to the shipping.

The total exports have rarely exceeded half a million cwt. In 1895–6 they were returned at 633,199 cwt., but the mean of the decade ending March 1904 comes to only 335,000 cwt., or 0·632 per cent. of the estimated total production. In 1906–7 they were 846,583 cwt., valued at Rs. 32,31,744. But of the exports a mean of about 35,000 cwt. goes from Madras, and should therefore be removed from the returns of *Cicer arietinum* and credited to those of horse-gram (*Dolichos biflorus*), so that this correction would very possibly bring the exports down to approximately ½ per cent. on production. A feature of interest in recent returns is the growing importance of Sind (Karachi) as an exporting centre. Still another fact may be added, namely that the major portion of the exports is commonly consigned to Mauritius, but sometimes to the United Kingdom; the traffic with the latter, however, seems subject to extreme fluctuations. By the coastwise trade 692,212 cwt. were carried in 1905–6, of which 370,165 cwt. went to Madras, about half from Bombay, and one-sixth each from Bengal, Sind and Burma. Of the rail-borne traffic nothing can be said, since gram is collectively returned with pulses.

Turning now to the available particulars regarding prices of gram. The years 1896 to 1901 have to be excluded from consideration as these were characterised all over India as years of scarcity and famine. But the effect of the increased facilities of railway communication may be said to have raised the price in centres where it was abnormally cheap and lowered the price where it was abnormally dear. Taking India as a whole the price seems to have been slightly increased, but not disproportionately with other commodities or with wages. In Assam gram sold in 1884 at 12·4 seers to the rupee (or say 1½d. per 2 lb.), and in 1903 at 11·85 seers. In Bengal for the corresponding years it was 18·1 and 16·71; in the province of Agra 24·12 and 19·8; in Oudh 25·66 and 22·54; in Rajputana and Central India 21·36 and 18·31; in the Pajab 32·22 and 21·06; in Sind and Baluchistan 20·49 and 15·76; in Bombay 18·08 and 14·2; in the Central Provinces 26·81 and 17·75; and in Berar 19·84 and 14·81. The mean of all these returns would be 21·9 in 1884 and 17·79 in 1903. That is to say one seer (2 lb.) would in the former year have cost 0·7306 of an anna (or of one penny), and in the latter year 0·8939. But the selection of single years for comparison, and the striking of means and averages in
CINCHONA

THE CINCHONA PLANT

Introduction into India

despite, can never be seriously advanced as evidence of value. For one thing it seems likely that the full effect of the years of famine was not effaced by 1903, and that better results would be shown in subsequent years. Local and accidental peculiarities are ignored by all such calculations. Still, the figures given are of some interest. Later returns for 1905, which have since come to hand, show the following prices (scorns to the rupee):—
Eastern Bengal and Assam, 12:61; Bengal, 14:99; Agra, 17:34; Oudh, 17:21; Rajputana, 16:3; Central India, 15:71; Panjab and N.W. Frontier, 20:63; Sind and Baluchistan, 15:5; Bombay, 13:59; Central Provinces, 16:49; and Berar, 15:14.

Peruvian Bark.

D.E.P., ii. 289-316.

CINCHONA, Linn.; CINCHONA and PERUVIAN BARK, JESUITS' BARK; ecorce de quinquina (Fr.); chinarine (Germ.); RUHIAZEE.
The species of CINCHONA that yield QUININE are the most recently cultivated of all important plants. They are natives of the mountain forests of Bolivia, Peru, and Ecuador, and are chiefly met with in the valleys with an eastern trend from the great Andes, at altitudes between 3,000 and 9,000 feet and also in the western valleys of the central area.

History.—Sir George King,—than whom few persons have a higher claim on the respect of the people of India—opens his Manual on CINCHONA CULTIVATION with the following passages:—"Of the date and manner of the first discovery of the curative effects of CINCHONA Bark, in malarious fevers, we know nothing. And we are almost equally ignorant who the discoverers were, some writers claiming that merit for the aborigines of South America, while others assert, and with apparently greater accuracy, that not only did the Indians know nothing of the virtues of the bark, until these were pointed out by their conquerors the Spaniards, but that they still refuse to use the bark as a febrifuge. The introduction of this medicine to Europe is associated with the Countess of Chinchon, wife of a Spanish Viceroy of Peru, who having been cured by its use of an attack of fever, contracted while in that country, brought a quantity of the bark to Europe on her return from South America about the year 1639." Acquaintance with the virtue of the bark seems, however, to have been disseminated over the world with remarkable rapidity. It was discussed, extolled, and defended by Chiflet in 1653; by Badius in 1656; by Roland Sturm in 1659; by Morton in 1692; and by Pomet in 1694. It was known in London in 1655, and became official in the Pharmacopoeia in 1677. Fryer, who visited India in 1675, speaks of a "BRACHMIN" who gave a powder prepared from natural cinnamon in the cure of fever "which works as infallibly as the Peruvian Bark." This curiously interesting anecdote shows the rapidity with which the knowledge of this drug was carried across the globe. A century later it was fully described in an Indian work on Materia Medica under the name "Bark." This was written by Mir Muhammad Husain (Makhzan-el-Adwiya, 1770), who specially remarks that its virtues had been discovered by a sect of Christians called Jesuits. He adds that it bears the name of kina-kina. This is its name in the language of the Inca, and it gave origin to the French name quinquina, as given by Condamine originally, and to chiña in Spanish. The French obtained the bark in 1679, for it is recorded that Louis XIV, purchased a supply from an Englishman of the name of Talbor or Tabor. Talbor, like many of the Native doctors of India to-day, made his reputation and fortune through a fever mixture the chief ingredient of which was quinine. Nothing, however, was known to the botanical world of the plant from which the medicinal bark was procured until 1739, when MM. La Condamine and Jussieu studied it, during an astronomical expedition to South America. The former sent a sample to Linnaeus from Cajanuma, and in consequence in 1742 it was named Cinchona, and in 1753 Linnaeus established the species C. officinalis. The plant is sometimes now known as var. Condaminea after its discoverer.

Plants named Botanically.

The first living plant was shown in Europe in 1840, having been raised in Paris from Weddell's Bolivian seed, namely, \textit{C. caulisaya}. Thus, briefly, the medicinal bark was discovered in 1640; the plant was named a century later; and still another century later a specimen was grown in the Jardin des Plantes of Paris.
PERUVIAN OR JESUITS' BARK

But if a lady was directly instrumental in the discovery of the great merits of this drug, a no less distinguished lady, the wife of a Viceroy of India (Lady Canning), was closely connected with its ultimate successful cultivation in India. Dr. Ainslie in 1813 lamented the fact that Cinchona was not grown in India. Dr. Hoyle in 1835 recommended that the Cinchona plants should be taken to India and grown on the Khasia and Nilgiri hills. About the same time Tretze, Miqel and other botanists advanced the claims of Java. No effort was, however, made for twenty years, not in fact until the heavy mortality through fever, during the Indian Mutiny, forced the subject into public attention. It was, moreover, well known that a reckless and selfish process of bark-collection was seriously endangering the world's future supplies of the drug. These circumstances combined to lay emphasis on the final recommendation of the Government of India, viz. that seed and plants should be procured for experimental cultivation in India. In consequence, Mr. (now Sir) Clements R. Markham was entrusted with the delicate and difficult task of procuring supplies. The subsequent incidents and final success which he attained are matters of history, and need not be here detailed. Sir Clements procured the services of several gentlemen whose names are all closely associated with his own, namely Spruce, Fritchett, Weir and Cross. The recommendation of the Director of the Royal Gardens, Kew, guided and controlled all the subsequent efforts. Various consignments of plants and seeds were taken to Kew, and finally carried to India, certain plants having in due course been established on the Nilgiri hills. So far, however, the attempt to introduce the trees into Bengal had been a failure. On the other hand, the efforts of the Dutch botanists and chemists in the naturalisation of C. Calisaya and C. Paludiana were crowned with complete success, and in consequence the noble Lady Canning discussed with Dr. Thomas Anderson, of the Royal Botanic Gardens, Calcutta, the desirability of a further effort being made to introduce the most useful species, if possible, from Java into the mountains of Bengal. Shortly after Lady Canning herself fell a victim to the scourge that she aimed at alleviating. Dr. Anderson was, however, deputed to Java, and he brought back with him a fairly large consignment of plants, some of which he left in Ceylon, others in the Nilgiri hills, and finally took a set to Calcutta Botanic Gardens and ultimately to Darjeeling. But many mistakes as to altitude, climate, method of treatment, best stock and the like, had to be corrected before a plantation could be established. Dr. Anderson lived, however, to see his labours brought to a satisfactory conclusion, and then, like the great lady who had sent him to Java, he died suddenly of malarial fever. But his laborious work was placed in the hands of a worthy successor—Sir George King. It would occupy many pages to narrate even the more striking features of the subsequent achievements. Anderson acclimatised the plants in Sikkim; King made their cultivation and the manufacture of quinine a commercial success. Suffice it, therefore, to say that a department has been so organised that the Government of India have long since discontinued to import quinine; the hospitals have been given a limitless supply of the finest quality at less per pound than a few years ago it sold at per ounce, and lastly, by far the most remarkable accomplishment, packets of one dose are now sold in every Post Office, throughout the fever-stricken tracts, at the nominal cost of one farthing. This invaluable medicine has thus been brought to the very door of even the poorest peasant of India, and it is no wonder, therefore, that recurrent vital statistics mark year by year the steady conquest of India's greatest and direst scourge. Truly, therefore, may it be said of Lady Canning that she died to save others.

[ Cf. the following works, in amplification of the enumeration given in the Dictionary, may assist the reader to discover the fuller particulars which he may desire regarding the history, botany and cultivation of the Cinchona-yielding plants:—Lambert, Genera Cinchona, etc., incl. THE CINCHONA PLANT

Species, Varieties and Races.—There are about 30 to 40 species of Cinchona, and also numerous hybrids, varieties, and special cultivated races. Indeed so readily do the species cross and sport that it is impossible to grow two or more side by side and obtain from them uniformly pure seed. On this account grave doubts have been entertained regarding the specific values of many well-known forms. The commercial barks of to-day are obtained from about a dozen forms of which C. Calisaya and Ledgeriana are the most highly valued. To these would have to be added the special hybrid that appeared in Sikkim some few years ago, and is now spoken of as "the hybrid." The following brief abstract of the more important species may be useful:—

C. Calisaya, Weddell; The Calisaya Bark, Yellow Bark, etc. A very variable species with a trunk, when full grown, twice as thick as a man's body. Largely grown in Sikkim, at moderate elevations (1,500 to 3,000 feet), and one of the most valuable of all forms, but is difficult to cultivate. The seed of this form was originally sent to Europe by Weddell. It was raised in Paris in 1851 and one plant was presented to the Dutch, by whom it was successfully conveyed to Java; and in 1873 Dr. van Gorkum reported that it was the chief form grown in Java— its most important alkaloid being QUININE. It was the species Markham specially charged himself with the task of securing in Bolivia and Peru. But it has many varieties, one of which is of very special merit, viz:—

Var. Ledgeriana.—The story of the origin of this form is very interesting. Mr. C. Ledger was travelling in South America on behalf of Australia in search of an animal resembling the alpaca sheep. His servant mentioned to him that it was difficult for collectors to procure the seed of the finest quality of cinchona because of the suspicion in which all persons interested in that drug were held. Accordingly Mr. Ledger said he would like to get some of the best seed, and in due time he was supplied. This was taken to Europe and sold. The major portion went to Java, but a small quantity found its way to the Nilgiri hills and a still smaller portion to Sikkim. The Java seed yielded 20,000 plants, the Nilgiri either failed to germinate or was neglected and lost, and the Sikkim grew and in time became the parent stock of the plants in the present Bengal plantations. In 1880 Mr. Gammie reported of Sikkim that he had 10 acres under Ledgeriana, and last year's report shows that out of the total 3,306,763 trees in the Government of Bengal's plantations, 2,566,057 were Ledgeriana. This plant was subsequently introduced into the South Indian plantations, and flourishes well in the Wynaad at 3,000 feet altitude. It yields a high percentage of quinine, and is deservedly the most popular of all stocks. But it is comparatively a small tree, and the yield of bark correspondingly less than with the larger forms. In Java some of the richest stocks are never allowed to seed, but are grafted on to other seedlings of this variety, and the high-yielding forms thus carefully developed and conserved. The same plant taken to India will, however, yield less than half the regular produce in Java.
C. officinalis, Hook.; the Loxa or Crown Bark, the Pale Bark of commerce. This is a native of Ecuador and Peru, and with C. succirubra was the species assigned by Markham to his colleague Spruce to discover. It is grown at high elevations (above 7,000 feet) in the Nilgiris, Ceylon and Sikkim, but not extensively. It is a weak, straggling tree, attaining at most only 20 feet in height. Its cultivation in Sikkim has, however, been almost abandoned owing to the climate being too moist, but it is perhaps the most important of the species grown in the Nilgiri hills.

C. succirubra, Pavon; the Red Bark. This is largely cultivated on the hills of South India at altitudes of from 4,500 to 6,000 feet; at higher altitudes the growth is too small to make its cultivation profitable. On the hills east of Toungoo in Burma and in some parts of the Satpura range of Central India it is grown, and also met with in the Government plantations of Sikkim, but is not popular, and is rapidly being replaced by Ledgeriana. It is a hardy plant with a bold sturdy stem. In rich and sheltered situations it grows to the height of 50 feet or more. The leaves are bright apple-green in colour, the plantation in consequence looking light and bright while one of C. officinalis looks dark and gloomy.

CULTIVATION.

Climate and Soil.—None of the medicinal species will stand frost, though they prefer a cool climate in which the contrasts between summer and winter and between day and night are not very great. At Ootacamund, about 7,500 feet above the sea, the minimum lowest temperature in the shade is about 49° and the maximum 69° F.; at Neddiwattum, 2,000 feet lower, the minimum is about 54° and the maximum 66° F. In the Rangbi Valley, Sikkim, at 3,332 feet in altitude the minimum may be given as 40° and the maximum at 88° F. This might be spoken of as ideal for succirubra but rather cold for Cusisuya. A more congenial climate for both species would therefore be at an altitude of 2,500 feet. In the matter of humidity, the requirements of the cinchona were at first misunderstood. It has been found in the Nilgiris that all the species (particularly the red barks) withstand longer droughts than were thought possible. All the species assume a yellow tinge during the rains, and in the Nilgiris all make their most vigorous growth during the time when sunshine and shower alternate. In Sikkim succirubra makes most progress during the latter half of the rains, but both on the Nilgiris and on the Himalaya the plants continue to grow for two months after the rains cease. The rainfall of Ootacamund is about 44 inches, that of Neddiwattum 105 inches per annum. The rainfall of the Sikkim Plantations of Rangbi is about 166 inches. The species are impatient of stagnant moisture, and therefore require an open gravelly subsoil, a sloping exposure, and a rich loam (especially so if of volcanic origin) to dry clay soil. Accordingly they succeed better on recently cleared forest than on old exposed grassy lands.

Propagation.—They may be raised from seeds or multiplied by cuttings or layerings. The seeds may be sown in open beds of specially prepared soil shaded by a temporary roof, or in shallow boxes. The seeds should be sown somewhat thickly and sprinkled over with fine soil. They should be watered fairly freely, and in six weeks they will germinate. When the seedlings have got two or three pairs of leaves they should be transplanted.

of 1\(^{1/2}\) to 2 inches in breadth, the whole stem being afterwards swathed in moss. When the wounds have been barked over, the intervening bands are stripped off and the mossing renewed. This was invented by McIvor in the Nilgiri hills, and is now abandoned in favour of the shaving system.

All renewed bark, whether produced by shaving or mossing, is found richer in alkaloid than the original bark, so that the shaving process, being less troublesome and the cambium less liable to injury, has come into fairly general practice; and moreover the yield of alkaloid is higher by this than by any other method. It may, however, be added that the renewed bark is never so thick as the original, and therefore less in weight. It becomes accordingly a question whether coppicing is not, after all, the most profitable system. It is certainly the least troublesome, and if followed by systematic uprooting and falling off of the land, allows of complete renovation.

**Drying and Packing.**—As already indicated, the bark, by whatever process procured, should be dried gradually. In rainy weather this may have to be accomplished in specially prepared drying-sheds, or the bark may be quickly dried in special evaporators. Sun-drying is the best. According to the age of the plant, method of collection and drying, there are various grades of each botanical bark. Thus, for example, root-bark, quilt-bark (that from the branches), shavings, and lastly flat-bark (that from large stems).

Exposure to a high temperature or to prolonged action of direct sun's rays injures the bark. It is best, therefore, to bark the trees in dry weather, to dry slowly, to turn the pieces repeatedly, and to take every precaution to prevent moulding or fermentation. Once properly dried, the bark will keep indefinitely, or at all events for many months, without deterioration; but in drying, the loss in weight depends on the species and method of treatment—the average is usually from 70 to 76 per cent. of the fresh weight.

**PRODUCTION AND MANUFACTURE.**—To trace, even in the very briefest manner possible, the history of the discovery and the development of all the methods of manufacture that exist, would take many pages and involve a complete review of the chemistry of cinchona. [Cf. *Jour. Pharmaceut. Soc. Gt. Brit.; Journ. Soc. Chem. Indust.; Chemist and Druggist; British and Colonial Druggist; Pharmacog. Ind.*, etc., etc.]

In 1888 the Government of India published for general information the final results of the experiments conducted by Sir George King and Mr. G. A. Gammie that may be said briefly to have resulted in the perfecting of the oil process of manufacture now very largely pursued. This may be said to mark the turning-point of the Indian industry from that of experiment to commercial attainment.

**Area.**—The area under this crop has been seriously curtailed. In 1897–8 an official publication reviewed the then available information. It was ascertained that there were 4,346 acres under the crop, of which 98 per cent. were situated in Southern India. The Bengal portion was 1,394 acres, of which only 10 acres were not owned by Government. In the Madras Presidency, on the other hand, the State plantations represented but 800 acres out of the total 2,952. But during the twelve years ending 1897–8 the area had fallen from 14,491 to 6,833 acres, and there is reason to believe that a temporary expansion has since taken place. This
CINCHONA

Manufacture

THE CINCHONA PLANT

remarkable decrease is believed to represent the discontinuance and adjustment of Indian production as a private venture. The reasons usually given for this are the fall in price of quinine, the greater margin of profit in tea, coffee and other commodities, and the more successful production in Java and other countries. According to the Agricultural Statistics, the area in 1898–9 was 6,192 acres; in 1899–1900, 5,006 acres; in 1900–1, 4,903 acres; in 1901–2, 4,930 acres; in 1902–3, 5,260 acres; in 1903–4, 5,014 acres; and in 1905–6, 5,309 acres. Of these areas Bengal had an average of 1,400 acres, of which 70 to 100 acres were private plantations. The area in 1904–5 was 5,269 acres (1,800 acres in Bengal, 3,293 in Madras, and 176 in Coorg). Indirectly certain additional particulars may be learned from the study of the exports to foreign countries. For a good few years past these have fluctuated severely, but manifested a steady decline which more or less corresponds with the curtailment of private interests. In 1899–1900 the exports of bark stood at 3,290,236 lb., but in 1906–7 they had fallen to 494,587 lb., and were made exclusively from South India.

Government Plantations and Factories.—Turning now to the reports of the Government plantations and quinine factories, of which we possess more or less definite information, we learn that in Bengal during 1903–4, according to the report issued by Lt.-Col. D. Prain, the estimated total acreage is not stated, but the expansion is shown to have come to approximately 180 acres. It seems likely that private interests have not, however, materially increased, and that therefore the total area returned by Government in the volume of the statistics of crops may be accepted as representing the Government plantations, viz. 1,400 acres. If doubt exists as to the exact area the number of trees grown is systematically given, and from that a more trustworthy conclusion may after all be drawn. In 1903–4 there were 3,306,763 trees, of which 2,566,057 were Ledgeriana, 257,602 succirubra, 2,130 officinalis, while 463,075 were Hybrid No. 1., and 17,899 were Hybrid No. 2. These figures show an expansion on the corresponding numbers for the previous year that comes to 291,163 trees (practically the equivalent of the expansion of 180 acres). The crop taken from the plantations came to 316,757 lb. of dry bark, but to meet the necessities of the factory 461,467 lb. of bark had to be purchased and mostly imported from Madras. The manufactured products of the year came to 16,404 lb., which consisted of sulphate of quinine (12,314), sulphate of cinchonidine (290), and cinchona febrifuge (3,800). The Bengal factory by official arrangement supplies Bengal, Assam and the Panjab. The issues from the factory were quinine 12,021 lb., which included an increase during the year in the form of pice packets that amounted to 1,500 lb. The sales of cinchona febrifuge manifested a decrease of 976 lb., and the final working of the Department showed a net surplus of Rs. 66,320.

In the latest report for 1906–7, by Capt. A. T. Gage, which has come to hand since the above was written, it is stated that ‘‘the number of Cinchona trees of all sorts on the permanent plantations on March 31, 1907, was 3,698,777. Of this number 3,006,847 were Cinchona Ledgeriana, there being 1,770,521 on Mungpoo Plantation and 1,236,326 on Munsong Plantation. The remainder consisted of Cinchona succirubra and 77,283 of Hybrid No. 2—both mostly on Mungpoo Plantation.’’ ‘‘The amount of bark yielded by both plantations was 429,557 lb., of which

308
376,025 lb. were *Cinchona Ledgeriana* bark, and the greater part of the remainder Hybrid No. 1 bark. Of the *Ledgeriana* bark, Mungpoo supplies 286,994 lb. and Munsong 89,031 lb. "The total quantity of bark worked up in the factory was 798,500 lb., made up of 513,180 lb. of *Ledgeriana* and 85,320 lb. of Hybrid No. 1. The output of Quinine Sulphate amounted to 16,065 lb. 4 oz., being an increase of 287 lb. 8 oz. on last year's output." The manufacture of cinchona febrifuge was suspended for part of the year and only 2,652 lb. were produced; no cinchonidine sulphate was manufactured, so that the total output of the factory was 18,717 lb. 4 oz. The average yield of quinine sulphate in the bark supplied to the factory was 2-68 per cent.

Correspondingly the records of the Madras plantations and factory may be reviewed. The chief districts are the Nilgiri hills, Malabar, Travancore, Mysore and Coorg—but mainly the Nilgiris. Mr. Standen in his Annual Report for 1903-4 speaks of the old plantations having consisted of 832 acres and the new extensions as being 440 acres, a total of 1,272 acres. The production was only 116,289 lb. of bark as against 166,220 lb. in 1901-2, the difference being due to the policy of restraint in cropping during years of cheap private supply. But to meet the demands of the factory 431,185 lb. of bark had to be purchased from private producers. The issues from the factory during the year were 15,040 lb. of quinine and 3,359 lb. of febrifuge. The supplies go to Madras and Mysore, Bombay, the Central Provinces, United Provinces, Rajputana and Central India, Hyderabad and Burma. The net profit of the department during the year was Rs. 83,340, a highly satisfactory state of affairs.

**Net Results.**—Practically, therefore, the Government of India's endeavours to acclimatise the cinchona plant may be said to come to this; the annual imports of the drug on behalf of the Government have been discontinued; India has been given a liberal supply of an invaluable drug at a remarkably low price; the working of the two sets of plantations and factories have given lucrative employment to a fair number of persons; lastly a net profit has been secured of Rs. 1,39,660 a year (say £9,310)—a truly creditable record. Recently the Government of India took into consideration the desirability of lowering the price of the packets sold at the post offices. It has been resolved that in future seven in place of five grains shall be given for one pice (one farthing). This has had the immediate effect of increasing the demand, and the future must of necessity witness a considerable expansion both of production and manufacture.

**TRADE.**—It has been shown that the two Government factories in 1903-4 supplied between them 27,061 lb. of quinine to the hospitals, jails, post offices, etc., of India. In addition there was imported during the preceding five years an annual average of 54,000 lb. of quinine—chiefly from the United Kingdom and mainly into Bengal. In 1904-5 the imports were 68,648 lb., valued at Rs. 6,92,329, and in 1906-7, the latest year available, 71,237 lb., valued at Rs. 6,28,430. These are significant figures. They would seem to show that a successful industry might be organised by private enterprise, to meet the demands that create these imports. But it has to be recollected that in Java both the climate and soil are peculiarly favourable to the cultivation of cinchonas with a high percentage of quinine. Java will, therefore, always hold its own against India, and thus lessen the prosperity of any resuscitated industry. The indents on Government...
CINNAMOMUM
Cassia Ligneà

THE CINNAMON PLANT

production have for years been steadily increasing, so that the plantations hardly do more than meet half the requirements of the Government factories; but it is probable the extensions that have been made will reduce the demand on private production. In spite of past failures, however, there would seem every hope that the cultivation of the most approved varieties might be made a profitable adjunct to tea, especially in the Darjeeling district. The difficulty is to obtain suitable land in desirable situations. There would also seem every likelihood that private manufacturing establishments, to use up the bark presently being exported, might prove successful. India’s demand for quinine is great and increasing.

The exports of bark were 3,290,236 lb. in 1889–1900; 2,753,858 lb. in 1900–1; 1,917,259 lb. in 1901–2; 1,579,498 lb. in 1902–3; 1,108,527 lb. in 1903–4; 1,177,394 lb. in 1904–5; and 494,587 lb. in 1906–7. These went almost exclusively from South India and to the United Kingdom. There are said to be in the world 18 quinine factories: 5 in France; 3 in England; 2 in Germany; 1 in Holland; 4 in America; 2 in India, and 1 in Java. But the modern trade centres mainly in Amsterdam. The world’s demands for bark average from 14 to 18 million pounds.

D.E.P., ii., 317-26. CINNAMOMUM, Blume; Fl. Br. Ind., v., 128-36; Pharmacog. Ind., iii., 199–210; Gamble, Man. Ind. Timbs., 560–4; Prain, Beng. Plants, ii., 898; Brandis, Ind. Trees, 532-4; LAURACEAE. Gamble observes that there are about 24 species placed under this genus and divided into two subgenera, MALABARTHUM taking 20 and CAMPHORA 4 species. It is not intended in this work to discuss at all fully more than two of these, viz. C. Tamala and C. zeylanicum. A third species, C. Camphora, will, however, be found separately dealt with under Camphor (p. 245).

Cassia Ligneà.

Cinnamomum Cassia, Bl.—This is the plant which in China is regarded as affording the finest quality of Cassia Ligneà—the true Cassia bark of the ancients. A sample of this bark was lately sent from the Patkai mountains, on the frontier of Assam, accompanied by fairly satisfactory botanical specimens. These were critically examined by Prain and myself and compared with authenticated specimens of the Chinese plant. There would, therefore, seem no doubt that the best qualities of Assam Cassia are the true Cassia Ligneà of commerce. It is possible that to this circumstance is due the improved trade in the Assam bark. [Of Thiselton-Dyer in Journ. Linn. Soc., xx., 19-24; Pharmacog. Ind., iii., 203–8; Gildehouse and Hoffmann, Volatile Oils, 382–81.]

Nepal Sasafras.

C. iners, Retan.; the hmanthiin of Burma. This large tree is met with in the forests of Tenasserim and the Malay Peninsula. Its timber is one of the camphor-woods of commerce, and according to some writers the bark is one of the qualities of Cassia Ligneà. It would seem probable that much of the economic information given in the Dictionary and in other works on Indian economic botany, under this species, should be transferred to the C. zeylanicum of Western and Southern India. [Of Holmes, Pharm. Soc. Mus. Rept., 1895-1902, 54.]
MALABATRUM AND DALCHINI

From the root bark, as also the leaves, Rhede remarks, an oil was prepared and used as an external medicine. It would seem probable also that this plant affords the kala-nagkesar or immature fruits that are sent to Bombay from the Malabar forests. Clusius in his version of Garcia de Orta (Hist. Exot. Pl., 1605, 173) gives a picture of tamalapatra, in which he shows unripe flower-buds that closely correspond with the kala-nagkesar of modern commerce. They were probably in ancient times employed in flavouring the wine known as Hippocrates. It is hardly necessary to give the warning that they must not be confused with CASSIE FLOWERS (see p. 14). The CASSIA BARK of Malabar may also come from this plant, though it is doubtless mainly procured from the wild plants of c. seynianum. [Cf. Jonston, Hist. Nat. de Arbor., 1662, 164.] Marco Polo gives interesting particulars of the Cinnamon and Cloves of Yunnan which in some respects recall the traffic in the Malabar products. [Cf. ed. Yule, ii., 32, 35, 38, etc.]

C. obtusifolium, Nees; the ramezpat, kinton, bara-singoli, nupxor, pathhonda, dupatti, krowai, luwingyaw, etc., is an overgreen tree of the outer Eastern Himalaya, Eastern Bengal, Khasia hills, Burma, Andaman Islands, etc. It gives a TRINER said to be useful for boxes, planking, etc. The leaves are aromatic and used as a spice in place of those of C. Tamala and the bark is one of the trade qualities of CASSIA LIONEA, and after C. Tamala is perhaps the best known of all the malabar barks in India; it comes from Assam, Darjeeling and Nepal to Bengal and the United Provinces.

C. Wightii, Melian.; is recorded as met with in the Nilgiri hills. Holmes (loc. 55) mentions a sample of thick unscraped bark attributed to this species and sent from Ootacumund. It had a sharp taste recalling the flavour of nutmeg.

C. Tamala, Nees; Agri. Ledg., 1896, No. 38. The CASSIA LIONEA or CASSIA CINNAMON; the taj, kikra, kirkiria, sinkumi, chota sinkoli, nupxor, dopatti, tamdla, thitchabo, thit-kya-bo, zarnab (tree), talkspatri, taliha-pattiri, tajpat or tejpat, lavanga patte, dieng latyrpat (leaves), etc. The word tamdli occurs in the Raja Virghanta, and tejpat is apparently derived from the Sanskrit tvach. A moderate-sized evergreen tree of the Himalaya, rare from the Indus to the Sutlej, but common thence eastwards to East Bengal, the Khasia hills and Burma, between 3,000 and 7,000 feet.

Adams (Comment. in Paulus Ægineta, iii., 238) and other writers have identified the Malabathrum of the Greeks and of the Romans with the tejpat of India. There seems no doubt that the leaf of this plant has been traded in and exported from India for many centuries. The leaf is, in fact, a more important product than the bark.

History of CASSIA LIONEA.—Owing to the confusion which existed in former times with regard to the CASSIA barks, it is almost impossible to give a connected résumé of the history of any one of them. It may be observed that even in the heyday of the East India Company the "Cassia" products mentioned in their records are almost invariably of Chinese origin. Hence Milburn (Or. Comm., 1813, ii., 500), who gives a very clear account of the trade, both in the bark and the buds, warns traders against the coarse, dark and badly packed CASSIA LIONEA of Malabar. It is, however, interesting to notice that the most recent investigations show such a close connection between the Cassia trees of China and India that the former, which appears actually to extend into Burma and Assam, has been regarded by some authorities as a mere variety of the Indian C. Tamala. As already observed, recent specimens of Cassia Lionea leave no room for doubt that the better qualities of the Assam bark are derived from the true C. Cassia, 8th., and are, therefore, the genuine Cassia Lionea of the ancients and the bark which is so largely exported at the present day from Canton. Concerning the Indian CASSIA LIONEA—the taj—there may be said to be two localities of supply, and thus two main sets of qualities: (a) Western and Southern India—the bark of C. seynianum mainly, and (b) Eastern and Northern India and Burma, obtained almost exclusively from C. Tamala and to a small extent from C. obtusifolium and C. iners. Gamble suggests that the necessary forest regulations of Darjeeling may have interfered with or restricted the trade. [Cf. Malabathrum, Garcia de Orta, Coll., xxiii.; also Comment, by Ball in Roy. Ir. Acad., 3rd ser., i., 400; Foliium Indicum

Cassia Lionea.

History.

Two Chief Qualities.
CULTIVATION.—In The Agricultural Ledger (t.o. 3) particulars will be
found of the cultivation of tejpat in the Khasia and Jaintia hills. About
six square miles are said to be under the tree. It is usually found in
gardens or plantations of mixed jack and betel-nut palms. It grows
readily where there is heavy periodical rain followed by brilliant sun-
shine, but excessive and continued moisture injures the flavour of the
leaves. In the Khasia and Jaintia hills the trees are grown in regular
plantations seven feet apart; the seedlings are raised in beds, and
planted out permanently when the plants are five years of age. The
tree takes five or six years to grow, comes into bearing at ten, and may
continue to give annual crops for one hundred years. The cultivation is in
the hands of the hill-men. In Sylhet the trees are self-sown; the ripe
seeds fall from the trees into the soil and germinate. When the plants
are about a foot high they are transplanted. Great care is bestowed
upon them when they are young and tender. As constant exposure to
the sun would kill the shoots, they are planted behind bushes or trees
for protection. The undergrowth is kept down twice a year in the plan-
tations for the first eight or nine years; after that the jungle is cleared
once a year in April. In some plantations the soil is dressed, but in most
it is never manured or irrigated.

The tejpat and cinnamon trees are different. The former are only
used for their leaves, and no bark or only a small quantity is collected in
the Khasia hills. No information is, in fact, available regarding special
Cassia Lignea plantations, though a fairly large trade exists in the bark.

Collection and Crop.—“Tejpat is plucked in dry and mild weather,
from October to December, and in some places the collecting is continued
to the month of March. The leaves are taken once a year from young
trees, and every other year from old and weak ones. On an average 15
seers may be obtained from one tree, but the quantity depends upon cir-
cumstances; a tree yields from 10 to 25 seers of leaves in a year. The
average yield of leaf per acre in the Jaintia parganas is about 30 seers
without, and 2 maunds with, twigs. The whole of the crop from 400 acres
was worth last year as much as Rs. 1,100. The quantity of leaves from the
Sylhet district last year calculated on the turnover of the traders was
estimated at 14,470 maunds, and from the Jaintia district 20,000 maunds.”

“In harvesting the tejpat the small branches are cut down with the
leaves and dried in the sun for three or four days. The leafy branches
are then tied up into convenient bundles ready for the market. In the
other case, the leaves are separated from the branches and packed in
bamboo nets of a cylindrical shape called bora or jinéra, which are four
feet long by two feet in diameter. The packages are carried down the
ghaut roads of the hills by coolies to Sylhet.” Mukerji (Handbook Ind.
Agri., 1901, 437-8) says that for propagation seed had best be obtained
from Sylhet.

Uses.—The leaves are commonly known as tezpat or tejpat, but since
the Natives call the leaves of any species of Cinnamonum by that name
there is some uncertainty as to which particular species is meant in certain
localities. It appears probable that C. Tamala and its variety inter-
medium provide the tezpat of Bengal, the United Provinces and the Panjáb,
whilst *C. obtusifolium* to some extent supplements the Bengal supply and *C. albitorum* that of the Lahore bazárs. Gamble says that both bark and leaves of *C. Tamala, Nees*, and *C. impressivirum*, Meiss., are collected and exported under the same names and without distinction from the Darjeeling forests. The leaves of all these species are used in food, and also employed with myrobalans in dyeing and in the manufacture of vinegar (see p. 1110).

The outer layer of Cassia bark yields an Oil which is utilised in the manufacture of soap. Full details of the Chinese and other Cassia Oil may be obtained from Schimmel & Co's. *Reports* (April-May, 1903, 16; April-May, 1904, 18-23, etc.). No oil is distilled from these barks in India. Both bark (*taf*) and leaves (*tejpát*) are employed in Medicine, the latter being commonly identified with the "Folia Malabathri," or "Indian Leaf," which was held in great repute by the ancients. But when the bark is used instead of cinnamon great care is necessary to ensure its not being adulterated with the injurious barks of several species of *Litsea*. *[Cf. Rept. Cent. Indig. Drugs Comm., i., 126.]*

A fairly large tree, native of Western and Southern India, Tenasserim and Ceylon; in the last-mentioned country it is extensively cultivated for its aromatic bark. There is no evidence of the economic cultivation in India of this tree, though it is occasionally planted as an ornamental and useful bush in Bombay, Madras and Bengal. As a wild tree, however, it is plentiful in Western and Southern India from the Konkan southwards, rising on the slopes of the Ghats to 6,000 feet in altitude.

**History.**—It is somewhat significant that while García de Orta (1563) gives full particulars of both the Malabar and Ceylon industry and speaks of the plant in the former as plentiful and wild, subsequent writers should have ignored this fact and confused the whole subject. Rheede figures and describes two forms of *Cinnamomum* as met with in Malabar. These are doubtless the *C. zeylanicum*, Breyn, and *C. macrocarpum*, Hook. f., discussed by Talbot. Is this the Camphor-wood called *Bhimsini* alluded to as a lofty tree of the Ghats by Abul Fazl in the *Ain-i-Akbari* (1590, 79) and by Kirkpatrick (*Letter of Tipoo*, 1786, 231)? Many cinnamon timbers are described as "Camphor-woods," and might easily have been thought to be obtained from the camphor tree. The name *lavanga* it will be seen is also given to the Clove (which see, p. 527) as well as to the Nutmeg (see p. 791), and perhaps points to the time when these plants were not separately recognised.

In India various barks, as also twigs with their adhering barks, are sold as *Cassia Lignea* and *Cinnamon*. But we are hardly more able to distinguish these than were the 16th and 17th century writers. Ceylon bark was historically the first to be known. The finest qualities were moreover said to come from China and the less valuable from Malabar. Cassia bark appears to have been known in China from about 2700 B.C. Malabar Cassia is mentioned by Strabo (A.D. 17) and in the *Peripius*, A.D. 63 (ed. McCrindle, 18). In most of the classic works of India and Arabia a bark is alluded to that can only have been Cassia Lignea or *Dár (dal) Chini*. It is in Sanskrit known as *tvech* and *guda-tvech* (= sweet-bark). But it is in comparatively modern times only that Ceylon cinnamon appeared in the markets of the world. García de Orta speaks of the Malabar as wild, thus leaving the inference permissible that Ceylon was cultivated (see below under Trade). He tells us that the Chinese traders exchanged their merchandise for the spicx barks of Ceylon and Malabar and carried these to Persian and Arabian ports. He suggests that the name *dárchini*, given to these barks, took its origin from this circumstance. García would thus seem to have been unaware that cassia bark was also well known in China and hence the Chinese may have only purchased
## THE CINNAMON PLANT

### Cinnamon

**Arab Influence.**

The Indian as a cheaper quality than their own. The Arabs, through whose hands much of the cinnamon passed, called it *kirjat-ed-dareini*, a word corrupted into *kijah* and which survives as *kaifah*, the name given to-day for the commercial bark of Malabar. Garcia observes that the Chinese, in order to enhance the value of the bark sold by them, gave it mythical names and stories. Strabo speaks of cinnamon growing in South India—at the beginning of the torrid zone. The name cinnamon is thus considerably older than the time of the Chinese trade with India and was, in fact, intimately associated with the very earliest Arab dealings.

The systematic cultivation in Ceylon does not appear to have been undertaken much before the Portuguese and Dutch conquests of the island (De Candolle). It became a State monopoly, and, as Garcia de Orta tells us, rose in price very greatly in consequence. The most stringent and cruel laws were instituted to protect the monopoly, which, on the island passing over to the British in 1796, were mitigated and finally in 1833 the cultivation was made free and thus ceased to be a State monopoly.

### Cultivation

**CULTIVATION AND PREPARATION.**—The following account of the propagation, cultivation, and method of preparing the bark is mainly an epitomised and annotated version of Nicholls’ article (*Textbook Trop. Agri.*, 190–3), and is therefore not a statement of any South Indian industry, for in fact none is known to exist.

Although in its wild condition it grows to a large tree, the plant exists under cultivation as a coppiced bush. It is cut down to the ground at about the sixth year, when straight shoots spring up to be again cut down two years after, and in time the stools become of great size. The straight shoots are mentioned by all the early writers and are figured by Jonston (*I. c. t. liii.*).

The best soil, says Nicholls, is a sandy loam mixed with humus, but the tree will grow in the tropics on almost any soil, though unsuitable soils and climates produce inferior bark. Plants may be raised by cuttings, layerings, or by ripe and fresh seed. The usual way is to plant the seed out in the fields, at distances of 6 or 7 feet apart; the ground being well broken up, and wood-ashes mixed with the soil. Four or five berries are sown in each hole and branches of trees are laid on the ground to protect the seedlings from the sun. But if dry weather follows germination, which takes place in from two to three weeks, many of the seedlings may perish, and it will in consequence be advisable to have a reserve of plants raised in nursery-beds to fill up vacancies. After the plants are established, little more cultivation is needed than to keep the ground free of weeds. By the sixth year the first shoots can be cut, when two or three will usually be 5 or 6 feet high, and in a condition for peeling. Two years afterwards the shoots that grow up after the first cutting may be reaped.

**Preparation.**—The shoots are cut off and the tops removed so that they are left from 3 to 5 feet long. The leaves and side branches are cleared and two longitudinal slits made with a sharp knife, one on each side of the shoots. When the cutting has taken place in rainy weather the bark comes away easily, but as a rule it is necessary to rub the sticks firmly with a piece of smooth wood, such as the handle of the knife; the rubbing helps to disengage the bark. The pieces of bark thus separated, after an hour or so, are put one within the other, collected

into bundles, pressed, and bound together. They are then left for a day or so, until a slight fermentation sets in, which allows of the scraping off of the epidermis and the pulpy matter underneath, by means of a curved knife. The barks are then put together as before, but cut into lengths of about 12 inches, placed on wickerwork platforms, and left to dry in the shade until the second day, then finished in the sun. As they dry they contract into the appearance of quills, hence that name was given to them. The dry spice is made up into bundles of about 30 lb. each, and three bundles are made into a small bale. The bark of the larger shoots cannot be made into quills, but is removed in thick pieces and sold with the bark of the prunings as "chips," which fetch a low price owing to inferior flavour. The estimated yield per acre is said to be 150 lb., but might probably be increased by high cultivation. The true cinnamon, it may be added, is very commonly adulterated, especially in powder form, with the Cassia Lignea discussed above.

Oils.—Three Oils are obtained from C. zeylanicum: the bark yields essential oil of cinnamon, to the extent of \(\frac{1}{2}\) to 1 per cent.; from the leaves is expressed a brown viscid essential oil, sometimes exported from Ceylon as "Clove Oil" (it has a somewhat similar medicinal value to the true oil of cloves); and from the root a yellow oil which is specifically lighter than water and has a strongly camphoraceous flavour. In their report for April—May, 1904, Schimmel & Co. discuss several reactions for distinguishing between Ceylon cinnamon oil and cassia oil, with which the former is not infrequently adulterated. [Cf. Gildemeister and Hoffmann, Volatile Oils, 1900, 377-92.]

**TRADE IN CASSIA AND CINNAMON.**—Cassia Lignea.—In Official Statistics returns are given of the imports from foreign countries and of the portions of these re-exported, but no mention is made of the exports of Indian-grown Cassia Lignea. On the other hand, under the name Cinnamon, returns are given of Indian-grown bark from Madras and Bengal, but no mention of Bombay. It would seem probable that these exports of Indian Cinnamon are, in reality, the exports of Indian Cassia Lignea. Regarding the Imports of the bark a slight increase is noticeable, viz. from 20,014 cwt., Rs. 5,41,135, in 1899-1900 to 24,075 cwt., Rs. 6,01,906, in 1902-3, and to 23,421 cwt., Rs. 6,92,559, in 1906-7. The most noticeable features in these imports are the extreme fluctuations in the trade from Hongkong (15,024 cwt. in 1899-1900 to 6,173 cwt. in 1903-4, and 10,955 cwt. in 1906-7), and the corresponding expansion in the traffic from Chinese treaty-ports. There was also a considerable increase (45 per cent.) in the imports from the Straits Settlements up to 1903-4, when the quantity imported was 5,795 cwt., but since then this has fallen to 467 cwt. in 1906-7. Three-fourths of these imports are taken by Bombay—the great Indian emporium in the drug trade. There is also a re-export which usually amounts in quantity and value to about one-fifth of the receipts. The chief countries to which the drug is re-exported are Persia and Turkey-in-Asia.

The bark known as kalfah (to which reference has been made) is imported by Bombay town, coastwise from Malabar, and is apparently used to adulterate the Chinese bark. It sells at about Rs. 5 per maund of 37\(\frac{1}{2}\) lb., or say 2\(\frac{1}{4}\) annas a pound. According to the *Report of the Central Indigenous Drugs Committee* (1901, i., 119), the price of Chinese
CITRULLUS VULGARIS

Water-melon

Cassia is from 3 to 5 or even 8 annas per lb., according to purity. [Cf. also Mus. Rept. Pharm. Soc. Gl. Brit., 1895-1902, 48-56.]

**Uses.**

The uses of cinnamon bark and oil, both in food and medicine, are sufficiently well known to render description unnecessary. In India and Ceylon cinnamon is largely replaced by 

taj or kalilah

barks. The position of the Ceylon cinnamon with India may be judged by the fact that the imports are unimportant, and moreover low-priced, so that it may be said there is hardly any demand in India for the fine qualities. But, conversely, the exports from India to Ceylon, of locally produced cassia bark or cinnamon, seem of expanding importance. This traffic was 5,393 lb., Rs. 2,530, in 1899-1900; 26,686 lb., Rs. 8,221, in 1903-4; and 21,040 lb., Rs. 7,697, in 1906-7. It goes mainly from Bengal and Madras and to a small extent from Burma. As already stated, there is no evidence whatever of any economic cultivation of

C. zeylanicum

in India, and the bark exported as cinnamon must therefore be Cassia Ligneae, or at most wild cinnamon, the collection of which in N. Kanara is mentioned both by Talbot and Dymock as important. It may be here added that so long ago as 1687 Thevenot (Trav. in Levant, Indostan, etc., pt. iii., 109) speaks of wild cinnamon in Cochin.

**Value.**

**CITRULLUS COLOCYNTHIS, Schrad.; Fl. Br. Ind., ii., 620; Duthie and Fuller, Field and Garden Crops, 1882, pt. ii., pl. 57; Pharmacog. Ind., ii., 59; White and Humphrey, Pharmacop., 1901, 145-6; Cooke, Fl. Pres. Bomb., i., 537; Duthie, Fl. Upper Gang. Plain, i., 374-5; CUCURBITACEAE. The Colocynth, indrayan, mákal or mukhál, khárutama, tuh or karva-tu, gháríumba, tráná deda, henzil, kiyaí, etc. A creeping or climbing herb found wild in the waste tracts of North-West (Sind, Dera Ismail Khan, Multan and Bhawalpur, etc.), Central and South India; indigenous also in Arabia, Western Asia, Tropical Africa and the Mediterranean region.

The fruit (the “wild gourd” of 2 Kings, iv., 39) is in size and shape much like an orange, marble-green on the surface and changing to yellow as it ripens. The fresh fruit is sold by the herbalists of India, being collected from wild supplies. To meet the requirements of the Medical Depots an effort has been made to cultivate it specially at the Saharanpur Botanic Gardens. The intensely bitter taste of the pulp is due to an amorphous yellow glucoside, colocynthin, which is found in it to the extent of about 0.6 per cent., but not in the seeds. The fruit is a drastic purgative, and is so used both in Native and European Medicine. The Indian extract is in fact quite as active as that of the European drug. The yield is about 110 lb. compound extract to 60 lb. dried fruit.

The seeds contain from 15 to 17 per cent. of a fixed oil, which is said to make a useful illuminant, but though inquiries were recently instituted in Sind and other localities, no one could be discovered who was in the habit of using the seeds in any form. For the London market the peeled fruit is imported chiefly from Smyrna, Trieste, France, Spain, and more rarely from Persia. The unpeeled fruit is brought from Mogador. The Indian fruit has a much thinner pulp, which cannot be separated from the rind. According to the authors of the Pharmacographia Indica, large parcels, collected and dried up country, come into market in December to January and are sold at about Rs. 1 per 100 fruits. [Cf. Rept. Cent. Indig. Drugs Comn., 1901, 154; Dowzard, Pharm. Journ., Sept. 12, 1903.]

hinderwa, kalingad, kalangari, karigo, pitchaplum, etc.; pateca, Portugese, and baticc indi (battik) Persian. It appears to be the Anguria of many ancient herbalists and travellers, and the bathice, botice, bitar, etc., of the Arabs. It is the abattichim (melons) sighed for by the Israelites after the exodus.

An extensive climbing annual, cultivated throughout India and all warm countries. It is supposed to be indigenous in tropical Africa. It is usually sown in January-February, the fruit ripening in the beginning of the hot season. In the United Provinces a special form, known as kalinda, is sown in June and ripens in October. In Western India (Sind more especially) the water-melon is a kharif crop mainly. Very frequently grown on the sandy beds of rivers, where plenty of room and a copious supply of water are available. Mention is often made, by writers on this subject, of a special form grown in Bikanir on almost pure sand, the fruits being often practically underneath the sand. There are thus doubtless many cultivated conditions or states, that vary in the colour and flavour of the pulp, and season and locality of production. The wild plant may be either bitter or sweet without any observable structural differences. The bitter form (C. amarus, Scharad.) comes very close to C. Colocynthis, when that species is cultivated. The bitter water-melon is in Sind known as kirbut and is used as a purgative medicine.

The water-melons of the Upper and Central Provinces are the best. They are extensively employed in the preparation of sherbets. The seeds yield a limpid oil used both as an illuminant and in cooking. In times of scarcity they are pulverised and baked into bread. In medicine, they are in considerable demand on account of their cooling, diuretic and strengthening qualities. Var. fistulosus, Stocks; Duthie and Fuller, l.c. pt. ii., pl. 47; the tandus, tendu, tensi, tinda, meho, alvinda, titak, etc.

This seems a peculiar form fairly local and much less known than the preceding. Chiefly met with in the United Provinces, Panjab and Sind, where it is specially designated dilpasand. Cultivated along with other melons from April to October, and eaten as a vegetable, not as a fruit, being cut into sections, the seeds removed, then boiled in water, next in milk. Cut into still smaller pieces it is cooked in curry, and also fairly largely pickled and candied. It is in much demand both by Muhammadans and Hindus, but appears as a rule unknown to Europeans. The seeds are used medicinally. They are also dried and eaten parched.

Production in the Tropics.
and the Pomelo constitute a tropical assemblage of fruits in many respects comparable with the apple, the pear, the peach, the plum and the cherry—a temperate series—though the former are infinitely more valuable than the latter, because more widely cultivated and more extensively used. Moreover, since the orange is consumed very largely in temperate climes, cultivation in the tropics has to be made on the basis of the foreign as well as the local demands, so that oranges, lemons, etc., have become regular articles of trade all over the world. Until very recently Europe obtained its supplies of these from the warm temperate tracts of South Europe itself and from the islands of the Mediterranean and the Atlantic, adjacent to Africa. For some years the quicker transit of steam navigation has permitted supplies to be drawn from a greater distance than formerly, and both Europe and America have, in consequence, come to be very largely supplied by the West Indies. The great success recently of the fruit trade of these islands has given a useful suggestion of India's possibilities. There would seem every chance that a large trade may in the future be done in exporting some of the fruits of India to Europe, more especially the thin-skinned Bombay pomelo. [Cf. Ferrari, Hesper., 1646; Jonston, Dendr. Hist. Nat. de Arbor., 1662, 10-27, pl. vi-xviii.; Commelny, Hesper., 1683, 1-47; Salmasius, Plin. Ezer., 1689, 666-77; Lecomte, Beschr. Keyser. History.—So much has been said on the history of the species of Citrus in the works above indicated, that it seems almost superfluous to attempt a review of the more interesting particulars, except such as have a practical bearing on India. The Sanskrit and Chinese records of the properties and uses of these plants carry our knowledge back to a time prior to the first mention of the European tradition of the Garden of Hesperides, with its golden-coloured and beautiful fruits, whatever these may have been. [Cf. Susruta, Ayurveda, (d'Hanvautare) ed. Hesaler, 1844, iii., 179.]

It seems fairly certain that the citrus fruit had been carried to Europe by traders long before the attempt was made to cultivate the plant there. It was valued as a perfume and also used to protect clothes from insects. Pieces of certain imported coniferous woods were similarly so employed, and the Romans appear to have supposed that the fruits brought from Media were those of the self-same plant as the scented cedron wood. There can be little doubt, therefore, that the modern word Citrus was derived from Cedron and owes its origin to the circumstance mentioned.

Theophrastus (about 330 B.C.) calls it the Malum Medicum or Malum Assyriam, and thus may be viewed as confirming the early traditional source of the Citron. But he speaks of it as raised from seed sown in vases and seems to be alluding to that instance from hearsay, as the practice with the Medes, rather than to be narrating a custom followed by the Greeks. There is, however, an amusing story contained in a fragment of the comedy of the Antiphanes, quoted by Athenaeus, which, if it can be trusted, would suggest a possible much earlier cultivation in Europe than can be established by direct historic facts. So again the compilation known as the Geoponica (prepared in the 10th century) is supposed to be quoting certain authors who describe the cultivation of the citron several centuries before Christ, but here again it is perhaps hardly desirable to put much confidence in these writers. It may thus be affirmed that
LIME AND POMELO

direct evidence of cultivation in the gardens of the Romans does not exist prior to the first century of our era.

Palladius (De Re Rustica, iv., 10), who lived possibly about the fifth century (A.D.), narrates the methods pursued by him in cultivating the plant in his Sardinian and Neapolitan possessions, so that its cultivation in Italy by the 3rd or 4th centuries may be accepted as having been fully established, though for many centuries the progress made in Europe was but slow, down to the 11th or 12th centuries.

It may be said that while the orange is indigenous to China, and the limes to India, that the citron originated very possibly in Persia and Media, while the lemon is so closely associated with the Arabs as to suggest its having come from Arabia. The Arabs, at all events, carried its cultivation to Africa, Egypt, and Europe. In the 10th century, for example, we read of them conveying it from the gardens of Oman to Palestine and Egypt. So also it is generally accepted that the fruit held in the hand by the Jews during the Feast of Tabernacles has for many centuries past been the citron. Risso has, however, produced evidence which he thinks goes to show that the Hebrews did not very possibly know the citron much before the beginning of the Christian era, hence he contends that it was very likely not the fruit so used by the early Jews. Other writers have, however, maintained that the Jews were scarcely likely to have changed the symbol and yet retained the ceremonial. And it is, moreover, well known that a close relationship subsisted for many centuries between the Hebrews and the people of Media and Persia, so that there is no reason why they should not have known of the citron long before the Romans. There is, however, a long interval between the first European classic references to the plant and the detailed accounts of medicinal and horticultural writers. To bridge over this gap, Loret assumes a knowledge in these plants, possessed by the Arabs, Jews and Egyptians, very much more ancient than the earliest historic record. For example, the earliest Arab and Persian writers who knew of the citron and lemon are:—Serapion (De Simpl., i., 1) and Rhases (Cont., i., ult. i., 219), who describe the former, while the latter is alluded to by Ibn Baithar. Avicenna (De Med., ii., 2, 116, 433)—the author most frequently cited—apparently confused these plants. [Cf. Paulus Aegineta (Adams Comment.), 1847, iii., 472.]

The orange was not known until much later than the citron or lemon. Targioni-Tozzetti tells us that it was conveyed from India to Arabia about the 9th century. We have no knowledge of its having reached Europe for a couple of centuries later, when it seems to have been carried by the Moors to Seville. In the 13th century we read of its cultivation at Palermo and Rome. But, according to the most generally accepted opinion, the bitter orange reached Europe before the sweet. Lecomte says that the Portuguese claim to have taken the sweet orange from China to Portugal somewhere about 1545.

It is remarkable that many of the Indian authors, who might be expected to afford useful historic particulars regarding the citron, lemon and orange, are silent regarding these plants. Marco Polo makes no reference to them, but Varthéma (Travesle, ed. Hakl. Soc.), 1863, 190), who in 1510 visited Cananor and subsequently Ceylon, speaks of the sweet oranges (melangoli) of both places, and says of Ceylon that they were the finest in the world. Vertomannus (Voy., in Hakl. Voy., 1811, iv., 577), a gentleman of the city of Rome, who also visited Cananor and Narsinga in 1508, says the "soyle beareth neyther wheate nor vynes, or fewe other fruites, except Oranges and Gourdes." Baber (Memoires, 1519 A.D., 327-9) mentions nine different kinds of Citrus, as known to him. This is the earliest complete statement regarding Indian cultivation. The Ain-i-Akbari, written 1590, amplifies some of the particulars given by Baber, but adds nothing very material. [Cf. Blochmann, transl., i., 69; also Jarrott, transl., ii., 124.] The Emperor Akbar, we are told, encouraged the cultivation of all fruits and brought expert gardeners for that purpose from Persia and Tartary, who doubtless carried to India with them all that was good and desirable in the way of new fruits from their own countries. Linschoten (Voy. E. Ind. (ed. Hakl. Soc.), 1598) makes frequent mention of the oranges, lemons, etc., of India, Ceylon and other countries visited, but in such language as to imply that his readers knew everything about them. Rhede, wild on the other hand, who, in 1686, figured and described the plants of Malabar, and thus practically of Cananor, makes no allusion to the orange or the lime, while Herbert (Travesle, 1677, 333) speaks in the highest terms of the oranges and lemons of Mangalore: in the case of the oranges, "the rind," he tells us, "was no less pleasant than the juice." A century or so later, Rhede and Herbert were followed by Rumphius, who gives a full description of several
THE BITTER AND SWEET ORANGES

CITRUS AURANTITL
Orange

oranges, lemons and pomelos. One or two of these he speaks of as wild. The sweet orange, however, he regarded as a native of China, but adds, "some consider it a native of Amboina." Numerous writers refer to the efforts made in India to improve and increase the orange and lemon supplies of that country. There need, therefore, be little cause for surprise that the oranges of Cintra should have reached India even before Baber's time. Dr. Hunter long years ago suggested that the name for one of our best-known forms of orange, viz. *sengtereh* (of Baber) or *santara* (as it is nowadays called), was but a Hindustani corruption of Cintra, thus indicating its having been brought from Portugal. The name *aurantium* given by botanists to the orange does not come from *auram* gold, but is derived from the Arabic *nárandi*. This became *nárando* (narang) in the Persian, and its equivalent in Sanskrit is *nágaranga* and in the Hindustani *nárangi*. Names that begin with *nur* generally denote fragrance. The name orange came to English through the Moors, and became *nárando* in Spanish, *tarango* in Portuguese, *arancio* in Italian, *orang* in French, *orangenaum* in German, and the like. [Cf. Ligon, Hist. Barbados, 1657, 69; Terry, Travels E. Ind., 1665 (ed. Havers), 343; Ovington, Voy. Suratt, 1689, 423; Le Comte, Mem. de la Chine, 1696, i., 173; also Bretschneider review, Hist. Europ. Bitter.

The bitter (or Seville) orange, though sometimes spoken of as indigenous to India, is there very little cultivated. The so-called wild, or perhaps only fully acclimatised plants that have been recorded as met with, are botanically nearer the sweet than the bitter (or marmalade) orange. It seems highly probable, on the other hand, that at least some of the forms of the Sweet Orange came to India via Assam, the route along which many other Chinese plants have passed westward into Hindustan. There may be said to be four or five chief centres of Indian orange production:—Sylhet in Assam; Nagpur in the Central Provinces; the lower ranges of the Eastern and Central Himalaya (Sikkim, Nepal, Garhwal and Kumaon); Delhi in the Panjab; and the Deccan and South India (Poona, Coorg, etc.).

Bonavia speaks of four chief races of this fruit, viz. (1) the Santara (a word which he writes "Suntara" and regards as of Sanskrit origin and not (as stated above) a corruption from Cintra); (2) Keonla, or the common naringi, produced here and there all over the country in gardens, not special plantations; (3) the Malta or Portugal—the blood-orange, introduced in 1852 and now fairly successfully produced at Gujranwala and also in gardens at Lucknow; and (4) the Mandarin of some writers (*C. nobilis*, var. *major*), a native of China and Cochin-China and the Tanjerine (*C. nobilis*, var. *minor*). Both these are occasionally met with in gardens but can hardly be regarded as important Indian fruits, although one of them appears to have been crossed with the santara in producing an orange commonly met with in some parts of the Deccan and South India, which is sometimes called "Indian Mandarin."

The santara or sungtura (nagaranga of Sanskrit) is by far the best

320
quality, and may be said to be distinguished by its yellow colour and loose skin or jacket. This is the orange of the special Indian plantations where orange-growing becomes an important industry. But there would appear in India to be several very distinct forms of the santara, due very possibly to peculiar methods of cultivation or special climates. The distribution of the races of santara orange might be given as follows:—
in the north, Nagpur, Delhi, Alwar, Gargao, Lahore and Multan; in the west and south, Poona, Shevaroy, Madras, Coorg and Ceylon; in the east, Nepal, Bhutan, Assam, Khasia and Burma.

The Sylhet or more correctly the Khasia orange is the best of the series, and it may be described as the fruit known in Europe as the China orange. One of the most useful papers on this subject is that by C. Brownlow (Journ. Agri.-Hort. Soc. Ind., 1869, 372, briefly reviewed in the Dictionary). The Sylhet orange, he says, is invariably raised from seed, and the plants come into bearing in four to six years. It is believed that the seedlings do better than grafts or buddings, though the latter come sooner to maturity and afford a more uniform quality. When grafting is pursued the stock usually employed is the lime, and some say the wild plant is preferable to the cultivated.

Since the present article was penned, B. C. Basu has contributed (Agri. Journ. Ind., 1906, i., pt. i., 62–7) a most interesting account of the Khasia hills orange and its cultivation, for which space can only be found for the merest abstract. The area where produced, he observes, is comprised within one hundred square miles. The plantations commence on the plains and rise to an elevation of 1,500 feet. The gardens extend thus for some distance into the interior along the deep valleys which cut up the southern face of the Khasia hills. From that narrow tract of country is drawn the bulk of the oranges consumed in Bengal and Assam. The great earthquake of June 1897 destroyed, however, a large number of the orange gardens, many of the most productive of which lay on the banks of the hill streams and owed their fertility to the silt left by the annual floods. The orange is said to do best on limestone soil. The Khasia people recognise only one variety, though they admit a wide range in quality exists—dependent mainly on soil and the aspect of the garden. The special merits of individual plants are not perpetuated owing to the almost invariable habit of raising stock from seed. The fruits with thick rind are preferred even though the pulp is less juicy, because they stand handling better. So also late ripening is advantageous in point of price.

Basu's account, it may be observed, differs here and there very slightly from that given by Brownlow. Seedlings, he says, are transplanted when two or three years old, and during May and June. A hole is made and the young plants deposited at distances approximately of 10 feet apart. Manure is never used. By the end of the rains a number of shoots have usually formed, and in time one of these is preserved, and the rest, as also the parent stem, removed. The plants begin to bear in eight to ten years and the duration is uncertain owing to the ravages of the borer insect, which destroys large numbers of plants annually. The orange season commences in November and closes in March. The export sales in the hands of Bengali traders, who mostly live in Sylhet, hence the orange being often spoken of under that name. The usual wholesale price is from Rs. 10 to 20 per "hundred," equivalent to about 2,500 fruits. The supply intended for Bengal is taken down to Chhatak. If carefully

arranged on a trellis, no two fruits being allowed to touch each other, and then suspended from the roof of the house, the fruit may be preserved for months.

This orange is conveyed by boat to Calcutta, where it is sometimes spoken of as kamlá-nebu, from which circumstance Prain thinks it may be inferred the orange was derived from the kingdom of Comilla to the east of Calcutta, and not from Upper India. There is but one complaint in Bengal against the present supply, namely that it comes in the cold in place of in the hot season. This has led to numerous efforts, with indifferent results, to obtain a second supply of equal merit from other localities. In Kullu, for example, the fruiting season is much later, and an effort has accordingly been put forth to send supplies to Simla in April and May.

Nagpur.—Mr. J. H. Stephen, Superintendent of the Government Botanic Gardens, Nagpur, published in 1899 an instructive account of the production of oranges in the Central Provinces. Mr. A. Ross, in a letter published in Firminger (l.c. 277), furnishes other particulars of interest. Stephen inspected several large orange plantations and found that where carefully cultivated and liberally irrigated the trees were healthy and fruited freely; where neglected, the yield was so low that the gardens were not remunerative. In every instance the plant grown was the Nagpur suntra budded on the sweet lime. This is believed to produce a thinner skin and a sweeter and more juicy fruit than when budded on the citron or jambiri. The Sylhet system of raising from seed seemed nowhere to be followed, because it is believed that such plants take from fifteen to twenty years to come into bearing. The lime is sown in January to March, and when a year old the budding of the orange is made on the seedlings. They mature in the sixth or seventh year, and in about nine to twelve years are in full bearing; after that date they decline. In Nagpur the orange yields (or can yield) two crops a year. The plants flower in February to March, and the fruit is ripe in November to December or January. The second flowering is in June to July, and the fruit ripens in March to April. The oranges of the second crop are the sweetest, and coming as they do at the beginning of the hot season, are much valued. These are plucked green, and thus are rarely allowed to change into the characteristic yellow colour of the other crop. On this account some writers have regarded them as being bergamot oranges.

About the middle of May the roots are exposed and the plants manured (according to Ross, the roots are exposed and the manure given in October). Pruning is unknown in the Nagpur groves, and, except to be watered freely in the hot season, the plants receive little or no further attention. R. S. Joshi, Rai Bahadur, has just published an account of the orange cultivation of these provinces (Agri. Journ. Ind., 1907, ii., pt. i., 64–9) which will be found to richly repay perusal. In the details of cultivation he makes, to all intents and purposes, the same facts as already exhibited. He urges the necessity for high cultivation, especially on soils with a liberal supply of lime, and reaffirms belief in budding. “The stock generally used,” he says, “is the sweet lime (mitha nimbu), but the common citron (zamburi) is also very often utilised. Buds of the orange grafted on the latter stock produce trees which yield fruits with a very loose skin, whilst those on the former stock have a more closely
adhering jacket, showing that the stock has a distinct influence on the bud. The loose-jacket oranges are preferred for local consumption but are not so good for export, as they do not stand carriage well. Trees raised from citron stock come into bearing more quickly and have a somewhat longer life, but the fruit from the sweet lime is sweeter and has a thinner skin."

Speaking of the diseases of the orange, Joshi says that in Nagpur the most serious is caused by a fungus which results first in the withering of the tips of the branches, the rot gradually extending down till the whole tree is destroyed. The produce of the Nagpur gardens goes mainly to Bombay, but recently Calcutta has drawn on the Central Provinces. If the late crop could be made a special feature, it seems probable the Nagpur supply would be much appreciated by Bengal.

**Delhi.**—The oranges of this locality are inferior to those of Sylhet and Nagpur. The rind is thick and the juice relatively poor, both in flavour and quantity. The supply of the so-called Delhi orange, which, in addition to meeting the local markets of the United Provinces and the Panjáb, is to some extent drawn upon by Bombay, comes from the neighbourhood of Delhi itself and from Gargaon, Saharanpur and Alwar, etc. Nepal, Garhwal and Kumaon produce small but sweetly flavoured *santara* oranges. Dr. Bonavia tells us that the sweetest orange he ever tasted was grown in Nepal.

**Poona.**—Woodrow wrote a useful report of the orange cultivation of Western India which was published by the Director of Land Records in 1890, and subsequently epitomised and amplified by Cooke. In addition to the *santara* orange, the *lādu* of the Deccan is largely produced. This has often a malformation in the form of a supplementary series of pips near the apex. The Mozambique orange and also the Mandarin, or what is so called (*lāl lādu*), are frequently met with. Indian Mandarins are good to look at but inferior in flavour, and, as already observed, the *lāl lādu* is probably only a hybrid Mandarin.

The *Coorg, Mysore and Nilgiri* oranges are much spoken of, and constitute the chief supply of the city of Madras. The Coorg is the form most in demand. It seems a cross between the ordinary *santara* and the Maltese. Mr. Gustav Haller (*Agr. Journ. Ind.*, 1906, i., pt. ii., 127–9) has very recently written a useful account of the "Orange Cultivation in Coorg." The method of cultivation he speaks of as very simple. Seeds are sown in nurseries, where the plants remain till they are one or two feet high, and are then transplanted 18 to 20 feet apart. The only subsequent attention given is to protect the plants from damage by cattle and to keep the fields clean. At six to seven years the first crop is picked; and if success is to be attained the plants must now be manured, but very little is usually done in this respect. The flowering seasons are October to December, and again April to June. The fruits of the former are of little consequence, as they do not ripen properly and constitute the so-called monsoon crop, for which there is little demand. The other crop is of great value, is harvested from January to March, and is known as the hot-season crop. The average duration of the plants would appear to be about thirty years. Lastly, Haller discusses the diseases and pests of the orange, and mentions a *Loranthus* parasite and the borer beetle as being the most prevalent.

**Trade in Oranges.**—It is quite impossible to furnish any particulars...
as to the extent of the traffic in these fruits. They do not appear separately in either of the records of internal traffic or external trade. In the Assam Administration Report for 1901-2 it is stated the exports from that province came to 74,000 maunds, valued at Rs. 2,80,000. But we have no information as to the area and yield for the whole of India, and therefore the total production cannot be even conjectured. The suggestion has been made above that India might with advantage follow the lead given by the West Indies, and look to Europe and even America as hopeful markets for the profitable disposal of surplus fruits. Before this can be seriously contemplated production must be put on a more certain basis than at present, and this is not likely to be accomplished until European planters of India are induced to become orange growers. Some few years ago (1894-5) a few parcels of Nagpur oranges were sent to London. Messrs. W. Hutchinson & Co. reported on these. The brokers pronounced the fruit the best they had ever seen, and valued the oranges at 3d. apiece. They arrived when the supply of oranges from other countries had come to an end, and were thus much appreciated. The supply was, however, discontinued, and never seems to have been again renewed. To organise and maintain a foreign market an unfailing supply of a fixed quality must be assured. This would mean increased production with the definite idea of export. The demands of the local markets seem to absorb the present supplies, and the profits of production are sufficiently high, it might be conjectured, to have tempted increased cultivation.

**C. decumana**, *Linn.; Fl. Br. Ind., i., 516; Tussac, Fl. Antl., 1824, iii., 73-4, pl. 17, 18; Bentham, Rev. of Targioni-Tozzetti, in Journ. Hort. Soc., 1855, ix., 172. The Shaddock, Pomelo, Pumelnose (*pampelmoussé, Fr.); the *maha-nibu, batávi-nébu, sadaphal, chakotra or chukotura, bator-nébu, bijoro, papanas, bombalinas, púmplemús*, etc. It has no Sanskrit name. It was known to the early Dutch traders as Pompelmoes (= pumpkin-citron), hence some of the modern names. It reached India and Ceylon in the 17th century. The pomelo is presumed to be a native of the Malay Archipelago. Introduced into India and Ceylon from Java, hence the name *batávi-nébu*; carried to the West Indies by a Capt. Shaddock. Rumphius, followed by Roxburgh, was the first botanical author who described this fruit, although the suggestion may be offered that the *Pomum Adami Commune* (or Black Lemon) of Ferrari and also of Commelin bears a strong resemblance to the pomelo. It is certain that neither Baber (1519) nor Akbar (1590) allude to it. Buchanan-Hamilton studied (1807-11) the districts of "Dinajpur, Rangpur, Paraniya, Bhagulpur, and Bihar, and the cities of Patna, Shahabad and Gorakhpur. Upon each of these he submitted to the Government a voluminous report," but only one, viz. Dinajpur, was ever published, as written by the author, and that not until 1833. He there says that this plant was known as *batabí*, but that it could scarcely yet be said to have made its way from the gardens of the Europeans (*Stat. Acc. Dinaj.*, 196). In 1897, I personally explored a considerable portion of the districts of Dinajpur, Rangpur and Bogra, and may safely affirm that no village exists now without its pomelo trees. In India and Burma at the present day, it is, in fact, one of the most common of fruits, but more especially so in Bengal and South India than in the United Provinces, the Central Provinces or the Panjáb. The best quality
THE GRAPE FRUIT

is the thin-skinned Bombay pomelo, hence the South Indian name of bombalinas.

It is a favourite with the Natives of India, the pulp being either white or red, according to the variety grown. The best fruit is to be had about Christmas time, but certain qualities may be got very nearly throughout the year. In Bengal the season is August to December. The name "Pomelo or Pompoeous" (in Cape Colony, Pomelinoise) is usually given to the large-sized fruit, "Shaddock" to intermediate sizes, and "Forbidden Fruit" to small forms. The cells of the pulp are very large and naturally separate from each other—a peculiarity that has led some people to speak of it as the "Grape Fruit" or "Grape Orange." The separated pulp is largely eaten in India as salad. The Bombay pomelo is the one that should be most cultivated and exported. It may be raised from seed sown in February, or by budding in February to March on the common lime, or by layers made in pots supported high among the branches. Seedlings take longer time to come into bearing than layerings or budtings, and are less certain.

The exports from the Bahamas, Cuba, Jamaica and Florida to the United States have recently assumed considerable importance. The traffic from the Bahamas alone was in 1902, 728,000 fruits. This shows what might be done were India to commence to export Bombay pomelos to the United Kingdom.

C. medica, Linn.; Fl. Br. Ind., i., 514. There are many very distinct forms of this species met with under cultivation in India. Of these, the following abstract of the voluminous information available may help the reader to discover the special details desired:

1. Var. medica proper.—The Citron, Adam's Apple, etc. Bears many names in the vernaculars of India, such as bījaurā or bājauri and bījori (suggestive of the province of that name in Kafaristan which Baber tells us was famous for its citrons even in 1519), laimbu, nimbu (or bara nimbū) turanj (its Persian name), honsa nebu, beg-pura, balank, mawalung, etc. Its Sanskrit names are māṭulunga, phalapura and vijapura. Is said to have been found wild in Chittagong (an opinion not alluded to in Prain's Bengal Plants); by others it has been reported as wild in the Khasia and Garo hills and also in Kumaon.

The Citron is cultivated sparingly in the warm moist regions of India, one form being so large as to resemble a pomelo (is possibly the Poncire citron of Europe.) Another is the fingered citron, a curious fruit that Bonavia recognises in some of the decorative designs of Assyria. It seems to be intimately associated with most of the weird fables that gravitate around the Citrus. The citron is best propagated by seeds or layers. Firminger alludes to the fruits being in Assam ripened within earthen jars before being removed from the tree. A similar practice may have originated the stories of citrons in the form of human faces, owing to the fruits having been grown within moulds of the desired form.

2. Var. Limonum or Lemon.—The word lemon comes from the Arabic līmīn, and through the Persian became the Hindi limu, limbu or nimbu. It is specifically known to the Indian people as the pahari (hill) nimbu, karna (or karna) nebu, kimti, meta-limbu, thora-limbu, and as the kalambak of Arabic and kalambak of Persian.

The wild form of the lemon has not been recorded as met with in India—the plant mentioned by Royle, Madden and others was more probably the lime than the lemon. Lemons are, however, fairly extensively cultivated here and there all over India. Still, the true lemon.
THE SOUR AND SWEET LIMES

is hardly one of the regularly grown fruits, in the gardens of the people generally, but rather of the well-to-do and the curious.

Sour Lime.

3. Var. aegida; Kew Bull., 1894, 113–6, 177–82 and pl.; the Sour Lime of India.—This is the lemon of most popular writers, and is undoubtedly a native of India. It is the true nibu or nebu, nimbu, libu, etc., and is the jambiri of Baber, the jambira, limpaka, nimbuka, vijapura and vijaka (according to Dutt) of the Sanskrit authors (Suvaruta (ed. Hesseler), 1844, i., 86). This is the plant usually met with in a wild state in the warm valleys of the Himalaya. There are numerous cultivated forms of it, the two chief being a round lime (páti-nimbu) and a long lime (kágzí or kaguijí -nimbu or thin-skinned nebu). The thin-skinned limes of Jaipur and Azamgarh are celebrated. Then there are in addition the pati or small round lime, the góré or oval fruit, the Chini-góra, which much resembles an orange, the kárudáli, a very large lime, the khatta of Upper India, the Bajoura limes—a sort of citron-lemon, the gungoli and Bihari and many others.

Cultivation.

The Sour Lime is easily reproduced by layers or seeds, the finer qualities being budded on the commoner and hardier wild stocks. The wild lime is, in fact, the chief budding stock for all species of orange, lemon or citron. The juice of this fruit is universally used for flavouring soups, curries, fish, etc., since it imparts a pleasant acid taste and agreeable flavour. It is also largely used in domestic medicine. The small sour limes are extensively employed for sherbets and in the manufacture of lime-juice, and the large ones made into various preserves. Baber refers to several forms of lime, so that we have abundant evidence that they have been known and valued in India for many centuries.

West Indies.

In the West Indies the lime is specially grown in Montserrat, Dominica, Jamaica and Trinidad on account of the juice—the lime-juice of commerce. The reader will find a highly instructive paper on the West Indian Lime Industry, written by A. J. Brooks (Journ. Roy. Hort. Soc., 1907, xxxii., 172–88). It will be found to deal with the following among other subjects of interest:—History, Cultivation, Pests, Fruiting, Essential Oil, Raw Juice, Concentrated Juice, Cultivate of Lime, Green Limes, Improvement of the Lime, etc. Brooks informs us that “the juice is exported in its natural or 'raw' state, or as ‘concentrated’ juice, the latter being one of the chief sources of citric acid.” There would seem no good reason why India might not participate in this trade.

4. Var. Limetta or Sweet Lime of India—the santara nibu, mitha-nibu, amritphal, elemitchum, thanbaya, etc., and the madhukarkatika of Sanskrit.

Wight regarded the sweet lime as indigenous to the Nilgiri hills. It was known to Baber, who apparently did not much appreciate sweet limes or sweet oranges. In the Turki copy of his Memoirs there is a footnote written by his son Humain to the effect that Baber's dislike to the amratphal was a consequence of his having been long and much addicted to the use of strong drinks, whence he naturally did not like sweet things.” It has, however, very little flavour except that of sweetness, but being in season in August to October, when oranges are not procurable, it is much appreciated by many persons as a cooling and refreshing fruit. But it seems highly likely that the sweet lime has by many writers been frequently confused with the bergamot or green orange. It is eaten fresh or after being preserved or cooked.

The sweet lime is very largely employed by the Delhi orange-growers as a stock on which to bud the santara orange, and this circumstance may to some extent account for the peculiar flavour of the best Delhi oranges.

Conclusion.—It has not been found possible to afford space for more
than the merest outline of this subject. Details of cultivation, of the diseases to which the various species are liable, as well as of their respective industrial and medicinal uses, have had to be all but omitted (see Vinegar, p. 1110). Consult the Pharmacographia Indica for therapeutic facts, and for particulars regarding the perfumes, Gildeimeister and Hoffmann's Volatile Oils (1900, 460–85); as also the admirable paper by Burgess and Child in the Journal Society Chemical Industry (December 1901).

The cultivation of oranges, lemons, pomelos and limes of India, if organised on a more extended and systematic fashion than at present, would of necessity involve full advantage being taken of each and every profitable outlet, such as the preservation of the fruit (candied), the production of lime-juice, and the manufacture of perfumes and oils (citral, bergamot, neroli, etc., etc.). The "oil of lemon" is one of the chief industries of Sicily. The summer crop is exported as fresh fruit, the autumn or winter crop is manufactured locally into the juice and oil for which that island is famed. But it is regarded as very injurious to allow a tree to fruit twice a year, and hence the December crop is, as a rule, preferred. The lemon begins to yield when five years old. When fifteen to twenty years it gives 1,000 fruits, and when full grown may afford from 3,000 to 5,000. In the production of oil and juice, the fruit is cut into pieces, the pulp scooped out from these, the peel soaked in water for an hour or two, and then pressed by hand over a sponge in order to separate the oil. If candied peel is to be prepared, only half the oil is so expressed, otherwise as much as can be squeezed out is taken, and the waste peel given to cattle. The pulp is pressed for juice and the residue used as cattle food. Such is in brief the process usually adopted in the preparation of lemon oil and lemon juice in Sicily.

If an Indian industry were therefore organised, a large share in the profits of cultivation would have to be derived from these and other sources. Much care would have to be expended in selecting the best stock and in ascertaining if the lime, in place of the lemon, would meet all the necessities of trade. The lime would in all probability be better suited to the climate of most districts of India, but there exists a wide range of forms from which to select. To organise an export traffic in fresh fruit, it would be indispensable to have special shipping arrangements, since the fruit would be greatly injured if consigned to the hold along with mixed cargoes. Quick transit, careful packing, and good storage are essential to success. [Cf. Kew Bull., 1892, 108; 1894, 114; 1895, 266–71.]

Sir T. H. Holland, Director of the Geological Survey of India, in his Review of Mineral Production (l.c. 104), observes that "no statistics approaching any degree of completeness are obtainable to show the extent of the undoubtedly great industrial value of the clays in India. They include the common clays used all over the country for the manufacture of bricks, tiles, and the cheaper forms of pottery; finer varieties, used
Bricks and Tiles.

History of European Production.

Early Indian Production.

Three Kinds.

Strength and Durability.

Machine-made.

k and Tile Clays.—Until the middle of the last century it was thought necessary to import bricks from England, and that prejudice served to destroy the hopes of Mr. George Macdonald, who in 1866 became virtually the pioneer of European brick-making and pottery in India. He failed disastrously to interest the Government engineers and the building trade in the products of his factory at Raniganj (Raneegunge). In 1881 Mr. J. H. Glass directed attention to the Jabalpur supplies, and as a consequence the Geological Department deputed Mallet to inquire into the clays of the Central Provinces, the result being that the claims of Umaria were urged very strongly. It was pointed out that Gondwana clays were abundant, coal and fire-clay on the spot, felspar obtainable within four miles, while chalcedony might be collected in the Mahanadi near Chandia. Messrs. Burn & Co. had meantime founded their potteries on the very spot where Macdonald failed. It is said they now turn out about 30,000 bricks a day, including glazed bricks for bathrooms, and blue-chequered damp-proof bricks for stores and godowns. And about the time of Mallet’s report they extended their operations by opening out their Jabalpur works.

But bricks were used in India long before the arrival of the English, and some very old edifices, fortifications, etc., seem to have been constructed with large thin bricks not unlike those employed in ancient Europe. Such bricks were recently found, for example, by Dr. Stein in the ruins of the stupas, etc., of ancient Khotan, of a date of the 7th or 8th century. Abul Fazl, the chronicler of the Emperor Akbar’s reign, mentions three kinds of bricks, “burnt, half-burnt, unburnt,” and observes that the Emperor had fixed the price for these. The first kind, he adds, were usually made very heavy. [Cf. Ain-i-Akbari, 1590 (Blochmann, transl.), 1873, 223.] These three grades are met with to the present day all over India, and in fact most houses, garden walls, etc., of the peasants of India are mainly constructed (when bricks are used at all) of sun-dried bricks. But if Indian fired bricks have not hitherto borne a very high reputation for strength and durability, it has been upheld that the cause of inferiority should more often be sought in the process of manufacture than in the material used. A writer in Indian Engineering (August 4, 1900) pointed out that in making bricks by hand it was very difficult to get the edges sharp and well defined, the only way to obtain this being to use none but well-made moulds and to reject at once any mould found to be in the slightest degree cracked or damaged. That difficulty is to a large extent overcome by the use of machinery, though an even greater disadvantage at once arises, namely that machine-made bricks have to be transported from the brick-field to the building site, thus materially adding to their cost. In India it is usual to manufacture hand-made bricks near the place where they are to be used, and it is highly
likely, therefore, that the clay employed is not always the best that could be desired or discovered; were a search made a little farther afield. Finally, of course, the Indian climate is a very serious consideration.

With regard to Native-made bricks, interesting particulars have been published by Hoey (Monog. Trade and Manuf., N. Ind., 1880, 162). He there observes that "good bricks of the size used in Government buildings are sold by the pu sauwaola at Rs. 7 per 1,000," whilst the "imperfectly burnt are called tharro, and sell at Rs. 4 per 1,000." Lucknow, of which Hoey was specially writing, is naturally a great brick-burning centre, owing to the lack of stone thereabouts. Ornamental bricks, moulded on the face with figures and patterns, were formerly made in many parts of Bengal. Good examples are to be seen in some of the temples in Chander Nagore and Hughli, but more especially at the Kantanagar temple near Dinaapur. In North India, more especially in Lahore, carved bricks may be seen in the buildings of the well-to-do.

It would seem likely, however, that the most important brick-making centre of India is the immediate neighbourhood of Calcutta. Tanks are dug that can, as desired, be flooded from the river. A deposit of fine clay is laid down and successive floodings are made till a workable bed of clay has been secured. Statistics are unfortunately not available as to the extent of production, but that the traffic is large can be judged by the fact that practically all the better-class houses of Calcutta are constructed entirely of brick. It is said that the largest brick factory in India is that of Akra, near Calcutta, which turns out 20 to 30 million bricks annually. The Calcutta bricks are, for the most part, fired by furnaces, not kilns. [Cf. Min. Rev., 1898, 59.]

Tiles.—The firms concerned in the manufacture of bricks are also, in many cases, producers as well of tiles, pipes, etc. To a very large extent machine-made tiles, being lighter, better and more durable, are displacing the old heavy clay tiles made by village potters.

Brick and Tile Works.—It is sometimes affirmed, however, that the best tiles employed in India are still imported from Europe, the price being Rs. 15 per 100 (Capital, Oct. 15, 1903). In the S. Kanara district there were in 1894, 1,097 brick and tile burners and sellers; also eleven brick and tile factories in the town of Mangalore, eight being managed by Natives. Mr. Sturrock estimated the annual outturn of bricks at these factories to be 300,000, most of which are exported by sea to Bombay and other west-coast ports. The manufacturers sell the bricks at Rs. 35 per 1,000. [Cf. Man. S. Kanara, 1895, 143-5.] According to official statistics, the brick and tile works or factories throughout India employed in 1902, 6,255 persons; in 1903, 6,435; and in 1904 double the number, viz. 13,781. These figures are admittedly open to question since they can hardly include the Native brick-makers, but represent rather the personnel of the Brick, Tile and Pottery Works run on European methods, such as those at Raniganj, Jhabalpur, Aligarh, Bareilly, Mangalore, Feroke, etc. It may be mentioned that at the Raniganj potteries alone over 1,400 persons are employed, of whom about one-quarter are women engaged in porterage. The three tile works of the Basel Mission near Mangalore employed 540 hands in 1903, and the three works at Feroke, Malabar, 650 hands.

Fuller's-earth, also Edible and Medicinal Clays.—There is little information of a recent nature on these materials. Rauwolf, who travelled in the East (in the middle of the 16th century), mentioned of Tripoli that an ash-coloured earth called natun was employed for washing the head, and that another earth called jisabar was eaten by women. That sentence might be almost given as true of India to-day. A pale

**Multāni Matti.** yellow mud is eaten medicinally, and sold under the name Multāni matti. An earth known as sang-i-basri is said to be imported from Persia and used in tonic preparations, owing to the iron which it contains. Saucer-shaped chips of partially baked clay are sold in the Calcutta bazar for eating. Montgomery Martin (Hist. E. Ind., 1838, ii., 167) refers to a substance called khari eaten by women in Bengal. Hooper (Rept. Labor. Ind. Mus., 1905–6, 37–8) gives particulars of 33 samples examined. Silica was the largest constituent, eight samples having 50, twelve 70, and six 60 per cent. The analysis showed that these clays had no food value. [Cf. Hooper and Mann, Memoirs As. Soc. Beng., i., No. 12, 249–70.] It is probable that all these clays are nearly allied to fuller's-earth, which in India is employed as an external application to purify the hair and skin, in washing the cloths used in the manufacture of lac, indigo, etc., as also for weighting fabrics. It is interesting to add that the Institutes of Manu records the punishment to be meted out to manufacturers who add too great a weight to the textiles they produce. The following are said to be the best-known Indian sources of fuller's-earth—Colgong in the Bhagalpur Division of Bengal; the Central Provinces; the district near Kolath in Bikanir, Dera Ghazi Khan and Multan in the Panjāb. Holland says fuller's-earth is mined in the Central Provinces and in Rajputana.

**Fire-clays.** These clays are capable of resisting a very high temperature without fusing or fissuring. They should be as nearly as possible free from lime, iron or alkaline earths, which promote the fusion of silica as in glass-making. In Europe the best clays for this purpose are found below coal-seams, and in spite of the different age of the Indian coal-fields, the underlying clays are found to be available for the production of a fairly good fire-brick material. Fire-bricks are manufactured in considerable quantities by Messrs. Burn & Co. at Raniganj, the clay being obtained locally. Promising fire-clays are also found at Jhabalpur, at Jowai in Assam, and at the Chanda, Umāria and Gondwana coal-fields. It is probable that with proper manipulation some of the pottery clays, not hitherto used for the purpose, would afford perfectly refractory materials.

**Pipe-clay** (namam, kharra, etc.), so called in English from its being used for tobacco-pipes. It much resembles China-clay, but possesses more silica. Ball makes no mention of the existence of pipe-clay in India, but Moore (Man. Trichinopoly, 1878, 67) states that a fine bed of it occurs between Terani and Kārāi. Pipe-clay has also been mentioned as a product of the Madras forests. [Cf. Madras Man. Admin., 1885, i., 313.] An anonymous correspondent of The Madras Weekly Mail (April 20, 1905) stated that the clay used in the ornamental pottery of Karigeri in North Arcot was a form of pipe-clay.

**Pottery-clays.**—The pottery-clays of India might be popularly assorted according to three degrees of purity, viz.:—(a) kaolin, China or porcelain clay; (b) ordinary white or glazed pottery clays; and (c) red or tile and flowerpot clays. The third has perhaps been sufficiently indicated above in connection with brick and tile clays, since most average good brick clays may be used for unglazed pottery. Kaolin, besides being employed for porcelain, is utilised in the paper and soap industries. It is sold in the form of large lumps of a white or yellowish-white
CERAMIC WARES

CLAYS

POTTERY-CLAYS

colour. It fills up the pores of the paper and gives a smoother and
more absorbent surface. [Cf. Cross and Bevan, Paper-making, 1900,
197.] It is formed by the gradual disintegration of felspar under
the action of air and water, and consists essentially of a silicate of alu-
minium. Its quality depends upon its whiteness and freedom from the
coarser micaceous particles. Although there is probably nowhere in
India an occurrence of the finest porcelain-clay, such as that of the south-
wester counties of England, yet there are several districts where fine
white clays exist and are utilised for pottery. In fact the chief districts
where such clays occur are naturally more or less identical with the localities
whence the Indian Art potteries are produced. The following brief state-
ment may be useful:—

Ceramic Ware.—There are three classes of pottery:—(a) Aboriginal
work, (b) Hindu work, and (c) Muhammadan work. Ceremonial usage
amongst the Hindus requires that pottery, whether polluted or not, shall
be thrown away on certain specified occasions, so that there has arisen a
large trade in a cheap material where artistic developments would be
superfluous. So far as the production of this everyday domestic pottery
is concerned, the potter will probably always hold an important position
in village life. But even he is beginning to feel the stress of competition.
Glazing is unnecessary unless the ware be meant to hold water, and since
artistic ware has mainly been produced in the way of grain or pickle jars,
painted or lacquered pottery is equally serviceable and infinitely cheaper
than glazed ware. Indeed, with the exception of the few examples dis-
covered in association with the Dravidians of South India and the fragments
of old pottery found in the Charsada excavations near Peshawar, there is
no reason to suppose that glazed earthenware vessels were at all used in
India prior to the Muhammadan conquests. The former of the two
exceptions possibly is suggestive of the origin of the apparently sponta-
aneous art of glazing found at Vellore in North Arcot. Beyond the
frontier of India, moreover, it has been recently shown by Stein (Ancient
Khotan) that an advanced knowledge existed from perhaps the second
century of our era. It is just possible, therefore, that the discoveries
both in the south and north of India of old glazed pottery (and even of glass)
indicate Buddhist rather than Hindu work. But that the glazed pottery
of India, as generally accepted by European connoisseurs, began with the
Muhammadan traffic in coloured tiles for mosques and tombs there can be
no doubt. To this day the village potter (kumhâr) is nearly always a
Hindu, and he makes unglazed pottery, whilst the ceramic artist (kuzagár,
kashigâr) is ordinarily a Muhammadan (except in such rare and notable
cases as that of the Hindu kuzagâr of Delhi). Moreover the kuzagâr
often purchases from the village potter sun-dried vessels which he after-
wards ornaments and fires. It is a matter of everyday knowledge that
the glazed vessels of recent times, so eagerly purchased by visitors to
India, are but special adaptations gladly pursued by the Indian craftsmen
with the decadence of the demand for tiles. In any case all present-day
of glazed pottery in India (except perhaps the Vellore work) is Indo-Saracenin
design, is made by Muhammadans, and sold exclusively to Muhammadans
or Christians. Mr. Hughes Buller and Mr. Gupte recently discovered a
kiln and rude contrivance for making pottery in Baluchistan, which seemed
to have been used for making glazed-ware, since fragments of such pottery
were found near by. Mr. Buller is of opinion that the fragments in ques-
COAL.

Trade in Earthenware

Deterioration.

The modern demand for cheap Indian work is rapidly causing a deterioration from the original tile models of former times. Fortunately the shapes of the glazed and painted wares, platters, cooking-pots, water-jars, etc., are as yet uncontaminated by foreign demands and hence remain graceful and well worthy of study, alike by the antiquary and the artist.

Trade.—The value of the EARTHENWARE and PORCELAIN (excluding earthenware piping) imported in 1899-1900 was Rs. 19,90,369, but it rose in the succeeding years, until in 1903-4 it reached Rs. 28,00,038, and in 1906-7 Rs. 38,99,824. The United Kingdom usually supplies 50 per cent., whilst Belgium, Germany and the Straits Settlements contribute between them about 40 per cent. The chief receiving provinces in 1906-7 were Bengal, Bombay and Burma, which took respectively quantities valued at Rs. 14,22,977, Rs. 12,27,104, and Rs. 8,93,767. A small proportion (Rs. 2,58,929 in 1906-7) was re-exported and sent to Persia, Arabia, the United Kingdom, Turkey-in-Asia, East Africa, etc. EARTHENWARE PIPING (which is mentioned separately in official statistics) is imported from the United Kingdom, and in 1906-7 amounted to 31,347 cwt. (Rs. 2,16,808), most of it being received by Bombay. BRICKS AND TILES are taken by India, principally from the United Kingdom and into Bombay. Both in quantity and value the imports increased by more than 100 per cent. during the five years ending 1903-4. In the first year of that series they were in number 3,641,594, valued at Rs. 2,14,255, and in 1903-4 they were 7,135,872, valued at Rs. 5,16,610. Since then they have continued to increase to 14,922,191 (Rs. 10,64,560) in 1906-7. India also imports a small quantity of CLAY. The amount in 1906-7 was 56,889 cwt., valued at Rs. 96,557, and the country chiefly concerned may be said to be the United Kingdom, the supply being consigned to Bombay, Bengal and Burma.

The total value of Indian EARTHENWARE (except piping) exported in 1906-7 was only Rs. 44,709, consisting of certain small consignments from Madras, Bombay and Bengal to Ceylon and the United Kingdom. EARTHENWARE PIPING, not included in the above, is exported chiefly from Bengal to the Straits Settlements. The amount in 1906-7 was 7,690 cwt. (Rs. 34,368). The exports of Indian bricks and tiles go principally from Madras to Ceylon. In 1899-1900 they were valued at Rs. 68,797, and in 1906-7, Rs. 1,03,314.

BIRTH OF INDIAN COAL TRADE

1890 to 1904, etc. etc. The koyelah, koyala, koelo, kola, kari, simai-karri, bogyu, simu bogyu, idallu, misu-e, midu-ye, etc.

History.—Coal has doubtless been known to the Natives from time immemorial, but was neither mined nor traded in until sought out by the early European residents in India. Even at the present date it is little if at all used in the purely indigenous industries, and hardly ever employed for domestic purposes. But this state of affairs is perhaps little to be surprised at when it is recollected that the first licence to dig for coal in England was granted by Henry III. in 1239: it was then designated “sea-coal.” In 1396 the use of coal in London was prohibited, but in 1325 a trade had been organised between England and France in which coal was exported and grain imported. About this time also Newcastle became famous for its coal, and for a couple of centuries at least fleets of ships sailed from thence to supply London and the other ports of England, as also France, Holland and Germany. It would be beyond the scope of this article to follow the growth of the European knowledge in coal or to narrate the discovery of the other coal-deposits that finally overthrew the supremacy of Newcastle. By 1776 we read that Sunderland, Blyth, Hartley, Durham and several other centres in both England and Scotland had commenced to export coal independently of Newcastle and of the charters granted to the original seat of the trade. It was only natural, therefore, that the European residents in India, in the middle of the 18th century, should have begun to think of a possible Indian supply of an article that had been proved of so great value in their home countries.

In 1774 Warren Hastings granted a mining license to two of the Company’s servants, namely Mr. Suetonius Grant Heatly and Mr. John Sumner. The former gentleman, we learn, had discovered coal in the districts of Bheerbroom and Pachete. Mr. Heatly (son of the discoverer and original worker of the Bengal mines) tells the story of his father’s labours, in an article which will be found in the Journal of the Asiatic Society of Bengal (1842, xi., 811–35). Unfortunately the coal Heatly produced was reported as being much inferior to that of England, and this circumstance, together with the indifference of Lord Cornwallis to measures calculated to develop the internal resources or promote the external commerce of India, led (according to Heatly, junior) to the neglect and apathy that characterised the first few years of coal-mining in India. In 1777 Farquhar and Motte asked permission “to bore cannon and to cast shot and shell in the district of Jharia, lying between the rivers Dummuda and Burrraker.” They gave as their reason for the selection of that locality that it “abounds in iron ore and is contiguous to the coal-mines of Messrs. Sumner & Heatly.” Williamson (Wild Sports in the East, 1808, i., 7, 8) alludes to Indian coal, but remarks that the Company “finds it easier to send coal from England, as ballast, to their arsenals abroad, where quantities are occasionally used in fusing metals for casting ordnances.” But apparently about this very time the London Directors of the East India Company had actually complained of the heavy charges involved by the indent for the coal made by their Indian representatives, and they accordingly recommended an inquiry whether charcoal could not be substituted; and if not, they further recommended the transference of the ordnance works to England. The Earl of Minto was at the time Governor-General of India, and to his enlightened action may be attributed the birth of the present prosperous trade in coal. He directed that Indian coal should be submitted to actual tests by the military authorities in India. Col. Hardwicke accordingly performed experiments but reported once more very unfavourably (dated May 19, 1809), and the subject of coal for a time dropped out of notice. But in 1814 the Marquis of Hastings once more urged on the Military Board the desirability of ascertaining beyond doubt “whether the coal of India was of a quality calculated for the purpose of the forge.” His lordship announced that a fully qualified person would be appointed to examine the mines, who would be furnished with the necessary apparatus to make borings and who would for experimental purposes procure a supply of coal from such a depth as to ensure that it would represent the average quality. Previous experiments were thus discredited owing to the coal used having been obtained from the surface and therefore much deteriorated. By this time we hear of a Calcutta merchant having commenced to use Bengal coal, notwithstanding the unfavourable reports published by the Military Board. Coal was, in fact, being regularly conveyed by boat down the Damuda river to Calcutta, and it is therefore not to be wondered at that
Coal

History

THE INDIAN COAL INDUSTRY

the Viceroy should have once more called for a thorough inquiry. Mr. Rupert Jones accordingly went from England on purpose to examine the Bengal coalfields, and his report (written in 1815) will be found in the Asiatic Researches (1833, xviii., 163–70). Needless to say this gave new life to the Indian mines and proved that indifference and obstruction to the use of a new material had more to say to the unfavourable opinions previously published than the actual inferiority of the coal—at least for many of the purposes for which English coal was being imported. But in passing it may be added that Mr. Jones himself did not realise the full value of his investigations. He foretold increased prosperity to Calcutta, through the coal he had discovered being a better and more economical fuel for burning the Sylhet limestone than the firewood then in use. Jones apparently knew little of the great revolution steam was destined to effect, nor of the imperative necessity of an abundant and cheap supply of coal for commercial and industrial prosperity.

Mr. Jones received an advance from Government of £4,000, on easy terms, to enable him to work the mines, but in 1820 he came utterly to grief. Fortunately a number of Calcutta firms stepped into the breach. The first regularly constituted Indian mine under European supervision and capital was opened in Bengal in 1820 (Raniganj mine). In 1820 the output was 36,000 tons. Still, little progress was made till the construction of the East Indian Railway in 1854 tapped the coalfields. But even then the progress was but slow until the jute-mills of Calcutta had been started and the other directions of manufacturing skill originated, that gave vitality to the Eastern capital. Apparently 1857–8 was the first year of specially recorded production, when 293,443 tons were taken from the Indian mines and 92,983 tons imported. From that date the prosperity of coal-mining was assured. It became the direct expression of a rapidly expanding modern commerce. This may be briefly exemplified. In 1868 the output was 459,408 tons; in 1875, 925,494 tons; in 1898, 4,608,196 tons; in 1904, 5,348,561 tons; and in 1906, 9,783,250 tons. Of these the Bengal mines supplied 88 per cent. [Cf. Moral and Prof. Ind., 1906–7, 114.]

One of the difficulties experienced in this remarkable trade has been for the railways to keep pace in the supply of the rolling stock necessary. In 1885 there were 95 mines, of which 90 were in Bengal; in 1900 there were 286 coal-mines in operation, of which 271 were in Bengal; in 1906 there were 307, of which 274 were in Bengal. The number of mines only partially represents progress, on account of the tendency for small mines to be grouped together as a smaller number of large ones. The greatest development has taken place in the Raniganj field, owing to the collieries being only 120 to 140 miles from Calcutta. Jherria, some 40 miles more distant, has recently given evidence of having very likely permanently overtaken Raniganj. But no less vigorously have the Giridih fields been pushed forward. It can now be affirmed that India is rapidly approaching the state of being able to meet all her own wants for fuel. The imports have been shrinking steadily for years, and in 1903–4 were only one-fourth of the quantity taken nine years previously. And of these imports Bombay — a province remote from a consuming market — by far the major portion, viz. 148,311 tons out of a total of 179,935 tons in 1905–6. England, Australia and Japan are the supplying countries. But a new trade has arisen, namely in coal exported to Indian Ocean ports—a traffic that it would seem is instantly stimulated and permanently strengthened by the strikes and other accidental causes which in Europe and Japan tend to raise the price of coal. A vivid conception of the present magnitude and importance of the Indian coal industry may be had from the circumstance that in 1903 the output came to 7½ million tons, while the outputs of both Canada and Australia were equal just under 7 million tons; and the Indian production has since risen to almost 10 million tons. But a still more significant fact may be added in conclusion, namely that Indian coal is the cheapest in the world. The average pitmouth price was in 1902, Rs. 2–12 (3s. 5d.) and in 1906 Rs. 2–15 (3s. 11d.) per ton, while in the United States the corresponding average price was 58. 83d.; in Australia 7s. 9d.; in the United Kingdom 8s. 2½d.; in Germany 8s. 10½d.; in Canada 9s. 3d.; and in New Zealand 10s. 6d. An interesting series of articles on "Dear Coal" will be found in The Textile Journal (May, July and December, 1900).

The annual reports, etc., of the Indian Mining Association and those of the Bengal Chamber of Commerce are usually of the greatest interest and value in setting forth the progress or the disabilities of the mining industry. But it
GROUPS OF MINES

COAL

may be added that none of the early European travellers in India make any mention of coal, prior to the first decade of the 19th century. This is abundantly exemplified by the silence of Milburn (Or. Comm., 1813) and of Macpherson (Hist. Europ. Comm. Ind., 1812), two authors who were certain to have had chapters on Indian coal and India's requirements in coal had these been questions of public importance at the time in which they wrote.

**OCCURRENCE AND DISTRIBUTION OF COAL IN INDIA.**

Holland (Rev. Min. Prod. Ind., 1905, 1907) has furnished so comprehensive a statement of India's coal resources that it is hardly necessary to do more than give an abstract of his opinions in order to bring the Dictionary up to date. He confines attention to the coalfields actually being worked or those likely to be worked in the near future. The particulars that follow in this chapter are, therefore, derived very largely from Holland's instructive and practical Reviews:—

"Most of the coal raised has been obtained from the Gondwana system of strata in Peninsular India, where the coal-mines, being nearer the coast and generally within touch of the main railway lines, have been developed more rapidly than those of the extra-Peninsular Cretaceous and Tertiary coal-beds." The Gondwana mines furnished in 1906, 95.56 per cent. of the total supply. It may be useful to exhibit the chief groups of mines categorically:—

(A) **GONDWANA COALFIELDS.**—1. Raniganj and JherrJa in Bengal.—Raniganj was the first to be developed and formerly had the largest output, but since 1906 the lead has been taken by the JherrJa mines farther west in the Damuda valley. These mines are tapped by the E.I.R. and by the B.N.R. systems. "The coal from the Raniganj field is mainly derived from seams in the highest beds of the Damuda series, the lowest, or Barakar stage, being less developed in the exposures along the northern margin of the field. In the JherrJa field the converse is the case: the uppermost stage has yielded poor coal, whilst in the Barakar series there are some eighteen well defined seams of which the upper eight include enormous supplies of good coal. The two classes of coal present a well-marked and constant difference in the amount of moisture they contain: the older, Barakar, coals, both in the Raniganj field and in JherrJa, contain on an average about 1 per cent. of moisture, whilst the average for the younger coal of the Raniganj series is 3.8 per cent. in the lower seams, and nearly 7 per cent. in the upper seams. There is a corresponding, but less marked, difference in the proportion of volatile hydrocarbons, which form a larger percentage of the younger coals than of those at lower stages in the Damuda series."

2. Giridih in Bengal.—"The small patch of coal-bearing Gondwana rocks near Giridih is practically divided between the Bengal Coal and the East Indian Railway Companies. The chief wealth of the field is stored in a 15-foot seam of good steam and coking coal near the base of the Damuda series." It has been estimated that the remaining workable supplies probably do not exceed 77 million tons. [Cf. Saise, Giridih Coal Fields and Notes on Methods of Working, in Rec. Geol. Surv. Ind., 1894, xxvii., 86-100.]

3. Pench Valley in the Central Provinces.—An interesting development is the opening out of the Pench supplies. In 1905 the production was 1,104 tons, and in 1906, 32,102—in spite (adds Holland) of the imperfect railway facilities. This field is of special value to the mills of Bombay and the Deccan.

This colliery has been worked since 1862 by the Nerbudda Coal and Iron Company. It has made little progress, but a new area some two miles farther west has been discovered and operations commenced. Medlicott published in 1872 a paper entitled Notes on the Satpura Coal-basin that should be consulted regarding the coal of this area. More recently Mr. C. J. Dalby of the Bengal-Nagpur Railway submitted in 1892 a report on the Rampur Coalfield. Also Mr. G. F. Reader, Mining Specialist, published (Mem. Geol. Surv. Ind., 1901, xxxii.) a more detailed account of these fields.

5. Warora in the Chanda District of the Central Provinces, and about 62 miles south of Nagpur, has been worked since 1871 by the State. About half the coal raised is taken by the G.I.P. Railway, the rest going to the cotton-mills and factories of the Central Provinces. This coal is liable to spontaneous combustion, and a large part of the field has been lost through fire. "The Warora colliery has been worked under distinctively greater natural difficulties than those usually met with in Bengal."

"The returns for labour at Warora, notwithstanding the difficulties arising from water and liability to spontaneous combustion, show that the system of mining adopted permits of a satisfactory output per person employed, whilst the deaths due to accidents have been reduced to a low rate."

"Another three or four years will probably see the end of the Warora colliery, but, with the extension of the Wardha Valley line southwards, the extensive deposits near Bellarpur will be opened up." Prospecting operations have recently commenced on the known thick coal-seams in the Wun district, Berar. These coal-fields are fully described by Hughes. [Cf. Mem. Geol., l.c. xiii., 1.]

6. Singareni in the Nizam's Dominions.—"The great belt of Gondwana rocks near the north-west end of which Warora is situated stretches down the Godavari valley as far as Rajamundry, and at one or two places the equivalents of the coal-bearing Damuda series in Bengal are found cropping up from below the Upper Gondwana rocks. One of these occurrences near Yellandu in the Nizam's Dominions forms the coal-field well known by the name of Singareni. The principal seam of coal, some 5 to 6 feet thick, being worked at the Singareni colliery was discovered by the late Dr. W. King of the Geological Survey in 1872, but mining operations were not commenced until 1886."

"Coal-mining at Singareni has been accompanied by a heavier loss of life by accidents than in the general run of Gondwana fields." The opinion seems upheld that for steam purposes Singareni coal is considerably inferior to Bengal coal and is not a coking coal. These circumstances would seem largely to account for the slow progress made with this coal in South India. The Reports of the Hyderabad (Deccan) Company, Ltd., afford useful particulars regarding the mine.

7. Umaria, Rewah State, Central India.—The Bilaspur-Katni Branch of the Bengal-Nagpur Railway passes through this small coalfield. "The quantity of workable coal in this field is estimated at about 24 million tons." "The four coal-seams being worked vary from 3 to 12 feet in thickness and dip about 4° to the north-east. The mines were opened in 1882 under the direction of Mr. T. W. H. Hughes of the Geological Survey and were controlled by Government until the 1st of January, 1900, when they were handed over to the Rewah State."

Most of the
INdian Tertiary COAL

Coal raised is sold to the Indian Midland and to the Bengal-Nagpur Railways. [Cf. Ann. Repts. Revah State Collieries, 1899-1903.]

(B) Cretaceous and Tertiary Coalfields.—"The younger coals are nearly all of Cretaceous and Tertiary age, although some thin and poor seams of Upper Jurassic coal have been worked in Kach. The Cretaceous beds occur in the Khasia and Garo hills of Assam, where they are found in small basins resting on the Archean schists and gneisses. The Cretaceous coals of Assam are generally distinguished by the inclusion in them of nests of fossil resin, and this character was noticed in the coal recently discovered to the north of Shillong."

"Coal of Tertiary age is found in Sind, Rajputana, Baluchistan and along the foothills of the Himalaya, further east in Assam, in Burma, and in the Andaman and Nicobar Islands. The most frequent occurrence is in association with nummulitic limestones, though the richest deposits, namely those in North-East Assam, are younger, probably Miocene in age. Of these extra-Peninsular fields, the only ones producing coal are of Tertiary age."

"On the whole, the younger coals, which are being worked in extra-Peninsular areas, differ from the Gondwana coals in containing a larger proportion of moisture and volatile hydrocarbons, and though as variable in composition as they are in thickness of seam, coals are obtained, as for instance in Assam, with a remarkably low percentage of ash, and having a high calorific value."

8. Makum in North-East Assam.—This is being worked by the Assam Railways and Trading Company, who commenced operations in 1881. The collieries are connected by a metre-gauge railway with Dibrugarh on the Brahmaputra river, which, being navigable, forms both a market and a means of transport for the coal. The most valuable seams occur between the Tirap and Namdang streams, where, for a distance of about five miles, the seams vary from 15 to 75 feet in thickness. The average dip is 40°, but as the outcrops in many places are several hundred feet above the plains, facilities exist for working the coal by adit levels. "The coal has the reputation of being a good fuel, and forms an excellent coke." [Cf. Mallet, Coal Fields Naga Hills, Assam, in Mem. Geol. Surv. Ind., 1876, xii.; La Touche, Coal Fields Jaintia Hills, 1889; Bose, Rept. on Um-Rileng Coal-beds, Assam, in Rec. Geol. Surv. Ind., 1904, xxxi.; A.R.T.C., Ltd., Ann. Repts., Nos. 1-21.]

9. Shwebo District in Burma.—Coal occurs in various parts of Burma. Within the past few years it has, for example, been definitely ascertained that in the Nammaw field (30 miles from the Mandalay-Lashio Railway) there are seams of lignitic coal 10 feet thick. [Cf. Jones, Notes on Coal, Upper Burma, in Rec. Geol. Surv. Ind., 1887, xx., 170-93; Noeting, Upper Chindwin Coal-fields, 1890; Primrose, Rept. Prosp. Oper. in Tenasserim, 1891-2; Bose, Notes on Geol. Tenasserim Valley, in Rec. Geol. Surv. Ind., 1893, xxvi., 148-64; George Scott, Upper Burma Gaz., ii., pt. 1, 230-8; Nisbet, Burma Under Brit. Rule and Before, 1901, i., 389-92.]

10. Baluchistan.—Possibly the most important coal-deposits of the west are those in Baluchistan, where, however, the disturbed state of the rocks makes mining difficult, expensive and dangerous. The best mines are those of Sor (south-east of Quetta), the Bolan and Khost. From the last-mentioned mine the output in 1906 amounted to 32,500 tons.

11. Dandot in the Jhelum District of the Panjáb.—The Dandot
COAL
Indian Mines

plateau of the Salt Range. The only valuable seam varies in thickness from 18 to 39 inches and forms a basin under the nummulitic limestone. The mines have been worked by the North-Western Railway since 1884. [Cf. N.W.R., Ann Rept. Working Mines, 1896-1903.]

12. Bhaganwala.—At the eastern end of the Salt Range—a seam of variable thickness also worked by the N.W.R. [Cf. Baden-Powell, Pb. Prod., 1868, i., 27-34; Morris, Hazara Coal, 1889; La Touche, Bhag-
wan Coal Fields, Rec. Geol. Surv. Ind., 1894, xxvii.]

13. Mianwalli District, about two miles north of Kalabagh. This is classed as Jurassic coal, but so far regular mining has not been started. More promising Tertiary coal occurs at Maidan, 24 miles further west. [Cf. Simpson, Rept. on Coal, Is Khet, in Rec. Geol. Surv. Ind., 1904, xxxi.]

14. Kashmir.—The Jammu Coalfields—Tertiary; commenced to be worked in 1903. Washed and briquetted Ladda coal would be nearly as valuable as Bengal coal, but could not compete in price. [Cf. La Touche, Lc. xxi., 188; Simpson, Mem. Geol. Surv. Ind., 1904, xxxii.]

Bikanir.

15. Bikanir in Rajputana.—A lignite of dark-brown colour, with included lumps of fossil resin, occurs in association with nummulitic rocks at Palana in the Bikanir State. In 1898 mining operations were commenced at a point where the seam was found to be 20 feet thick. “The physical characters of the natural fuel form a drawback to its use in locomotives, but experiments recently made are said to show that satisfactory briquettes can be made in which the proportion of moisture is reduced, and the fuel made less vulnerable to atmospheric action.” The proximity to railway demands seems likely to counterbalance the inferiority of this coal, of which the output in 1906 amounted to 32,372 tons.

Labour.

WORKING OF MINES: Labour, etc.—Holland may be still further placed under contribution: “Coal-mining in India, from the point of view of labour, is quite ahead of all other forms of mining. The number of persons employed daily has averaged 84,805 for the years 1898 to 1903.” During 1904 the number rose to 92,740, of which 75,749 were employed at the Bengal mines. The Bengal coal-mines thus took 81.7 per cent. of the total labour supply. “It will not be surprising to those who know the habits of the Indian coal-miner to learn that the output per person employed is lower than in any other part of the British Empire except in Cape Colony, where cheap Native labour is largely employed. During the years 1901 and 1902 the outputs of coal per person employed in Indian mines were respectively 70 and 75 tons, whilst for the rest of the British Empire the corresponding figures were 281 and 285 tons.” “An important consideration, naturally, in every mining community is the risk of life involved in the occupation. As far as coal-mining is concerned in India, the industry, so far as it has progressed, has shown not only a very low death-rate from isolated accidents, but also a noteworthy freedom from disasters, which in European countries have done more perhaps than statistics to force special legislation for the protection of workers in ‘dangerous’ occupations.” “The average death-rate from such accidents has been 0.88 per thousand employed, while the average for the rest of the British Empire comes to 1.54 per thousand—in the U.K. 1.24.” But if the death-rate be expressed to the tonnage of coal raised, India is shown up in a much less favourable light. New Zealand heads the list of successful mining from this standpoint with 1.47 persons killed per one million tons of coal raised in 1902; Queensland 1.99; Nova

Output per Person.

338
COMPOSITION OF INDIAN COAL

COAL Properties

Scotia 4·35; United Kingdom 4·42; Victoria 4·44; India 10·23; Transvaal 14·47; New South Wales 17·67; Cape Colony 24·16; Natal 26·99; and British Columbia 99·48. India is thus no means the country in the British Empire that shows the worst result.

"The almost universal practice in Indian coal-mines is to extract the coal on the system variously known as the "bord and pillar," "post and stall," or "stoop and room" system. Although this system in Europe is fast being superseded by the more economical "long-wall" method, yet, owing to the thickness of most of the Indian seams, it is not easy to devise any more suitable plan of working. It is undoubtedly wasteful, for the pillars form from 25 to 65 per cent. of the available coal, and at the present time except in certain mines, where local-trained labour and efficient supervision are possible, their extraction is not even contemplated."

Holland points out that the strong roof in the Gondwana rocks, the freedom from disturbances, and the comparative lightness of the overburden are features of strength and safety not fully appreciated by those who have gained their experience in countries where these advantages do not prevail. In the Giridih coalfield the system of working thick seams there pursued, which is a modification of the South Staffordshire method suggested by Mr. T. H. Ward, allows of 90 per cent. of the coal being removed. Adamson (Trans. Min. and Mech. Engin., 1903, lii., 202) has described fully the "working of a thick coal-seam in Bengal." "In the Makum field a highly inclined seam, 75 feet thick, is worked also on a modification of the South Staffordshire system of 'square work.' The coal is removed in two, or sometimes three sections, the top section being removed first, and a parting of stone and coal being left untouched between each pair of sections. In the Dandot and Khost mines, thin seams are worked in one operation, on modified 'long-wall' system."

PROPERTIES AND USES.—It is difficult, if not impossible, to give a general statement of the properties of Indian coal: the two great geological groups already established differ in almost every essential, and, moreover, the coal varies not only between mines within the same formation but even within the seams of one and the same mine. Averages are therefore often very misleading. The late Mr. H. B. Medlicott accordingly very rightly observed, "In both regions the quality of the coal varies much, as in all coal-measures; but the best in both reaches a very high standard, almost if not quite up to that of high-class English coals. In the Gondwana (Bengal) coal the general defect is an excess of ash, and also in some an excess of moisture; while in the Tertiary (Assam) coal the percentage of ash is low, but that of the volatile combustible matter high, producing a lighter fuel." Medlicott then furnished a table to show the results of various chemical examinations, and, as little of material importance has since been learned, it may be here reproduced:—

THE INDIAN COAL INDUSTRY

These average results, so far as averages go, will be found sufficiently near the truth for all practical purposes.

The moisture and the ash are the chief detraactive features of coal. "Dr. Saise (Rec. Geol. Surv. Ind., 1904, xxxi., 104-7) calls attention, however, to the remarkably constant differences in the percentages of moisture held by coals from the different geological horizons in the fields. In the case of the Barakar stage, which is the lowest in the series, the moisture amounts to only 1 per cent., while in the lower seams of the Raniganj stage it averages 3.81 and in the upper seams 6.86 per cent. There is a parallel but less pronounced variation in the amount of volatile hydrocarbons: in coal from the Barakar stage the average is 26.57 per cent.; in the lower seams of the Raniganj stage it is 31.70, and in the upper seams 32.22 per cent."

In the Records of the Geological Survey of India (1904, xxxi., 237-9) will be found certain results of the coal and coke assays made by Mr. E. P. Martin and Prof. H. Louis at the instance of the Right Hon. Sir E. Cassel, on carefully procured samples from the Jherria and Raniganj fields. It is explained that the samples reported on had been taken from across the entire working face of the seam, and were not picked from a promiscuous pile at the pit mouth or taken from a particular part of the seam. Space cannot be afforded to republish the tables in the original form in which they appeared, but the following averages of the returns may be here given:

Commenting on these results, Holland observes: "The beds in which the coal is now being mined in the Jherria field were long ago correlated by the Geological Survey with the Barakar series of the Raniganj coal-field, and it is interesting to notice that the low percentage of moisture recorded by Saise in the coal of the Barakar series in the Raniganj field is characteristic also of the Barakar coal in the Jherria field. In the case of the Barakar coal from the Raniganj field the moisture amounted on an average to 1.9 per cent., whilst in the case of these Jherria coals the average for moisture is 0.90 per cent."

A comprehensive report on the composition and quality of Indian coals, by Dunstan, will be found in the Records of the Geological Survey of India (l.c. 1906), where complete analyses of coal from all fields above mentioned (excepting those recently opened) are recorded.

In a recent practical experiment conducted with Seebpore coal at the National Jute Mills, Calcutta, by Mr. F. Grover of Leeds, it was found that that particular coal would evaporate 7.97 lb. of water, equivalent,
RELATIVE VALUE OF INDIAN COAL

had certain conditions obtainable in England prevailed, to 8'5 lb. The corresponding efficiency of the best Cardiff coal, it is believed, is but 9 lb. This result has been hailed by certain Indian newspapers as a new discovery of the greatest public interest and value, and one which refutes completely the unfavourable opinions often upheld regarding Indian coal in general. From the remarks already made it may have been inferred that for many years past it has been recognised that the finest Indian coals are little inferior to the best English and Welsh. But laboratory results are theoretical more than practical, and Mr. Grover's experiments are therefore of considerable importance. He has shown, for example, that the assays revealed the percentage of ash to be 11'5, while in the practical tests it came to 16'7 of the original weight. This is the expression of the practical difficulty of firing, and similar instances exist in other directions without invalidating the relative values of chemical assays. But so important is this question of ash that, as pointed out by Grover, a sample of coal could be carried 54 miles farther than another with which it was compared without exceeding the cost per ton of its combustible constituents.

TRADE.—Production and Supply.—In 1883 there were but two localities of Indian coal-production, viz. Bengal and the Central Provinces, and the total output from the mines in these provinces came to only 1,315,976 tons. Ten years later there were nine Indian centres of production (Burma, Assam, Bengal, Central India, Panjâb, Baluchistan, Central Provinces, Nizam's Dominions and Madras) and the output had been doubled (2,562,001 tons valued at Rs. 86,20,278). Still ten years later (1903) there were ten centres of production (Madras had disappeared and Kashmir and Bikanir had been added), but the output increased to 7,438,386 tons, valued at Rs. 1,94,95,741. These figures speak volumes for the mining enterprise of India, but the low price obtained (3s. 8d. per ton at the pit mouth in 1903) probably indicated that until the metallurgical industries have developed into important consumers of coal, present production may be viewed as approaching the limits of demand. But a hopeful sign of the suitability of Indian coal for all ordinary industrial purposes is the downward course of the imports of foreign and the upward tendency of the new trade in exporting Indian coal. This view receives confirmation when it is known that the increased production of the Indian mines has been on a higher ratio than necessitated by the enhanced demands of the railway plus the exports, so that we are warranted in concluding that the industries of India have made a substantial advance within the period in question.

Foreign Trade.—The record year in the imports was 1888-9, when (including Government Stores) India drew from foreign countries (mostly the United Kingdom) 877,843 tons of coal, coke and patent fuel, valued at Rs. 2,00,95,105. Five years later (1893-4) the imports were 591,007 tons, valued at Rs. 1,03,52,699; in 1898-9 they had decreased to 379,225 tons, valued at Rs. 73,60,786; in 1903-4. they were only 206,829 tons, valued at Rs. 38,66,882; and in 1906-7, 262,286 tons, valued at Rs. 49,47,445. Thus there can be little doubt the imports have given place to local production, and obviously so when in 1903, 7,438,386 tons of Indian coal were supplied for about the same sum as fetched only 877,843 tons of foreign coal in 1888.

The following shows the Imports and Exports of Coal, Coke and

341
THE INDIAN COAL INDUSTRY

Patent Fuel during the years 1897-8 to 1906-7 (including Government stores):—

**Average**: 272,486  520,873

In these returns each ton of coke has been counted as 1½ tons of coal.

It has been urged that the above figures are unimportant when contrasted with present production. That may be quite true, but only so long as it is recollected that the imports are now just one-fourth the quantity of those in 1888-9 and that the exports have now (1906-7) exceeded the transactions of the record year of imports. As illustrative of the normal direction of the foreign traffic, it may be explained that by far the major portion of the imports comes from the United Kingdom. The analysis of the total supply in 1906-7 would be as follows:—from United Kingdom 227,158 tons; from Japan 4,505 tons; from Australia 25,863 tons, and from all other countries the balance. The receiving province is Bombay, which in 1906-7 took 220,751 tons out of the total (262,286 tons). Of the exports, Ceylon and the Straits Settlements are the most important foreign receiving countries. Out of the total exports in 1906-7 Ceylon took 404,149 tons and the Straits 293,788 tons, and these figures approximately represent the relative demands of the countries named during the past five years. Practically the whole of the exports are made from the port of Calcutta, which being near the Bengal fields is the natural centre of distribution.

To dream of a future of greatly expanded foreign export of coal from India does not necessarily involve the acceptance of a literal fulfilment of Horace Walpole’s reputed prophecy that “England will be some day conquered by New England or Bengal.” An export trade has become an established fact and one of great possibilities. His Excellency Lord Curzon, after inspecting a portion of the Jharia Coalfield, addressed a company of gentlemen interested in the coal-mining industry on January 22, 1903. Speaking of the foreign trade, his lordship said:—“Indian coal can hardly be expected to get beyond Suez on the west or Singapore on the east. At those points you come up against English coal on the one side and Japanese coal on the other. But I wish to point out that there is a pretty extensive market between, and I think that Indian coal should make a most determined effort to capture it.”

**Coasting Trade.**—The foreign exports represent, however (on an average) but one-fourth the total exports by sea from Calcutta. The other port towns of India itself draw very largely on Bengal for coal. Bombay is by far the most important receiving port: in 1905, 1,067,779 tons were consigned to the western capital. Then comes Rangoon, which in 1905 took 361,572 tons of Bengal coal; Karachi, 343,406; Madras,
LOCAL TRANSACTIONS

199,425; Goa, 21,228 tons, etc. It is by seizing this interprovincial trade that the Bengal mines have so effectually curtailed the foreign imports.

Rail-borne Traffic.—But it must not be forgotten that the figures quoted are neither the total exports from the Bengal mines nor the total receipts of the towns in question. Large quantities are carried by rail and river, and of course from all the other mines besides those of Bengal. The figures reviewed are alone those of the traffic by sea. The total transactions by rail in 1906–7 came to 7,648,688 tons. The corresponding returns for 1899–1900 were 3,921,623 tons. Calcutta drained in 1906–7, 5,353,013 tons, all but 1,868 tons being from the Bengal mines. The United Provinces of Agra and Oudh in the same year received 688,507 tons, chiefly from Bengal. This represents the manufacturing enterprise of Cawnpore mainly. Bombay Presidency obtained Bengal or foreign coal from Bombay town, but over and above fairly large quantities from the Nizam’s Dominions, the Central Provinces, Bengal and Rajputana. Madras Presidency procured its coal from the Nizam’s Dominions and the Madras ports (and therefore very largely Bengal coal). Lastly Mysore State drew on the Madras ports, and consequently consumed Bengal coal chiefly. The bulk of these rail-borne transactions, it may be presumed, are concerned with the internal industries, since the railways derive their supplies direct from the mines, which are often owned and worked by the railway companies.

OUTPUT OF THE INDIAN MINES.—It may suffice the purposes of this abstract of information regarding the location, extent and prosperity of the Indian mines to furnish a collective statement of the production for all India:

### Coal-gas: Coal-tar.

It is exceedingly difficult to obtain information regarding the gas-works of India. In the Financial and Commercial Statistics published by the Government of India for 1904 (more recent figures are not available), mention is made of two gas-works, one in Calcutta, the other in Bombay. These gave employment to 581 persons. It is believed that are other gas-works here and there all over the country, but mostly of a private nature, and therefore not returned under "Larger Industries." It is understood also that English coal is largely, if not exclusively, employed in gas-making, and the by-products of these works are doubtless disposed of but are not worked up to the extent customary in Europe. The coals most suited are coking coals that burn with a long flame.

In the dry distillation of coal and in the manufacture of illuminating gas, volatile products are obtained that condense and separate into (a) a watery liquid and (b) a tarry mass. The former is one of the chief sources of ammonia and its salts (see Alkalis, p. 48), and the latter constitutes coal-tar. (For Wood-Tar, see Pinus, p. 890.) The average results with good coal are:—gas 16.6 per cent.; ammoniacal liquor 14.1 per cent.; tar 5.5 per cent.
COAL-TAR COLOURS

cent., and coke 64 per. cent. From coal-tar may be prepared benzene (the commercial benzol), naphthalene, anthracene and phenol, also pitch. Briefly it may be said that benzene can be converted into aniline, naphthalene into indigotin (indigo), anthracene into alizarine, and phenol into carboxic acid. The reader will find numerous technical works that deal with these substances and their manufacture. [Cf. Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 55-87; Rawson, Gardner and Laycock, Dict. Dyes, Mordants, etc., 1901, 93-110.]

The coal-tar colours may be spoken of as discovered by Dr. (the late Sir) W. H. Perkin in 1856. He was then engaged in a study of the synthetic production of quinine, when he noticed that aniline on being oxidised gave a colouring matter. This he produced separately and gave to the trade under the name of "Mauve." This was the first of the long series of colours destined in a remarkably short time to revolutionise the tinctorial industries of the world—the Aniline and Alizarine Colours. The influence of these modern mineral dyes has been more destructive to the tinctorial and textile industries of India than is commonly supposed. They have deprived the artistic feelings of the people, and demoralised many of the indigenous crafts. But it doubtless can be upheld that the advances of modern tinctorial science have, in their ultimate issues, been in reality more constructive than destructive. The majority of the Indian vegetable dyes are fleeting, especially the yellows and greens. The best colours are the reds and blues. All Indian dyes are relatively expensive and troublesome, and one of the most imminent modern dangers lies in the fact that there are good and bad, cheap and dear, fast and fleeting qualities of the coal-tar dyes. It has been in fact computed that there are at present about 2,000 distinct colours of this kind offered for practical use, the manufacturers of which are often prepared to send expert dyers to the workshops of their customers in order to instruct the operatives in the technicalities of the dyes they sell. Recently it has moreover been proposed that a "key-board" of colours should be established, with fixed numbers for each shade, so that the buyers of Indian goods may be able to dictate the colours to be used. This may be desirable for certain commercial transactions, but with the art crafts it is likely to prove pernicious. All the famed natural dyes and tinctorial combinations of India have been already imitated and their vernacular names given to the fabricated coal-tar preparations (e.g. Peori dye, p. 785), so that nothing is left undone that could expedite the complete overthrow of the indigenous crafts. This statement is abundantly upheld by the returns of the imports. The Anilines and Alizarines received by India were in 1876-7 valued at Rs. 4,60,266; in 1886-7 they were Rs. 10,08,034; in 1896-7 Rs. 60,63,256; in 1903-4 Rs. 82,67,010; in 1905-6 a slight decrease, namely to Rs. 75,71,314; and in 1906-7, Rs. 74,92,704. In another article (under Indigofera, p. 683) mention will be found of the progress in synthetical production of indigo.

Coal: Coke.—An inferior quality of coke is obtained as a by-product of the gas-works. It should not contain more than 10 per cent. ash; it is useful for burning cement and lime, or for domestic purposes. When coal is carbonised in ovens for the express purpose of producing coke, larger quantities are used than during gas-making. Coke is the main product, not the by-product. The coke is therefore superior because it has a higher calorific value. Caking coals are those best suited for
THE INDIAN COAL INDUSTRY

COKING because they form a compact coherent coke, but mixtures of caking and non-caking coal can be successfully carbonised. [Cf. Blount and Bloxam, l.c. 83.]

For many years past the Raniganj, Jherria and Giridih mines have manufactured coke. Their output was in 1902 returned at 128,910 tons, of which Raniganj produced 86,000 tons. Coke-making is a most important industry, and one in which the future will doubtless record much progress. It means the profitable utilisation of coal waste, and the accompanying prosperity of the metallurgical industries. There are two qualities, "hard" and "soft." Ward (Rec. Geol. Surv. Ind., 1904, xxxi., 92 et seq.) has recently published an interesting paper in which he urges the necessity of introducing improved methods of manufacture of coke with a view to recover the valuable by-products presently being wasted. Commenting upon this paper, Holland has explained that the backwardness of India in this matter proceeds from the limited demand for coke for metallurgical purposes. "At present about 300,000 tons only of Indian coal are converted annually into coke, though a demand will naturally increase with the development of metallurgical industries. Even as matters stand at present Mr. Ward has shown that there is good ground for assuming that the additional outlay necessary for closed ovens of the 'recovery' as well as the 'non-recovery' type would be repaid. Assuming that the coal used for coke-making in India contains on an average 0.75 per cent. of available nitrogen, the present system of manufacture in open ovens means an annual loss of 2,250 tons of nitrogen, sufficient that is for the manufacture of 10,613 tons of sulphate of ammonia, which at £13 a ton is worth £137,969 or more than 20½ laks of rupees." As showing the full value of this contention it may be mentioned that it has been ascertained that Java imported in 1901, 21,700 tons, and in 1902, 23,400 tons, of sulphate of ammonia to be used as a sugar fertiliser.

Experiments recently made on a large scale in Germany and America have confirmed the conclusions referred to above with regard to the suitability of Bengal coal for the recovery of ammoniacal by-products, and arrangements are now well advanced for the erection of recovery-ovens on the Giridih, Raniganj and Jherria fields. With a view to improving the local market for the products, experiments are being conducted by the Agricultural Department to test the suitability of ammonium sulphate for Indian sugar-cane and other crops, whilst to meet the probable demand for sulphur the Geological Survey has organised prospecting operations on a large scale in connection with the copper sulphide deposits known to occur within easy distance of the coalfields in Bengal.

But to conclude these remarks on coke, it may be observed that so much has been written on the subject that to give even the more useful references would occupy much space. The Journal of the Society of Chemical Industry teems with descriptions of methods, apparatus and processes in all countries. Similarly, innumerable passages occur in these journals on the distillation of coal; on gas-making; on the gaseous products of coal; on the relation of petroleum to the hydrocarbons of coal; on the influence of lime on coal; on the determination of the nitrogen in coal; on coal-tar; on ammonia, etc., etc., subjects intimately associated with the future of the Indian coal and coke supplies. [Cf. Weeks, Man. of Coke, 1892.]
CoAL: Patent Fuel and Briquettes.—In connection with the observations already made regarding Bikanir, Kashmir and other coals it has been explained that an industry has been organised in the production of briquettes from these inferior coals. This overcomes their excessive moisture and makes them useful fuels. In Europe and America briquettes are produced in many different ways and of widely different materials. It would be beyond the scope of this work to deal with all the forms of briquettes, but the subject receives interest in India through the possibility afforded of utilising coal waste and working up inferior coals.

Other methods of utilising the waste coal and bituminous materials might be mentioned, such as the manufacture of what is known as "water gas," "monde gas" or "heating gas." [Cf. Imp. Inst. Tech. Repts., 1903, 345-6.] The conversion of the accumulation of combustible waste material, near the Indian mines, into gas and finally into electric power might become of infinite value not only to the mines but to numerous possible future industries likely to be originated in their immediate vicinity such as chemical works, potteries, etc.

COCCUS CACTI, Linn.; Milburn, Or. Comm., 1813, ii., 208; Proc. Board Agri. Madras, Nov. 18, 1895, Cocciide. The Cochineal-insect, Scharlach-worm, kirtindana, kirmaz, kiranda, kirm, etc. A Scale Insect native of Central and South America, Mexico, Guatemala, etc., and distributed by cultivation to the West Indies, Teneriffe, the Canary Islands, Algeria, to some extent even to Spain and also to Java, India, etc.

There are said to be two forms or qualities of this insect, the grana fina and grana sylvestris. The former is generally spoken of as the cultivated and the latter as the wild cochineal. The cultivated insect is both larger and more valuable than the wild, but whether these are distinct species or only races of the same insect cannot even now be said to have been definitely settled. The grana fina is reported to be a native of Mexico, whilst the grana sylvestris comes from South America. As against all this confusion only two certain facts can be set forth, the first being that recent and properly authenticated attempts to cultivate the true grana fina in India have utterly failed; the second that on three occasions a Coccus (possibly grana sylvestris) has, so to speak, broken loose in India and utterly destroyed the Opuntia throughout large tracts of the country.

The Cochineal insect was discovered by the Spaniards in Mexico in 1518 and made known to Europe in 1522, but it was not until 1703 that Leeuwenhoek exposed the error of regarding the insect as a seed (grana). It is just possible that the Portuguese may have attempted to introduce it into India in the 17th century, since in 1786 Dr. Anderson of Madras sent to Sir Joseph Banks specimens of a dye-yielding Coccus which may have been a form of cochineal; and this seems to have determined the East India Company to endeavour to introduce the true insect. Accordingly in 1795 Captain Neilson (Royle, Prod. Res. Ind., 1840, 60) brought from Brazil some Opuntia leaves with the insects still adhering. This was apparently, however, the grana sylvestris. But, as already stated, there is no knowledge of the acclimatisation of the grana fina in India. I may express my indebtedness to Major D. G. Crawford, I.M.S., for having called my attention to a passage in Seton Karr’s Selections from the Calcutta Gazetteer (ii., 602) — "Nov. 10th, 1796. Riska advises for sale 'that pleasant and well-known villa of Rissura, about 50 bighas of ground and 120 bighas of Nepaulry, fully planted and now ready to receive the insect.' The well-known villa may have been Warren Hastings’ house at Risha." It is not known whether a purchaser was ever found, but there is no doubt that about the time indicated, Indian public opinion was greatly concerned with the prospect of a satisfactory acclimatisation of the true cochineal. The chemical achievements of subsequent years completely obliterated, however, all interest in the dye, and Riska is no more a popular resort but a jungle of Opuntia and other weeds. [Cf. F. Brandt. Cult. of Silk, résumé from Rec. Madras Govt. and Board of Rev., 1871, 2 (Cochineal

Two Forms of the Insect.

Habitat.

History.

Introduction into India.

Nepaulry.

Warren Hastings’ House.
introduced by Dr. Anderson); also "Nopalry" (defined as "Garden for Cultivation of Cochineal Plant and Insect.").

The favourite (and apparently the exclusive) food-plants of cochinche are various forms of *Opuntia* or *Nopal*—the prickly pear (see *Opuntia*, p. 822). The *grana* feeds mostly on *Opuntia coecinillifera*, Haw., whilst the *grana* *sylvestris* is reported to live on several species, including *O. monacantha*, Haw., and the common Indian form *O. Dillettii*, Haw. Considering the prevalence of the species of *Opuntia*, it may be said there are not many recently collected specimens of the genus from India in the Royal Herbarium, Kew. Five species are, however, represented by the sets present, and these in alphabetical sequence are: *O. decumanus*, *O. Dillettii*, *O. fleus-indicus*, *O. monacantha* and *O. tuna*. There is no specimen of *O. coecinillifera*, and—which may also be regarded as somewhat significant—there is only one specimen of *O. Dillettii* from Madras, and that contributed in 1886, so that it would almost seem as if that plant had not been known, or at all events little experimented with in South India, much before the first decade of the 19th century. On the other hand, there are admirable samples from Madras of the other species just named, which are stated to have been collected from Dr. Anderson's garden on April 19, 1809. These are accordingly historic specimens. Of *O. monacantha* it is said that it was "the food of the wild cochinche." That same species has on two subsequent occasions been sent from Madras Presidency and once from the Panjáb, so that it is probably widely distributed in India, and completely acclimatised. Of *O. fleus-indicus* another Madras historic sheet bears on the label the following observation: "It is not eaten by the wild cochinche." The specimen of *O. decumanus* was wrongly named *O. coecinillifera* in the series from Dr. Anderson's garden, but there is no mention of whether or not the true cochinche insect fed on this or any other species grown in Madras. *O. decumanus* has more recently, however, been sent from Madras, so that it appears to have become acclimatised. Lastly there is only one sheet of *O. tuna*, and it also came from Dr. Anderson's garden in Madras.

Most of the Indian specimens of *Opuntia* preserved in the Herbarium, Kew, bear a parasitic scale insect (possibly a species of *Diaplocus*), but no trace of cochineal. It thus seems possible the sudden extermination of the Opuntias of certain districts (such as that mentioned in Wilks, *Hist. Mysore*, iii., 89, in connection with Tippu Sultan) might be accomplished by the parasite mentioned, without supposing the sudden appearance and disappearance of a form of cochineal. The fact, however, that certain Indian writers affirm that the cochineal will only feed on red-flowered Opuntia while others say that it prefers the yellow-flowered plant, is perhaps best explained by the supposition that there are at least two races or species of cochinche in India, though as yet not separately recognised by entomologists. Dr. Bourne (Rept., July 26, 1897) obtained *grana sylvestris* insects from Ganjam and found these on the yellow-flowered *Opuntia*; they lived for a short time, and only a little longer on the red. He accordingly inferred that as a measure of extermination of *Opuntia* the rearing of any form of cochineal was attended with so much difficulty that it was a failure. But it cannot thus be asked, would similar failure necessarily result with all the other species of Scale Insect seen on the Opuntias?

The cochineal insect at its birth is viviparous and the male and female larve are not distinguishable even under the microscope. After a few days, however, they fasten to the cactus-leaf, lose the power of locomotion, and become covered—the *grana fina* by a short white down, and the *grana sylvestris* by a much longer cottony substance which conceals the insect. The creature destined to become the male is enveloped, along with the females, but in time becomes encased within a separate pouch or purse open at the bottom. From this in due time it emerges as a scarlet fly possessed of long transparent wings. It rarely flies, however, to any distance but jumps and flutters about while visiting the females, and shortly after dies. The female, on the other hand, never emerges from her case as a winged insect, in fact never moves again from the position she took as a larva, but becomes absolutely torpid, round in shape, loses her eyes and even all form of a head. She derives nourishment by means of a hollow pointed tube, which she plunges into the fleshy texture of the cactus. She begins to yield her offspring after about three months, and it is at this stage that the process of "nesting" is begun. Some eight or ten females are picked off the cactus and put into a little bag of cotton-gauze or other cellular tissue, which is fastened to the underside of a fresh cactus-leaf by means of a thorn. The young larve escape, seek out good positions, and when fixed repeat their cycle of birth, growth and death.
HISTORY OF COCHINEAL DYE

The female alone produces the dye, and is gathered for that purpose immediately before the birth of her young. It is said that if the insects are stove-dried, their natural white powderly covering is retained, and the more valuable "silver-grey cochineal" produced, but if killed by steam or hot water they lose their covering and "black cochineal" is the result. There is, however, an alternative opinion to the effect that quality depends on choosing the right period to gather the insects. There are three commercial grades, viz. "silver grain," "black grain," and the little valued "granilla."

USES AND COMMERCIAL FORMS OF COCHINEAL.—Cochineal was formerly much employed in dyeing wool, silk, and cotton: to-day it is a colour-ingredient of drugs and confectionery, and an artists' pigment. It is almost entirely replaced by aniline dyes. Two different reds are obtainable from it—a bluish-red called crimson, and a fiery-red called scarlet. The great reputation these dyes enjoyed for many years gave to the English language the expression "ingrained."

Cochineal is comparatively rich in tinctorial matter compared with most of the other natural dyes; it contains from 10 to 20 per cent, of the pure substance which exists as a glucoside, "carminic acid," from which the true colouring matter, carmine red, is readily produced. The dye-stuff requires no preparation for the market, but before being employed by the dyer the insects are beaten to a powder. As already observed, the most valuable commercial form is "silver-grey" or "silver grain," the white film which is here retained being due to a natural wax coccein amounting to about 1 or 2 per cent, of the weight of the substance. This silvery coating is sometimes imitated by facing the cochineal with talc and other mineral matter. In dyeing, cochineal is almost exclusively used for the production of scarlet shades on wool in conjunction with a mordant of tin. With alum mordant it yields a crimson shade. The Spanish historian Herrera tells us that alum was the mordant used by the Mexicans, and certainly, as far as Europe is concerned, it was not until 1643 that "Kuster or Kesler, a German chemist," brought to London the secret of using a tin solution in producing the true scarlet. This secret he communicated to a Flemish painter, who in turn told or sold it to the famous Gobelins, whose tapestries embraced practically the first instances of scarlet-dyed hangings.

In connection with painters' colours, red inks, etc., the best-known modern application of cochineal is in combination with alumina and tin to produce Carminine (D.E.P., ii. 167) which is an almost pure lake. The best quality is known commercially as acarant carmine and is insoluble in water, alcohol, ether, turpentine, etc., but soluble in strong mineral acids. Other lakes prepared with cochineal are Florentine and Crimson-lake. None of the preparations retain their intensity of colour when long exposed to light. [Cf. Hurst, Painters' Colours, etc., 1901, 261; Rawson, Gardner and Laycock, Dict. Dyes, etc., 1901, 119; Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 327.]

TRADE.—As a dye, cochineal has been to a great extent superseded by aniline dyes, and this supersession appears to be steadily increasing. Thus the average quantity of cochineal imported by India annually during the five years 1894-5 to 1898-9 was 1,829 cwt. During the seven years 1899-1900 to 1905-6 the average was only 1,553 cwt. In 1905-6 the amount had fallen to 1,156 cwt., valued at Rs. 1,19,417, though in 1904-5 it rose to 1,350 cwt. (Rs. 2,22,914), and in 1905-6 to 1,533 cwt. (Rs. 2,62,568). In the same period of twelve years the imports of aniline dyes had increased by just over 100 per cent, totalling in 1906-7, 6,003,849 lb., valued at Rs. 45,55,054. Cochineal comes almost exclusively from the United Kingdom and France to Bombay. The re-export trade has practically vanished. [Cf. Paulus Egirneta (Adams Comment.), 1847, iii., 180; Honigberger, Thirty-five Years in the East, ii., 258; Hoey, Monog. Trade and Manuf. N. Ind., 1850, 170; Pharmacog. Cocoanut.
THE COCOANUT PALM

284–7; Cook, Orig. and Dist. Cocoa Palm (contrib. from Nat. Herb. U.S.A.), 1901, 257–93; Gamble, Man. Ind. Timbs., 1902, 739; Safford, Useful Pl. of Guam (contrib. from U.S.A.), 1905, 233–43; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 198–200; Palmeae. The Cocoanut (Coconut) Palm, Porcupine-wood, known as the chief Indian and Eastern vernaculars as nādi, nāriyal, nārikel, nāryil, maar, tenga, thenpinna, kōbbi, nar, kalapa, (Mal.), pol (Sinh.), ong (Burm.), niu (Poly.), etc., etc. This tall pinnate-leaved palm is indigenous to the islands of the Indian and Pacific Oceans, but now cultivated throughout the tropics in all warm moist situations, such as along the sea-coasts of India and Burma.

Habitat.—The cocoanut is essentially a tropical plant, and while it can grow up to the 25th degree N. or S. latitudes, it but rarely ripens fruit in the extreme limits of its region. From the Bay of Bengal it follows the Gangetic basin inland some 200 miles, but on the coast of India generally does not penetrate for more than half that distance. Buchanan-Hamilton (Stat. Acc. Dinajp., 1833, 150) found that it ripened fruit with difficulty at Dinajpur, but I have seen it do so at Falakata, which is considerably farther to the north, and a writer (Journ. Agri.-Hort. Soc. Ind., 1898) speaks of it fruiting freely at Dam Dim in Jalpaiguri, or 300 miles from the sea. It also fruits abundantly in South Sylhet. It would thus appear that the limit of fruit-production, viz. the 25th degree, is frequently exceeded in the immediate basins of large rivers. Hence it may even grow in Assam, though it will there ripen its fruits very indifferently. On the west and south coasts of India, on the other hand, its cultivated distribution is much more restricted. In Kolaba and elsewhere it may be found on the immediate shore and for 50 to 80 miles inland, ascending the hills to about 3,000 feet. Further to the South in Mysore, for example, it passes inland to nearly double that distance. It very possibly gave the name to the Coco Islands and is plentiful on the Laccadive and Nicobar groups, but not in South Andaman. Gamble says "the cocoanut palm is not, like the palmyra, a forest tree, though it may be seen practically in forest, grown in gregarious plantations all round the Indian coasts and on some of the islands." The Indian region may thus be said to be the lower basins of the Ganges, Brahmaputra and Irrawaddy, also the Malabar and Coromandel Coasts and adjacent islands—Madras Presidency being the chief producing area.

History.—On the assumption that it originated in the islands of the Indian and Pacific, there would be little to prevent its having been carried even by currents of the sea, or in some cases by primitive man, to the western shores of America and to the coasts of Southern China, Siam, Burma and India, in prehistoric times. This is so natural and obvious a supposition as to render most of the learned arguments indulged in by authors on this subject superfluous. The Spanish, Portuguese and Dutch travellers may have greatly aided in its distribution, more especially in conveying it to the east coast of America, to the West Indies and to Africa, but a wide natural distribution had doubtless taken place long anterior to the discovery of America. It is, therefore, hardly of serious consequence whether or not it may have been indigenous to tropical America as well as to certain of the islands of the Pacific. Its natural habitat is undoubtedly maritime. It is known by so many widely diversified names, in the regions of its present production, as to necessitate a vast antiquity. But as possibly indicative of a stronger claim for an Asiatic than an American origin, derivatives from its Sanskrit name nāri-kēla have accompanied the palm eastward very nearly to the shores of America and westward to Madagascar and Turkey, to a far greater extent than can be shown for any other classic or ancient name that it possesses. This does not of necessity involve its being accepted as indigenous to India, but simply that its extended cultivation accompanied Sanskrit influence.
DE Candolle ultimately inclined to the idea of an origin in the Indian Archipelago. [Cf. Orig. Cult. Plants, 429-35.] Cook has taken great pains to refute De Candolle's arguments and thus to stoutly uphold an American origin. He maintains that it is no fault of the palm that the early inhabitants of America neglected to record its history, but similarly neither was that neglect India's "fault." We are justified in dealing with the records that exist. Wiesner (Die Rohst. des Pflanzenr., 1903, ii., 419) advances no personal opinion but quotes authority for a dual nationality (American and Asiatic.) Junelle (Les Cult. Colon., 1901, 88-101) is opposed to the belief that the nuts were brought by currents from America to India and inclines rather to the view of an Indian origin. The plant was known to Cosmas in the 6th century A.D. (who calls it argellion, a name doubtless derived from the Sanskrit), and John of Monte Corvino, in the 13th century, speaks of it as the "Indian Nut " (as the Arabs do to this day). [Cf. Yule, Cathay and The Way Thither (ed. Hakl. Soc.), clxxvi., 213.] It was also seen and mentioned by Marco Polo in the 13th century, under the name "Indian Nut.” [Cf. Travels (ed. Yule), i., 102; ii., 236, 248, etc.] In later times exhaustive and most picturesque accounts of the cocoanut in India were given by Varthema (Travels, 1510 (ed. Hakl. Soc.), 163), by Linschoten (1598 (ed. Hakl. Soc.), ii., 43-51), by Baber (Memoire, 1526, Leyden and Erskine, transl., 327), and by Abul Fazl (Ain-i-Akbari), etc., etc., to whose accounts the well-known description in Household Words, and later that of Tschirch (Indische Heil- und Nutzpflanzen, 1892, 144-56) appear to owe much. The question of the early European knowledge of the cocoanut is discussed by Rumphius (Herb. Amb., 1750, i., 8), who quotes the passages of Theophrastus (Hist. Pl., iv., 2 (ed. Scaliger), 1644, 286) and of Pliny (Hist. Nat., xiii., ch. 9 (Holland transl.), 1601, 399) which have been supposed to refer to *Cocos nucifera*. The names given by these ancient authors are Cucif&era and Cocos, but cocus might be given to any nut. A much more likely derivation is that furnished by Barros (1553), Garcia de Orta and Linschoten, viz. from the Spanish coco (macaco, Portuguese) applied to a monkey's face, an admirable allusion to the three scars or markings on the base of the shell. Coca (a shell) might have been the primitive suggestion of that name. [Cf. Oviedo, Hist. Gen. Nat. de las Ind., 1526 (ed. 1851), i., 335: Garcia de Orta, 1563, Coll., xvi.; Acosta, Tract. de las Drogas, 1578, 107; Pyrard, Voy. E. Ind., 1601 (ed. Hakl. Soc.), ii., 372-86, etc.]; Clusius, Arom. Hist., 1605, i., ch. xxvi.; Boym, Pl. Sin., 1656, i-12; Thevenot, Travels in Levant, Indostan, etc., 1687, pt. iii., 17; Hamilton, New Acc. E. Ind., 1727, i., 296, 306; Forster, Pl. Esc., 1786, 45; Sprengel, Hist. Rei Herb., 1808, 103, 269; Milburn, Or. Comm., 1813 i., p. 277-8; Paulus Agrineta (Adams Comment.), 1847, iii., 438-9; Hobson-Jobson (ed. Crooke), 1903, 228-9, 233-4; Joret, Les Pl. dans l’Antiqu., 1904, ii., 299, 360.]

**CULTIVATION.**—For seed purposes ripe nuts should be chosen from trees of mature growth but not too old. After being kept from four to six weeks, seed-nuts are planted just below the surface of the soil and about a foot apart. Ashes and salt are freely scattered in the trenches as manure and as a protection against insects. The seedlings thus obtained may be planted out from two to six or more months later, preferably at the beginning of the rains. Such is the usual method, which will be found described fully in the Dictionary. In some parts of India, however, the young plants are not removed from the seed-beds for one or even two years. In Java and the South Sea Islands the Natives hang the nuts for some months in the open air, under the eaves of their houses, until the shoots and roots appear. The seedlings are then put into the positions which they are to occupy permanently. This method has been freely adopted by European planters owing to its great saving of labour and the ready facility it affords for rejecting bad or weak plants. A further method is to leave the nuts to dry for four to six weeks and then to lay them close together in a damp shady place until the shoots that appear from them are about 10 to 12 inches long. They are then planted in their permanent positions, and should not stand nearer each other than from 25 to 30 feet apart each way. It should be remembered that for

fructification the cocoanut requires absolutely open air and plenty of sunshine. The subsequent treatment consists in hoeing the ground around the stems and manuring them, especially with salt, at the beginning of the rains. They may be easily transplanted when only a few years old, and in many cases with advantage, but the new pits into which they are placed must be filled with good soil, manure, and a little salt. [Cf. Produce World, Jan. 17, 1896.]

Yield.—Cocoanut palms will bear fruit, according to the locality and the care expended on them, in from five to ten years. They throw out a spathe and a leaf every month, and each flowering spike yields from ten to twenty-five nuts. The yield varies according to the soil, climate, care expended, and also variety grown. It has been placed by some authors as high as 200 to 300, by others as low as 30 nuts per tree per annum, but a safe average might be 80 to 100, or say 5,000 nuts per acre; and at 4 lb. to each fruit this would give a total crop weight of 6½ tons an acre. Lastly, the palm will continue to bear such crops for 70 to 80 years.

Cultivated Forms.—Although the Natives recognise many varieties or races, these are doubtfully distinct botanically. Moreover, they are so numerous that it would be almost impossible to enumerate even the better known "sports" and cultivated conditions that are claimed to exist. There are, for example, 25 commonly counted in Java—Miquel especially describes and names 18 of these and calls them varieties; 40 in the Philippines; 5 recognised in Ceylon; 30 in Travancore alone according to Dr. Shortt; lastly, Junelle (l.c. 92) and Firminger, both compiling from M. Le Goux de Flaise, say of India that it is customary to recognise 7 forms:—(1) Coromandel or Brahmin nut, a yellowish-red form; (2) the Kanara, a very woody ovoid nut; (3) the Malabar; (4) Maldives, small and spherical; (5) Achem, small and ovoid; (6) Nicobar or pointed nut, the biggest of all, and (7) the Ceylon nut. The Brahmin nut is esteemed for its milk but is inferior in kopra and coir. Of Ceylon it is said there are two special dwarf forms: (a) the King Cocoanut, which produces a golden-coloured fruit, but rarely attains a greater height than 20 feet. It is confined to the gardens of the better classes. (b) A still smaller plant much sought after.

Soil and Climate.—All writers admit that the palm will grow effectively on sandy soil, but Semler and others point out quite clearly that it must not be dry sand. Many soils otherwise unsuitable can be adapted by adding the necessary manures; thus clay soils can be made porous by admixture of sand and fertilised by the addition of calcareous salts. Junelle observes that the cocoanut requires heat, moisture, a porous soil, calcareous salts, alkaline salts, a certain quantity of sea-salt, and a fair amount of animal manure. It should be noted, however, that animal manure if too freely applied is apt to encourage a weevil pest (vide infra). The best manure (vegetable) appears to be cocoanut husks. [Cf. Trop. Agr. , 1893, xiii., 106-8.] Semler observes that the most desirable position is a porous soil sufficiently near the sea that at high tides the sea-water may permeate the trenches cut for that purpose. Cochran (Trop. Agr. , 1897, xvii., 173) and Junelle (l.c. 94) give chemical analyses to show how very important salt is as a manure for this palm.

It is necessary that the temperature should be fairly even all the year round, 75° and 50° F. being the extremes. If the rainfall be evenly distributed throughout the year some 48 to 50 in. will suffice, but if less, 352
CULTIVATION IN INDIA

the planter must resort to artificial irrigation. [Cf. Baur, Ind. Gard., Dec. 14, 1899; Cochran, Trop. Agri., 1900, xix.]

ADDITIONAL PECULIARITIES OF INDIAN CULTIVATION.—Bombay.—The cocoanut is only common in the south of this Presidency, and its chief value lies in the rich supply of toddy it affords. In Kolaba district, however, the soil and climate are found so suitable that the toddy exceeds the demand. The average annual yield of nuts is said to be about 120 per tree, and each palm may be reckoned to have cost about Rs. 9 up to the point at which it begins to yield. In Thana district the annual yield is estimated at 75 nuts to each palm. The dry nuts are sometimes thrown into a well and left to sprout there, being subsequently put into a nursery: or they are allowed to fall from the tree and then buried. In the Kathiavar district they are planted and grown in pits 31 by 3 feet in diameter, cut out of solid limestone and filled with mould. In Kanara, Kathiavar and Ratnagiri the cocoanut is abundant, and in the latter district the average annual profit from each tree is said to be about Rs. 1-3-0. During the "Naral Purnima" or Cocoanut Festival of the Hindus, which is supposed to mark the end of the monsoon in August, Bombay Natives throw nuts into the sea to propitiate the god of storms. [Cf. Madras Mail, Aug. 23, 1899.]

Madras.—This Presidency, especially the Malabar and Coromandel Coasts, is the chief seat of the Indian cocoanut industry. The Laccadivo Islands also send their contingents to ports on the Malabar Coast, the produce of both being reckoned together. The Maldives are under a Sultan who is subordinate to the Governor of Ceylon; the coir produced is conveyed to India and lost sight of in the customary trade returns. The Godavari district has been called the "Paradise of the Cocoanut palm," the delta of the river showing an abundance of the trees. Mr. Lushington, District Forest Officer of Kistna, stated in the Tropical Agriculturist (Jan. 1, 1895, xiv., 437) that 200 nuts per annum was a very moderate estimate for good fruiting trees in the Godavari district, and indeed an even higher average (250 to 300 nuts per annum) has been quoted for Ceylon.

Godavarei.

In Trivancore, 800,000 trees were counted during settlement operations in 1902, and it is estimated that 25 per cent. should be added for non-taxpaying areas. [Cf. Capital, Oct. 30, 1902.] In South Kanara, plantations extend along the whole coast-line, the average to the acre being about 120 trees each, yielding 40 to 50 nuts annually. The seed-nuts are usually not plucked but allowed to fall from the trees.

In Mysore there are said to be four varieties of the cocoanut—red, red and green, light green and dark green. Toddy is not made from the palm, as the fruit is more valuable. Occasionally a few green nuts are cut for the juice and for their fibre. The Mysore cultivation is to some extent peculiar, and a full account of it will be found in the Dictionary.

On the Nicobar Islands the palm is very abundant, the annual yield being estimated at about 10,000,000 nuts. In the Andamans it is said to be a comparatively recent introduction. In 1901–2 there were estimated to be 42,997 cocoanut trees in bearing and 64,921 not, and in the same year 428,897 nuts were received into the oil-factory at Viper.

In Burma success would appear to depend largely on the district. Mason (Burma and Its People (ed. Theobald), 1883, ii., 143) says that the palm will not thrive except near the sea, and in many parts the seedlings are believed to damping off. Some years ago it was reported there were 10,000 acres under coconuts in the Bassin district of Pegu alone.

In Bengal the cocoanut is plentiful throughout the lower Gangetic basin, but as a rule only in garden cultivation, and the produce is not much in excess of local demand. Phoenix and not Coccos is the palm used in this province as the source of toddy and sugar. In the districts of Barrisaal, Backergange and Noakhali it is extensively grown in plantations by itself or along with the Areca-nut palm. Throughout Bengal the opinion prevails that to fruit well the lower two or three leaves must be removed in September.

In Upper India and the Central Provinces the cocoanut is not cultivated.

ENEMIES TO THE COCOANUT.—The greatest danger to which this palm is subject arises from the attacks of various insects, mostly the grubs of beetles. Of these the Borer savus, a large insect with a reddish-brown head, appears to attack the root and subsequently to find its way into the stem; it is believed to be especially prevalent when the ground has been too richly manured. Junellus (L. 100) says a similar insect lays its eggs in the stem and the larvae bore...
their way to the terminal bud, which they devour. The danger of such pests is averted in the Straits Settlements by sprinkling the young palms with salt water. Another destructive beetle is Calandra palaearcr, a species of Elephant-beetle which destroys both the young leaves and the terminal bud, thus rapidly killing the palm. It is especially prevalent in the Malay States. On the Coromandel Coast boring grubs are extracted by means of a barbed steel probe. They are eaten as a delicacy by the Burmans, who are great adepts at extracting them. The Rhinoceros-beetle (Oryctes rhinoceros, Linn.), a large black or brown scarab, has been reported as especially destructive to palm trees in Madras and Singapore. It damages the trees by cutting holes through the young leaf-shoots. The larvae of a large weevil (Rhyynchophorus ferrugineus, Ills.) kill a great number of trees by tunnelling into the trunks. The only cure for this is extraction, though the use of salt and brine is often beneficial.

The leaves of the palm are also much injured by other insect pests and the life-sap sucked from the plant. Certain of the COCCIDE—namely, the Scale Blights—such as Aspidiotus destructor, Signoret, and Dactylipiws coccis, Maskell, are especially destructive in the Laccadive Islands, and are the more dangerous because it is difficult to proceed against them by ordinary methods of spraying. [Cf. Maskell, in Ind. Mus. Notes, 1896, ii., 1, 66-7.] Semler says (I.c. 645) that a large wasp is in the habit of making its nest in the young fruit. The only remedy is the destruction of the nest.

Larger and more easily checked enemies are rats, squirrels, flying-foxes, wild cats, tree-dogs (Paradoxurus), etc., which sometimes eat the young fruits and often destroy the terminal bud. As a remedy, Semler suggests that a preparation of cocoanut kernel with arsenic, pulverised glass and strychnine, or the like, should be put into cocoanut shells and hung in the trees. Against rats the mongoose is the best protection. Nicholls recommends covering the trunk of the palm with sheets of tin or galvanised iron for some twelve inches, the rats being unable to climb over these. The young plants must also be protected against the ravages of wild hogs, elephants, cows and porcupines. When a palm is actually been killed by beetles or other pests, care should be taken to destroy the whole stem by fire, as a single palm left lying or utilised for posts, rails, handrails to foot-bridges, etc., may contain and send out enough of the pests to destroy an entire plantation. It has accordingly been suggested that the preservation by planters of infected timber as well as the non-destruction of infected cocoanut-refuse should be made a statutory offence, since such nearly always constitutes a public nuisance and too often involves a public disaster. [Cf. Ridley, Rept. on Destruction of Cocoanuts by Beetles, Singapore, 1889; Tonnell, Ceylon, ii., 529; Ind. Mus. Notes, 1891, i., 8-9; 1893, 175; 1903, v., 127; Watt, Plague in Betel-nuts, Agri. Lecdg., 1901, No. 8, 149; Trop. Agri., 1904, xxii., 636; Butler, Diseases of Cocoanut, in Board Rev. Madras, 1908, No. 768.]

FIBRE.—This useful plant yields various fibres or fibrous materials. A delicate tomentum or cotton, found at the base of the leaf, is employed as a styptic. The leaves may be used like those of other palms for many of the purposes of paper. The leaflets of two or more leaves are braided into mats that are used in house-construction. They are also often stripped off and made into brooms, or their midribs separated and so used. Again, the leaves are frequently employed as thatch, and dried they may be utilised as crude torches. The half-fruit (nut with adhering pericarp) is largely used as a scrubber.

History.—The important fibre, however, is of course the Coir which is obtained from the thick outer wall of the fruit (or husk). This seems to have been known to the early Arab writers as kanbár, being so called, for example, by Albirúni (cf. Journ. As., ser. iv., tom. viii., 266) in the 11th and by Ibn Batuta (Voyages, etc., Soc. Asiatische, 1858, iv., 121) in the 14th centuries. Correa (Lendas da India, ii., 129-30) tells us that the Governor (Alboquerque) of Cananor devoted much care (1510 A.D.) to the preparation of cables and rigging of coir (cairo), of which there was great abundance. Pyrrard (Voy. E. Ind. (ed. Hakl. Soc.), 1887, i., 250) speaks of the revenue having been paid (in 1610 A.D.) of cairo by the Mal-
COIR FIBRE

dives. The word coir did not come into the English language until the eighteenth century. It is doubtless an Anglicised version through Portuguese coil of the Malayal verb kâyâru = to twist (kâyâr, Mal. and kâyîru, Tamm.). Both the fibre and the rope made from it appear to have been exported to Europe in the middle of the 16th century under the name kâmbar, a misrendering, very possibly, of kâyâr. But it was actually not until the Great Exhibition of 1851 that coir rope and matting attained commercial importance in England. Thus Milburn, writing as late as 1813, observes that cocoanuts are an article of considerable trade in all parts of India, and that coir ropes are much esteemed there. He says nothing at all of any exports to Europe. It deserves notice, too, that the collections of early letters of the East India Co.'s servants, published by Mr. W. Foster, contain no reference to the cocoanut fibre.

Production.—Taking India as a whole, coir is only obtained as a by-product. As will be seen under the notes on trade, the present-day Indian exports are almost entirely made from Bombay and Madras, and it may be said that Madras, Cochin, the Laccadives and Malabar are the only parts of India that produce coir on a commercial scale. According to the Manual of S. Kanara (1895, ii., 147–8) about 5,000 persons depend for their living on the manufacture and sale of coir in that district. It is further said that 3,000 cocoanuts produce 1 candy of coir. The cost of raw material and manufacture is about Rs. 15 and the selling price about Rs. 20 per candy. Elsewhere in India the fibre is dark and coarse, and not comparable to the fine qualities of the above-named districts or to that of Ceylon or Singapore. There are many reasons for this. Situation is one; the fibre would seem to become coarser at a distance from the coast; but variety, age at which the nut is gathered, care and skill in steeping, beating, and cleaning the fibre, etc., etc., are all factors of no small importance. If the palm be cultivated for the supply of juice or to afford ripe fruit, the fibre usually proves in the one case imperfectly formed and in the other overripe. Such, at least, is the common opinion, although according to Wiesner (l.c. ii., 420) only three varieties of C. nucifera are really suitable for the production of coir, viz. rutila, cupuliformis, and stupposa, and the first named gives the finest and most elastic fibre. These are three out of the eighteen forms given by Miquel. Wiesner, however, would appear to have adopted for general application a criticism which Miquel (l.c. 65) originally intended exclusively for the Dutch East Indies. In many countries such as Guam a specially long fruit is grown for the express purpose of affording the long straight-ristle fibre. Of Indian coir it has been commonly affirmed that the best comes from Cochin, and that as a result attempts have been made to imitate the light colour of the Cochin fibre by bleaching. But the chemicals used in this process destroy the elasticity of the fibre and render good qualities bad and inferior qualities worthless. Neither does it seem quite clear whether by Cochin coir is meant commercially the produce of the Native State or that of the whole coast of Malabar, or indeed all high qualities from whatever country obtained. It is said that for fibre the nuts should be cut in the tenth month; it would appear, however that a large quantity of ripe nuts are exported to Europe in husk and the coir separated on arrival.

Manipulation.—Concise accounts of the various local methods of removing the fibre from the shell and of separating and cleaning the coir have been given in the Dictionary (l.c. 428–30), to which the reader is referred.
THE COCOANUT PALM

Briefly it may be said that for the first process an iron spike is fixed in the ground with point upwards, and that the nut is so struck on this that the point penetrates between the nut and the husk, and causes them to separate. A Native can treat in this way about 1,000 nuts daily. Although many machines have been tried for this purpose, hitherto none have been found which can compete with hand-labour. The husks after being retted in brackish or sweet water for 7 to 18 months are crushed either by hand or by machinery, and the fibre extracted. Fresh water is said to injure the fibre. The retting process is sometimes dispensed with, the husk being steamed till the fibre separates. After ing dried the fibre is "willowed" or cleaned of dust and refuse, and it is finally separated into various grades or qualities such as "mat" or long fibres (used for spinning purposes); "brush and broom 'bristle'"—the shorter and stiffer fibres; upholstery, the tow or curled fibre; and the dust or refuse employed as a manure and for other purposes. The best bristle fibre done up in small bundles, and with the fibre stretched straight and clean, may fetch £30 a ton. The mat fibre is worth £20 per ton and the waste £10 a ton.

Under a high pressure a cocoanut dust was found to make a rather brittle cardboard which on being touched by water would instantly swell up and close any hole made in it. This was looked upon, some ten years ago, as a valuable discovery for rendering warships practically unsinkable by gun-fire. The ordinary uses of coir, coir-yarn, etc., are so well known in most households, that it seems superfluous to attempt an enumeration. Coir-matting, coir-ropes, cocoanut brooms and besoms, hussocks, hammer, "bass" for nursery men, bags for seed-crushers, oil-presses, etc., are amongst the many forms of manufactured coir. Coir rope is especially serviceable in India because it does not suffer from the damp climate, and sails are accordingly sometimes made of coarse coir-cloth. In the Laccadive Islands mats made of cocoanut leaves are used as sails. In Ceylon and India the fronds are split and woven into neat baskets. [Cf. Dodge, *Useful Fibre Plants of the World*, 120-3.]

**Yield.**—As regards yield of fibre per nut and price, it has been said that 10,000 husks treated in England yield about 50 cwt. of spinning fibre and 10 cwt. of brush fibre. In Ceylon 40 nuts are reported to give 6 lb. of coir (or say 13½ cwt. to 10,000); in Madras 18 large nuts and in the Laccadives 60 small nuts give a similar amount; but whereas a pound of Laccadive coir spins to 35 fathoms (210 feet), a pound of the coir from large Madras nuts will only measure 22 fathoms (132 feet).

**Prices.**—The quotations for Coir on the London market, as published by Messrs. Ide & Christie, October 15, 1907, may be here given. The spot values were as follows:--

COPRA (KOPRA) AND OIL.—The kernel of the cocoanut sliced and dried either in the sun or artificially is called Copra (Kopra). It contains from 30 to 50, some say even up to 70 per cent. of fixed oil. The fully ripe cocoanuts only are used in making copra, but though the quantity is less the quality is said to be higher in three-quarters ripe than in fully ripe fruits. But the oil may be expressed either from the fresh kernel or from the dried kernel, and by a hot wet or dry cold process. Artificially dried copra is often smoked, and as this colours the oil its value is thereby lowered. Mr. Cochran (Man. Chem. Anal.; also Trop. Agr., May 1, 1893, xii., 665; July 1, 1899, xix., 44) gives the composition of copra thus:—moisture 6 per cent.; oil 67 per cent.; albuminoids 6-69 per cent.; carbohydrates 15:21 per cent.; woody fibre 2:11 per cent.; and ash 2:99 per cent. Smelser (loc. cit.) observes that sun-dried copra contains about 50 per cent. of oil, artificially dried 60 per cent., and if dried at the boiling point of water it may contain 66 per cent.

Oil.—Dunstan (Edible Oils, loc. 129) gives his examination of Malabar, Bengal and Bombay samples. The Malabar had an acid value as KOH of 35:21 as compared with Bengal 11:84, and Bombay 9:95; the saponification value of Malabar was 258:2, Bengal being 255:6, and Bombay 255:5; the iodine value of Malabar was 8:54, of Bengal 8:41, and of Bombay 8:25; the Reichert-meissel value of all three was found to be higher than the ordinary standard, viz. Malabar 6:71, Bengal 6:79, and Bombay 6:65; lastly the melting-points were Malabar 23:5° C., Bengal 24:5° C., and Bombay 25:0° C. Blount and Bloxam (Chem. for Engrin. and Manuf., 1900, 236) give the saponification of this oil as 209 to 228 and iodine absorption as 7 to 9. [Cf. Greschoff, Rept. Kolon. Mus. Haarlem, 1903; Bachofen, Complete Anal. of Cocoanut, showing its demands on the Soil, in Times of Ceylon, Nov. 1899.]

Extraction.—Various methods of obtaining the oil are resorted to: for example, when pure colourless oil is required the copra is boiled with water, grated and squeezed, the resulting emulsion being again boiled till the oil rises to the surface. This is thus a hot wet process. If fresh kernels are used this is called destoil oil, and if from copra it is muthel. Moreover there are several special modifications chiefly intended to produce the very

357
THE COCOANUT PALM

pure white oil which has the highest commercial value. Crude or ordinary cocoanut oil is, on the other hand, produced by crushing the copra in a native oil-mill worked by oxen. This is a cold dry process, but some of the most highly prized grades have been cold drawn. The mill is really little more than an enlargement of the druggist’s pestle and mortar, but it is so efficacious that the extra amount of oil obtained by employing European machinery does not counterbalance the expenditure involved. Moreover, the residue of the copra is sold as cocoanut oilcake (poonac), and the drier the cake the lower its value; the poonac is normally worth 25 per cent. of the copra.

The best East Indian cocoanut oil is known as “Cochin.” This is remarkable, since it is generally thought that ripe cocoanuts are necessary for the oil, whilst green nuts are best for the fibre. Yet “Cochin fibre” and “Cochin oil” both rank highest and possibly from the same reason, viz. that the name Cochin is given to all high grades. However, it is possible, as mentioned above, that what is called “Cochin coir” comes in reality very largely from the Laccadives and the Cocoanut oil may come from Cochin. In 1897-8 the Tropical Agriculturist opened its columns to a discussion as to the reason for the higher price obtained by Cochin compared with Ceylon cocoanut oil. The difference was then said to be about 36 per cent. But in January 1904 there was apparently little difference, and in May 1905 Cochin oil was selling at only 16 per cent. better than Ceylon; hence it may be assumed Ceylon had improved materially. During the discussion indicated an “Old Cocoonut Planter” observed that perfectly clean and dry copra yields an oil which if put in a tumbler is indistinguishable to the eye from a similar glass of water. The inquiry, it may be said in conclusion, resulted in a general agreement on several points, such as that the purity of colour and therefore higher price of Cochin oil were due to the greater care taken in the selection of nuts for crushing and in the preparation of the copra. It was acknowledged that smoke-dried copra usually resulted in a tainted oil; that none but quite ripe and quite sound nuts should be used (it was said, for example, that on the Cochin coast the nuts are allowed to drop off the trees); that great care should be taken to keep the split nuts free from dust and dirt whilst drying; and finally, that the excess of stearine in Cochin oil, which makes it preferable for candle-making, is due rather to the superior quality of the nut and more careful cultivation than to any natural superiority of the soil. Almost all Ceylon (European) growers, it may be observed, are agreed that one of the principal advantages of the Cochin climate lies in the fact that the copra can be dried in the sun. In the controversy above indicated it was stated, however, that if the copra were dried at an even temperature, where smoke could not reach it, the result would be equally good with the sun-dried nut. But it may be added the difference between cold dry and hot wet expressed oil may be a far more important factor than hitherto recognised in determining the value of cocoanut oil. All the cocoanut products seem subject to extreme fluctuations in price. It is generally accepted that the safest standard to purchase copra or cocoanuts is the price ruling for the oil.

The oil is largely used in India both in cooking and for toilet purposes. Its employment as an illuminant was at one time important but has considerably diminished owing to the introduction of cheap American kerosene, the best qualities of which are cheaper than ordinary
cocoanut oil. It is still, however, occasionally found in some Roman Catholic churches, and in England and elsewhere it is made into candles, especially nightlights. The latter use was a discovery made by Messrs. Price & Co., who introduced candles made with cocoanut oil for public illumination at the time of Queen Victoria's wedding; but in ordinary candle-manufacture the oil has been somewhat displaced of late by palm-oil. [Cf. Board of Trade Journ., Feb. 1898.] In Europe it is extensively employed, particularly in France, where pomades and other fancy toilet articles are produced in great quantity and variety. It is also utilised in the manufacture of salves and lotions of various kinds and to adulterate cod-liver oil. It is considered an effective hair-restorer and is universally so used all over India. The long, black, lustrous tresses of the Filipino women have been attributed to the use of this oil. [Cf. Hides and Leather, June 25, 1904.]

As regards the soap industry, cocoanut oil makes a white, hard soap, which is more readily soluble than almost any other in hard or even salt-water. The form known as "Marine Soap" may be used medicinally in plaster-making and in the preparation of soap liniment, but it has the disadvantage of imparting an unpleasant odour to garments or to the human skin. The Messrs. Lever's Sunlight Soap factories use a large amount of cocoanut oil. A fair proportion of the Native-made soap of India is also prepared by boiling this oil with dhobie's earth, salt, saltpetre, quicklime and water.

**Vegetable Butter.**—The various methods and contrivances for producing vegetable butter—cocoanut butter more especially—may be said to have originated one of the many new aspects of value in this palm. Pure cocoanut oil has for some time been used in part manufacture of margarine, and with advantage, since it supplies a certain amount of glyceryl salts, of fairly low fatty acids, whose absence from ordinary margarine constitute chemically the principal difference between that product and butter. For this purpose the characteristic odour of the oil is removed by treatment with alcohol and animal charcoal. [Cf. Blount and Bloxam, l.c. 238.] But a far more important industry than the adulteration or fabrication of margarine is the production of cocoanut butter (see Cacao Butter, p. 1076). The process of producing cocoanut butter or, as it was subsequently termed, "Palmin," is said to have been discovered by a German professor, Dr. Schlinck, and developed by him at Ludwigshafen. He produced a pure vegetable fat which for culinary and edible purposes was claimed to be much superior to butter, lard or tallow, all of which contain acids that through heat form undesirable products. [Cf. Ind. Agri., Sept. 17, 1887; Kew Bull., 1890, 230–3; Basu, in Journ. Agri.-Hort. Soc. Ind. (Proc.), 1890, ix., 62–3.] Dr. Therner, Second Physician of the Imperial Hospital, Vienna, pointed out (Centralblatt für die gesammte Terapie, Oct. 1889) that a firm at Mannheim had also produced a cocoanut butter free of fatty acids, such as was suited for persons of impaired digestion. [Cf. Journ. Board Trade, June 1901.] The manufacture of these and such like butters was naturally very quickly extended, and indeed Messrs. Loder & Nucoiline, Ltd., of Silvertown, London, claim to have preceded even the German firms in producing cocoanut butter and cocoanut suet, which they called "Nucoiline" and "Vejsu." Their sales are now on a very large scale, so that their goods are coming daily into extended demand. "Vegetaline" is the name of the product as now manufactured in Marseilles. More recently Messrs. Gaudart
THE COCOANUT PALM

COCOS NUCIFERA
Cocoanut

"Cocotine."

& Co. have commenced making what they call "Cocotine" at Pondicherry. Similar factories have also been established in America and elsewhere. [Cf. Madras Mail, Jan. 23, 1902; Ind. Agr., Nov. 1902, xxvii., 348; etc., etc.]

There is thus an opening for Indian industries in this product which that country will be ill advised to neglect. The importance to Europe of the discoveries briefly indicated lies in the fact that cocoanut butter provides bakers and biscuit manufacturers with a substitute for butter which is not only pure and cheap but even better suited for baking purposes than butter proper. One of its chief advantages is that it does not readily become rancid, and recently the use of this butter has been authorised for culinary purposes in the French army, a fact significant of the future demands of the world. The consumption of this product must in fact yearly expand and the traffic become of infinite value. Confectioners are said to find cocoanut butter an entirely satisfactory substitute for the more expensive cacao butter (see p. 1076), the imports of which into England have in consequence for some years past materially declined. Cocoanut butter is not, however, strictly speaking, a substitute or even an adulterant of dairy butter, but a substance that commands independent recognition. [Cf. White and Humphrey, Pharmacop., 1901, 331; Revue des Cult. Colon., June 1903, No. 126, 324.]

**Adulteration.**—It should be added that cocoanut oil is sometimes used as an adulterant of volatile oils. It may be detected by the fact that oils so adulterated will solidify wholly or in part in a freezing mixture. Cocoanut oil has thus been found in *cananga*, citronella and palmarosa oils. [Cf. Gildemeister and Hoffmann, Volatile Oils, 1900, 201.] Cocoanut oil melts at 68° to 82° F.; its sp. gr. at 212° F. is 0·868 to 0·874 and its saponification from 209 to 228.

**Cocoanut Oilcake or Poonac.**—As observed above, this is the by-product of *copra*, after the expression of the oil. Voelcker (Essay on the Influence of Chem. Disc. on Agri. reviewed in Trop. Agrist., 1896, xv., 800) is said to have observed that the cocoanut cake is better adapted for fattening stock than for young growing animals or store-stock. Its analysis is as follows:—water 9·50; oil 8·43; albuminous bodies 30·40 (containing nitrogen 4·50); mucilage, sugar, fibre, etc.; 40·95; mineral matter (ash) 10·72. It was very largely taken up in Australia, after the establishment of Messrs. Lever Brothers’ Sydney Oilmills. In the Tropical Agriculturist (1898, xviii., 223) it is stated that cocoanut oilcake is not generally used for milch-cows or other milking stock, or in Ceylon for horses; but it is the common food of working bulls, and is considered an excellent fattener for pigs.

**Price.**

Official statistics of the Indian trade in cocoanut cake are not available, but according to a reply to a correspondent in Capital, Feb. 11, 1904, the price in Ceylon was from Rs. 67½ to Rs. 70 per ton, and from 12,000 to 15,000 tons were then shipped annually from Colombo, mostly to Germany and Belgium. The writer apparently did not consider it necessary to take India into consideration. In fact he says Indian *poonac* consists of rape-seed, castor-seed and gingelly (sesamum). Hanausek (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 403-6) gives the appearance of the cake under the microscope. The total exports of Indian oilcake, it may be observed, amounted in 1903-4 to about 60,000 tons, of which Madras contributed 47,500 tons. The exports of oilcake appear, however, under two headings (a) Cattle Food and (b) Manure.
STAPLE ARTICLE OF DIET

The total for 1906-7 came to 105,379 tons, valued at Rs. 75,99,121. Cocoa-nut oilcake is chiefly exported from Madras, and consequently constitutes an important item in these transactions. The value of the total traffic and its present prosperity may be inferred from the fact that from all India the exports in 1886-7 stood at only Rs. 1,71,107. This is, however, but indirect evidence of the extent of the Indian exports in cacao-nut cake. [Cf. Journ., 1897, 416; Leather, Agri. Ledg., 1897, No. 8, 159-60.]

**Medicine.**—Very full accounts of the medicinal properties of the cacao-nut are given in the Dictionary and in the Pharmacographia Indica (iii., 511-9). Briefly it may be said that, for European medicine, the most important advantages of *C. nucifera* are the anthelmintic action of the fresh fruit (especially of the volatile oil of the shell); the properties of the milk; as also the possibility of substituting the oil for cod-liver oil, in cases where the latter cannot be taken. For medicinal purposes the olein is separated from the solid fats, as in the preparation of what the Natives call ável. (According to some writers this is named muthel, the meanings of ável and muthel being perhaps reversed.) In making that substance the kernel of the fresh nut is pulped and strained and the oil separated from the milky fluid by heating. A preparation of the same kind is now known in Europe as “coco-olein.” Both by Native and European physicians in India the “milk” from the unripe fruit is recommended as a useful refrigerant in fever and urinary disorders, but in Bengal it is commonly believed that the consumption of too much cacao-nut milk tends to cause hydrocele. In dyspepsia and consumption Native practitioners prescribe the pulp of the ripe fruit made up with ghi, coriander, cumin, cardamoms, etc. This mixture is called nárikela-khanda. The flowers and fresh toddy are astringent. The soft, brown tomentum or cotton found outside the base of the leaf-sheath is an excellent styptic, like the corresponding products of *Borassus* and *Caryota*. For an abstract of the somewhat diverse and conflicting opinions of the Arab physicians—Rhases, Avicenna, Serapion, etc.—the reader should consult Adams (Comment. in Paulus Egineta, 1847, iii., 438).

**Food Products.**—With a large section of the Indian population the cacao-nut is almost a staple article of diet, and a very wholesome one. Natives of all classes consume the soft creamy pulp and cool refreshing water (milk) of the young nut (ddó), and also use the same in cooking curry. The terminal bud or “cabbage,” though esteemed a delicacy, is not often eaten, because its removal kills the palm. The harder pulp of the matured nut is dried either naturally or artificially and the copra thus formed is parched with rice, rasped, and put into curries or made into sweetmeats. The fresh or fermented juice of the stem is consumed as a beverage—toddy (tari); by evaporation it is made into jaggery (coarse sugar), and by subsequent treatment even refined sugar. Rheede (Hort. Mal., 1686, i., 6) states that in his day a coarse reddish sugar was obtained by boiling the juice mixed with lime. When distilled, tari becomes spirit or arak and finally vinegar (see p. 1111). The methods of collecting the juice and the manufacture of its products differ very little, however, from those employed with other palms. (See *Borassus flabellifer*, pp. 170-1; Ceghorn, in Edinb. New Phil. Journ., n.s., 1861, xiv.) Incidentally it should be observed that in Bengal the cacao-nut-palm is not tapped for toddy but in Bombay this is an important industry, although very little sugar is made from it. It may be noted that jaggery is not infrequently mixed with lime to make a strong cement which
THE COCOANUT PALM

Jaggery.

Carved Bowls.

Coir.

Exports, Coir.

Desiccated Coconuts.

Hulak-bowls.

Porcupine-bowls.

Timber.—The wood is commercially known as "Porcupine-bowls," and is used for rafters and for other building purposes. It makes very pretty and durable furniture, and is also converted into spear-handles, walking-sticks and other fancy articles. [Cf. Gamble, Man. Ind. Timbs., 1902, 739.]

Domestic and Sacred Uses.—By Hindus the dried shell is almost universally used as the water-bowl of their smoking-pipe or hulak (hence the name narghile); less frequently it is the sounding-drum of crude violins. In Madras the shells are made into elegantly carved ornamental vases, lamps, spoons, sugar-pots, teapots, and small unripe ones into snuff-boxes, scent-bottles and the like. Entire shells are obtained by filling them with salt water and burying them in sand. By this process the kernel is destroyed and may be washed out, but the shell will not quickly unless the nut so treated be fully ripe. [Cf. Ind. Art at Delhi, 1903, 133, 169, 196, etc.; Hoey, Monog. Trade and Manuf. N. Ind., 1880, 116.] According to the Emperor Baber (Memoirs (Leyden and Erskine, transl.), 327) and the Emperor Akbar (Ain-i-Akbari, 1509 (Blochmann, transl.), i., 71) the shell of the cocoanut was even then used to make a kind of violin or mandoline called ghichak. Within the nut there is occasionally found a small stone of a bluish-white colour called in India kalappa and regarded by the Chinese as a valuable amulet. These "cocoanut pearls" are very carefully described by Rumphius. They appear to be composed almost entirely of calcium carbonate and have a very small proportion of organic matter. The leaves of the palm are serviceable for thatch, screens, baskets, matwork, etc.

Trade. TRADE IN COCOANUT PRODUCTS.—No sort of estimate can be furnished of the area under this palm or of the total production. The trade returns are moreover scattered under several separate headings, so that a fairly complete statement of even the exports cannot be framed. It will be convenient, therefore, to take up the more important products of the palm separately:

Fibre. Coir.—Fibre, Rope and Manufactures therefrom. In trade statistics the exports are shown under the headings "unmanufactured coir," "manufactured coir" (exclusive of rope), and "cordage and rope" (including hemp and coir but excluding jute). The EXPORTS OF RAW COIR to foreign countries manifested a steady increase from 1894 to 1900. In the latter year they stood at 70,016 cwt., valued at Rs. 5,65,625. But since 1900 they have greatly fallen off, having been only 25,500 cwt., valued at Rs. 2,26,626, in 1903-4, and 11,317 cwt., valued at Rs. 1,06,634, in 1906-7. This circumstance may be due to increased traffic in manufactured coir (rope matting, etc.), to increased exports in made-up mats or rugs (not returned as coir at all), or to certain rearrangements in official statistics.

Of the MANUFACTURED COIR (excluding cordage and rope) the exports manifest a satisfactory improvement, the traffic for 1903-4 having been returned at 483,355 cwt., valued at Rs. 47,90,110, and for 1906-7 at 559,329
TOTAL TRADE IN COCOANUT

cwt., valued at Rs. 56,00,268. Almost the whole trade is in the hands of the merchants of the Madras ports, the receiving countries being the United Kingdom and Germany. Madras Presidency also supplies the other provinces of India with coir and coir manufactures. These internal transactions were in 1905–6 valued at 15 lakhs of rupees. As already indicated, coir cordage and rope cannot be ascertained separately from hemp, but the total transactions for all India in 1905–6 were 139,870 cwt., valued at Rs. 15,21,181; almost three-fourths went from Madras ports, and hence were in consequence chiefly coir (see Ropes and Cordage, p. 924).

The imports of coir are unimportant, and come mainly from Ceylon and are consigned to Bengal.

_Copra and Oil._—The exports of _copra_ to foreign countries in the five years 1899–1900 to 1903–4 show a remarkable increase. They stood at 97,029 cwt., valued at Rs. 9,89,377, in 1899–1900; and reached 353,724 cwt., valued at Rs. 42,24,614, in 1903–4; but fell to 126,454 cwt., valued at Rs. 18,95,341, in 1906–7. Of this last amount 125,129 cwt., valued at Rs. 18,76,172, went from Madras ports. The chief recipients were France and Germany. The coastwise traffic in _copra_ in 1905–6 amounted in all to 184,066 cwt., valued at Rs. 34,37,736. Bombay sent 47,218 cwt. chiefly to Sind, and Madras 134,546 cwt. chiefly to Bombay. The imports of _copra_ from foreign countries have been steadily diminishing and are now unimportant. Statistics of the trade in Indian coconuts are not obtainable separately from those of other kinds of oilcake. The traffic in coconuts oil to foreign countries in the five years 1899–1900 to 1903–4 increased from 2,245,502 gals., valued at Rs. 27,79,669, in 1899–1900 to 3,379,631 gals., valued at Rs. 48,81,588, in 1903–4; but the trade is subject to extreme fluctuations, and fell in 1906–7 to 959,772 cwt., valued at Rs. 14,17,794. The United Kingdom and United States are the best customers, and the trade is almost entirely in the hands of Madras merchants. The imports, chiefly from Ceylon and Mauritius, amounted to one million gals. in 1899–1900, but were only 999,556 gals. in 1906–7 and very largely from Ceylon. In the last-mentioned year Bengal received 731,281 gals. and Madras 171,215 gals.

_Nuts._—The exports of whole coconuts to foreign countries, though still small, show a tendency to increase. In 1899–1900 the total stood at 175,250 nuts, valued at Rs. 5,439; in 1902–3 it was 705,555 nuts, valued at Rs. 24,789; and in 1906–7, 365,890 nuts, valued at Rs. 13,853. Natal and Turkey-in-Asia are the chief receiving countries. The coastwise traffic in nuts is very considerable. In 1905–6 the total for all provinces was 81,920,724 nuts, valued at Rs. 25,50,384. Madras is of course chiefly responsible, having exported to Bombay 61,862,664 nuts, valued at Rs. 18,95,327. The imports of nuts from foreign countries amounted in 1906–7 to 10,975,127 nuts, valued at Rs. 4,98,090, and these came chiefly from the Straits Settlements, the Maldives and Ceylon. Bengal took 4,656,504 nuts, valued at Rs. 1,25,325, whilst Burma received 6,090,728 nuts, valued at Rs. 3,64,546.

India has not as yet figured in the returns of the world’s traffic in either desiccated coconuts or in coconuts butter.

The coffee plant

The names given to the plant, its fruits, its seeds and the beverage prepared from these, are mostly derived from either of two words: "kahwah," an Arabic term that originally denoted "wine," and "bun," the Abyssinian name for the coffee plant or its beans. From these we have cahua, kawa, chaube, kapi, câve, kava, café, coffee and cafetier; also boun, bun, ban, ben, bunu, buncha. The earliest Arabic writers, however, used the Abyssinian name by itself or in combination: thus Avicenna (11th century) calls it buncho and Rhaes bunco. It was by them viewed as a medicinal plant and one very possibly that came from Abyssinia, so that the appearance of the Arabic name kahwah may with safety be accepted as marking the progress into the final development as a beverage. The association with wine may be considered in fact as indicative either of the abhorrence of the zealous followers of the Prophet of anything that savoured of the prohibited alcohol or taken as the direct expression of the curious circumstance that when the coffee beverage was first made known to the Arabs it was in all probability distinctly alcoholic, and thus fully deserved the name kahwah.

Habitat.—The true coffee plant would appear to have been satisfactorily established by botanists as indigenous to certain hilly regions of Abyssinia, of the Soudan, of Guinea and of Mozambique. Some doubt still, however, prevails as to its being indigenous to Arabia, though this was claimed by the early writers. Richard throws out the suggestion that it may have been indigenous to Arabia, and carried from thence to Abyssinia. It is certainly extensively cultivated in that country, as for example at Enarrea, Kaffa and Harrar. But Richard adds (as it in part support of his view) that coffee is only used by the Muhammadans, not by the Abyssinians proper. Deflers, on the other hand, speaks of the plant as cultivated in Attara and elsewhere on the mountains up to alt. of 7,000 feet, but as nowhere seen wild in Arabia. These two botanical writers thus take opposite sides in the story of the Abyssinian conquests. Richard believes that coffee was carried back from Arabia, and Deflers that it was conveyed to Arabia, about 100 years before the birth of Muhammad. Raynal, Lecomte, and many authors accept the opinion that the plant was taken from Abyssinia to Yemen.

History.—If we turn to Arabic literature for confirmation of this view we learn for certain that coffee is not mentioned in the Koran, nor of course is there any allusion to it in the Hebrew Scriptures. Thus if the plant be viewed as indigenous to certain tracts of Arabia, it becomes necessary to believe that its merits (if known at all) were appreciated within a very restricted area. Everything, in fact, points to the conviction that the people of Mecca, Medina and Bagdad did not know of coffee till well into the 14th century of the Christian era. Ibn Baithar, born at Malaga and who travelled during the 13th century in North Africa and Syria, makes no mention of coffee. The art of roasting the beans and preparing from these a decoction was apparently a more recent discovery, and one which may have been made in Persia. Prior to that, the kahwah that first attracted attention, was a preparation from the succulent rind or pulp of the coffee-cherry. This contains a fair amount of sugar, is often pleasantly enough flavoured, and if a decoction made from it were allowed to stand for some short time it would for certain become alcoholic and might even be distilled into spirit.
DISCOVERY OF ROASTING THE BEANS

Giovanni Leone, who visited Egypt in 1513 and wrote a careful account of Cairo, makes no mention of the consumption of coffee, nor is the plant enumerated in his list of the most useful and novel African plants. On the other hand, seventy years later, Prosper Alpinus (De Pl. Egypti, 1592, 26) speaks of the box tree seen by him at Cairo in the conservatory of an Egyptian gentleman, and further he gives full particulars of the decoction, called causa, which he says they prepared from the seeds imported from Arabia Felix and sold in public taverns, in place of wine. In his other work (De Medecina Method.) Alpinus remarks that some of the Egyptians used the husks of the coffee-berries instead of the berries themselves. Vesling (in his edition of Alpinus' work published in 1735, 179) adds that coffee-cherries, brought from Yemen, were sold in Egypt as crystallised fruits and regarded as great luxuries. Verzaesch (Kräuter-Buch, 1678, 788), while reprinting the account given by Alpinus, speaks of the beverage being served in earthen pots entirely closed up, and adds that the husk makes a stronger infusion than the berries (seeds). The seeds, he observes, are called bon and the drink choas : he furnishes a picture of a roaster, so that by then, at all events, there would seem no doubt the seeds were regularly roasted and a beverage prepared from them, as well as from the husk. Sandy (Travels, 1610 (ed. 1670), 51) alludes to " Coffa-houses" of Constantinople. Pietro della Valle (Voy. East. Ind., 1605) speaks of coffee, it is " made by a black seed boiled in water which turns its inside to the same colour but doth very little alter the taste of the water; notwithstanding it is very good to help digestion, to quicken the spirits, and to cleanse the blood." Herbert (Travels, 1677, 113, 311) speaks of " Coffee or Coho " as a Persian beverage prepared from " the flower of the Bunny or Chouva- berry" and sold in shops. Fryer (New. Acc. E. Ind. and Pers., 1675 (ed. 1698), 225, speaks of " Coho or Tea, " as being served at a State ceremonial at which he was present at Bunder Abbas. An apology for mistakes explains that the text was printed in the absence of the author. Hence it may be inferred the "Explanatory Index" was not drawn up by Fryer. In that index " coffee " is given as the equivalent of coho. It is thus probable that Fryer himself accepted coho as a name fully understood in England. It is of course a variant of the Arabic kahwah, which originally denoted the wine prepared from the husk of the coffee- cherry, not the beverage of the roasted seeds. Niebuhr (Voy. Arabia, 1770) says that in Yemen coffee made from the seeds is supposed to heat the blood; accordingly the inhabitants of that province compose a drink of the hulls of coffee which in taste and colour much resembles tea. This they esteem wholesome and refreshing. It is prepared nearly in the same manner as that from the seed or bean and is the coffee à la Sultane of the French. Deflers observes, "It is well known that the pericarp of the fruit dried in the sun and powdered constitutes the product used under the name of qischar for the preparation of a stimulating drink rather like an infusion of tea." " Aromatised with ginger or other spices it is with qat the favourite stimulant of the Arabs of Yemen who abstain from the use of coffee prepared from the seed, ground in the Turkish and European fashion." Turning now to a few of the records regarding Abyssinia; Richard, as already observed, affirms that coffee was not in his time much used by the Abyssinians. Nearly all was taken to Messoa by caravans and from thence dispatched to Moka, where it was sold as Arabian coffee. Henry Lecomte gives a very different account: " From time immemorial the Gallas have used coffee both as food and drink. Originally they made a decoction of the beans and pulp cooked together. The system of roasting was only discovered later."

Such then are the observations of early travellers in Arabia, Abyssinia and Egypt, and these may now be linked up with the prevalent opinions and traditions. Coffee made of the roasted seeds would appear to have been first brought prominently to notice at Aden. It was known for centuries previously as a drug, and many of the Arab writers speak of having been made acquainted with its properties through the Persians. Abu Abdallah Muhammad Dhabbani Ibn Said had occasion to visit Persia (according to Galand, Roque and Ellis: Africa, according to Yule and Burnell; lastly Abyssinia according to the authors of the Pharmacographia Indica) during the 16th century. On that occasion he found the faithful partaking of coffee. Returning to Aden he took to drinking coffee himself, and recommended his followers to substitute that beverage for the kds (kath or kaah) which they were in the habit of using. Vaughan (Pharm. Journ., 1852, xii, the most reliable and novel regarding Muhammad Dhabbani, but throws no light on the country whence he obtained his knowledge, nor does de Sacy deal with this issue. From Aden, however, the knowledge seems to have spread
COFFEA ARABICA

History

to Mecca, Medina and Cairo, and finally within the century after its introduction to Aden, it had been conveyed to Damascus, Aleppo and Constantinople. But in due course the more strict in the tenets of their faith objected to public coffee-houses and to the gaming, singing and dancing that there took place. At various times the effort was accordingly made to repress the traffic and to close the coffee-houses. In 1511 the Governor of Mecca (the Viceroy of the Sultan of Egypt) issued a "Condemnation" of coffee as the united opinion of the priests, doctors and learned men of that town, on the ground that it was a form of wine (kawwah) and therefore contrary to the law. It is thus just possible that the beverage then in use was prepared from the pulp of the fruit and was, therefore, actually intoxicating. But the Sultan revoked the condemnation and reproved his viceroy for venturing to prohibit an article of daily food used by the people of the capital of the Empire (Cairo) and by the Sultan himself. Later on (1524), however, the coffee-houses of Mecca had become the scenes of so much rioting that they were closed, by order of the Kadi. In 1533 the people of Cairo were divided into two classes, those who considered coffee lawful, and those who did not. In 1554 the coffee-houses of Constantinople were closed on a new pretext, that possibly marks the more complete establishment of the habit of roasting the seeds. The charred berries (seeds) were considered as charcoal, and thus unlawful as articles of food.

Difference of opinion exists regarding the first European who saw and described both the plant and the beverage. Ramusio published in 1554 his Raccolta delle Navigazioni e Viaggi, the first work that mentions coffee as a beverage. In 1588, while on a journey from Aden to Rhada which he made as a prisoner. Incidentally he mentions coffee among the plants observed by him, but speaks of it as if he and all his readers were perfectly familiar with the plant so named. We know that by that time it was being used in Constantinople, so apparently it was known some time prior to the actual date of its being chronicled. De la Roque, while characterising the traffic in coffee as quite modern, points out that Peter Belon, who travelled in Egypt and Arabia in 1546-9 and described most of the curious and interesting plants seen by him, makes no sort of allusion to coffee. But about the same time, or shortly after, several other travellers visited both Arabia and Abyssinia, and some mention while others are silent regarding coffee. Similarly John Ray published in 1693 a collection of Voyages and Travels. A few of the authors whose works he gives, deal with Ethiopia and Arabia, and some mention coffee while others do not. Clusius (Arom. Hist. (Garcia de Orta), 1574, 214–5) received from Dr. Alphonse Pancius of Ferrara, during the summer of 1573, a few coffee-berries (seeds). These he figured and described, and tells us that they were called buna and by some elkaue (al kave) and that in Alexandria a drink was made from them. Rauwolf visited Aleppo in November 1573 and saw the coffee plant, as also the beverage. He published his account in 1583 (Beschriït der Raiss., 103). Thus Clusius, not Rauwolf, as is commonly affirmed, should be viewed as the first botanist who examined and described the coffee-berries. Prosper Alpinus, as already stated, had a few years still later given a full account both of the plant and of the beverage, and his statements were published time after time for a century subsequently, without any new information of value being made known.

Very few of the early rulers, travellers or botanists of India mention coffee, such as Marco Polo (1290), the Memoire of the Emperor Baber (1519), the Ains-i-Akbari (1690), Recess (1678), and Rumphius (1760). Linneschoten (1598) described the preparation of tea in Japan, and his contemporary and publisher Pulandus, in a footnote commenting on that passage, observes that in the same way the Turks prepare a beverage from "the fruit which is like unto the bakelaoe (laurel berry) and by the Egyptians is called bon or ban." Pyrard (Voy. E. Ind., 1610 (ed. Hakl. Soc.), i., 172) speaks of the king and great lords of the Maldives drinking coffee. Tavernier (Travels Ind., 1676, ii., 23–4) says that in his time coffee did not grow either in India or Persia, but that the supplies came from Arabia. He then adds that the principal coffee trade was from Hormuz and Bassora, "where the Dutch when returning empty from Mocha, load up as much as they can with that seed, it being an article which they sell well." From Hormuz it is exported to Persia, and from Bassora to Mesopotamia and other Turkish provinces. (For accounts by Bonitus, Mandelslo and Ovington, see Camb. ii., 219.)

Early Coffee Trade.

Coffee-drinking.

Down to the year 1690 the world's supply of coffee came from Arabia and Abyssinia. The following historic data may be accepted therefore as fittingly con-

366
CARRIED TO INDIA

Chilling this brief statement. In 1615 coffee-drinking was carried to Venice. In 1644 Peter della Valle took it to Marseilles. John Houghton (Phil. Trans. London, 1809, iv., 420) says that Rastall, an English merchant, went to Leghorn in 1651, and there found coffee-houses. In the following year Mr. Daniel Edwards, a merchant from Smyrna, brought to England a Greek servant named Pasqua, who made his coffee. Shortly after Pasqua was enabled to set up a public coffee-house in Cornhill. It is further affirmed by Houghton that Dr. Harvey, the discoverer of the circulation of the blood, frequently used coffee. But Henry Phillips (Pomarium Britan., 1820, 112) says that Nathaniel Conopios, a Cretan, made coffee his common beverage at Balliol College, Oxford, in 1641. This same fact is alluded to by Evelyn (Memoirs, 1819, 7) as having taken place in May 1637. In 1675 Charles II., by an ill-judged proclamation, in which he characterised the coffee-houses as seminaries of sedition, endeavoured to close them, but the Act was suspended a few days later. By 1688, according to John Ray, London rivalled the Grand Cairo in the number of its coffee-houses. Lord Bacon (Sylva Sylvar, 1658, Century viii., 185) speaks of the coffee drink used by the Turks, but he had apparently no personal knowledge of it. In 1657 the Turkish Ambassador Sulaiman Aga made coffee-drinking fashionable in Paris, and in consequence the roasted coffee-berries sold in Paris during 1670 at £5 a pound. It seems probable, however, that through M. Thevenot coffee was definitely introduced about 1667, but that the habit of coffee-drinking was not general in Paris until 1680. In 1690 live seeds having been conveyed to Batavia, a plant was shortly after taken to Amsterdam and in 1712 the Dutch presented a seedling from this to Louis XIV., and still later from that plant seedlings were sent to Martinique. Madame de Genlis (La Bot. Hist. et Littér., 1811, i., 193) tells how M. Deschieux, who went to Martinique in 1720, as Lieutenant of the King, in the same ship with the seedlings, gallantly saved them by depriving himself daily of the greater part of his allotted portion of water—the ship’s supplies having run short. He had in consequence the good fortune to see the plants arrive in safety and a new source of wealth thereby added to the island. M. de Candolle, M. Edelstein Jardin and many other writers allude to this incident. In 1723 coffee was taken by the Portuguese to Java; in 1728 Sir Nicholas Lawes introduced it into Jamaica, and in 1770 it was conveyed to Rio de Janeiro.

The history of the introduction of coffee into India is very obscure. Most writers agree that it was brought to Mysore some two centuries ago by a Muhammadan pilgrim named Baba Budan, who, on his return from Mecca, brought seven seeds with him. This tradition is so universally believed in, by the inhabitants of the greater part of South India, that there seems every chance of its being founded on fact. About the beginning of the 19th century there is no doubt coffee had found its way to India, and in 1823 a charter was granted to Fort Gloster, near Calcutta, authorising it to become a cotton mill, a coffee plantation and a rum distillery. Some of the coffee trees planted in fulfilment of that charter are supposed to be still alive, and about the same time coffee was successfully grown in the Botanic Gardens, Calcutta; but needless to say the industry of coffee planting nowhere found an abiding place on the plains of India but migrated to the hills of South India, in Mysore more especially, and thus into the very region where tradition affirms it had been introduced two centuries previously. The first systematic plantation was apparently Mr. Cannon’s near Chikmuglur. This was established in 1830. It is supposed, however, that Major Bevan may have actually grown coffee on the Wynaad at a slightly earlier date, and that Mr. Cockburn’s Shevaroy plantation bears the same date as Mr. Cannon’s. In 1840 Mr. Glasson formed a plantation at Manantoddy, and in 1846 plantations were organised on the Nilgiri hills. In Ceylon it is believed coffee was introduced by the Arabs prior to the Portuguese invasion of that island. It was commenced to be systematically cultivated by the Dutch from about 1690. In 1825 the first plantation by an Englishman was opened by Sir Edwards Barnes. In 1877 it was estimated that the capital invested in Ceylon coffee was close on £14,000,000. The fungal disease (Fusulina vasculatis) appeared about 1860 and spread rapidly, steadily weakening the bushes and reducing their yielding capacity, so that by 1887 the Ceylon industry was completely ruined.

It would occupy many pages to give anything like a complete enumeration of even the more important works on coffee. [The following in supplement of those already given in the Dictionary, and of those mentioned above, will be found specially worthy of study:—Thoenen, Travels in Levant, Indostan, etc. (Engl. trans.), 1867, pt. i., 162–3; pt. ii., 11, 21; Dafour, L’Emploi du Café, 1671; also 367
COFFEA ARABICA  
Species and Varieties  

**Distribution.**—The world's supply of coffee, we are thus justified in believing, came originally from Arabia and Abyssinia, but as the demand increased new localities of production were established. The Dutch East India Company pioneered the modern trade by their experimental cultivation in Batavia. Soon thereafter coffee cultivation was successfully introduced into the warm temperate areas (or hilly tracts) of most tropical countries, and in time these not only produced far more than the ancestral regions, but yielded a supply of an even superior quality. Improvements in quantity and quality of necessity rapidly extended consumption until they made coffee one of the most popular of all beverages, and hence with a large number of the inhabitants of the globe it passed from the position of an occasional luxury to that of a daily necessity, rivalled only by tea—the sister beverage of the breakfast table.

**Species and Varieties Cultivated.**—After the somewhat detailed account already furnished of the chief historic facts regarding the Abyssinian (commonly called the Arabian) coffee plant, it is perhaps hardly necessary to indicate that particular species any further for the present. It is to this day by far the most important cultivated stock, though its liability to blight has caused planters to seek out other forms, in the hope of being able either to replace *Coffea arabica* or to use these as strains in hybridisation or as stocks upon which to graft, in the production of blight-proof plants. In this modern aspect of the coffee-planting industry three plants have attracted special attention. These are:

368
PROPERTIES OF SPECIAL CROPS

COFFEA ARABICA
Species and Varieties

Produce World; Planting Opinion; Trop. Agrist.; Capital; Madras Mail, etc.

This species was thus first made known to Europe about the time the coffee-leaf disease appeared in Ceylon. Its hardier growth led to the opinion, to some extent realised, that it might withstand the action of the blight, and on this account demands were made on the Royal Botanic Gardens, Kew, for plants or seeds. Fortunately the Director of the Gardens was fully able to satisfy these, until the question of seed supply was taken up by the trade. The Kew Reports are full of the most interesting and suggestive details regarding the successes or failures attained through the experiments conducted, almost simultaneously, in all the tropical regions of the globe. But in one respect at least they have been disappointing, namely, the plant, though much hardier than the Arabian coffee, has not proved to possess immunity from blight. In fact Sir Daniel Morris pointed out long ago that in the nursery the seedlings often suffer from Hemileia quite as much as do those of C. arabica, but he added that the plants, if properly cared for, soon attain sufficient strength to withstand the disease.

The experience gained in India would seem to support belief that Liberian coffee requires quite as fertile and as deep soils as C. arabica. It prefers a warm moist atmosphere and not much less than 100 inches of rain, distributed if possible throughout the year; but it is very susceptible to drought. Where subjected to dry heat, therefore, shade-trees must be provided if they do not already exist. In Java Erythrina seedlings are first planted, but soon given too much shade and are accordingly replaced in about five years' time by Eriodendron seedlings.

A shallow soil or one with a large admixture of sand and stones is quite unsuited, as also are heavy clay soils and waterlogged subsoils. But Liberian coffee luxuriates on moisture-retaining soils and on lands that can bo, and are regularly irrigated. It, in fact, prefers low-lying tracts to high ground, and accordingly flourishes better on the plains than on the hills. It is true that on the Wynaad and elsewhere it has been successfully grown up to altitudes of 5,000 feet, but that circumstance does not materially detract from the opinion that it is better suited to the plains than those of the tropics than C. arabica. Hence Liberian coffee has attained its most extensive production in the West Indies, Ceylon, the Malay Peninsula (Selangor), North Borneo, Sumatra and Java, and in India seems likely to attain its chief production in Sylhet, Assam, Burma and the Andaman Islands. Larre says that it is "little thought of" in Brazil, since "it produces little and that irregularly." On the east-coast lands of Madagascar it has for some years been fairly extensively cultivated. M. Deslandes, Assistant Inspector of Agriculture, says that the plants there grown are hybrids and yield a berry superior to that of African coffee. Being large plants the custom exists of allowing them plenty of space, say 400 trees to the acre. There are several distinct races, some that form much larger plants than others and accordingly require more space. It is just as important with Liberian as with Arabian that the races of the plant should be critically studied. For some years past numerous hybrids have been cultivated all over the world. In the south such have appeared wherever Arabian and Liberian coffee were grown side by side. The stock thus obtained is much valued by many planters, being regarded as enjoying immunity from leaf-blight. But it is usually contended that for young colonies, Liberian has distinct and superior claims. It yields regularly and freely, the fruits do not fall so readily from the bush on their reaching maturity, and it is, when all is said and done, a much harder plant than the Arabian coffee. On low ground the harvest is abundant, the fruits are large (nearly twice the average size of the Arabian bean), not so delicately flavoured, though of good quality when grown on high altitudes. The berries are more difficult to clean than are those of the Arabian plant, but with proper machinery may be completely deprived of even the parchment; they are rank and oily, though if carefully and slowly dried will fetch a price sufficient to reward all the trouble and expense entailed. According to most writers a drawback to this coffee lies in the fact that it has never been pushed as a commercial commodity on its own merits. The beans seem universally used by middlemen for the purpose of strengthening grades which by themselves would be flavourless.

THE COFFEE PLANT

COFFEA ARABICA

Area

Trop. Agrik., 1897, i., 217; Der Tropenpflanzer, 1898, ii., 34, 263; Trinidad Bull., etc., 1899, 223; 1900, 315; Agri. News, West Indies, 1902, i., 278; ii., 237; Journ. Soc. Arts, 1903, 461; Trop. Agrist.; Planting Opinion; Madras Mail, etc., etc. "The Highland Coffee of Sierra Leone." This interesting West African species, Mr. Bentham thought, might be but a variety of C. arabica. The seeds were issued from Kew Gardens, and the plant is now being experimentally grown in Trinidad, Java, Ceylon, Mysore (not successfully) and elsewhere. Hybrids have also been formed between it and C. arabica, as also C. liberica. It grows freely, yields abundantly, but is longer in coming into bearing than C. liberica. It gives a highly flavoured Moka-like berry.

Hybrids.

(c) C. Laurentii, Wildern. (C. robusta, L. Lindu.), is another tropical African species that has attracted some attention, though it is but imperfectly known botanically. It is spoken of as "Congo Coffee." An article appeared in L'Horticole Coloniale (L.c. 64-6) in the year 1900 that gives a good account of this plant. It is spoken of as prolific, as almost immune from the ordinary diseases of coffee, and as yielding a berry of a superior quality with a delicate aroma. It frequently banks of streams and prefers situations moist and not too shady. The plant is not, like C. liberica, pyramidal in shape, but is rather rounded in outline. Jumelle (Les. Cult. Colon. (Aliment.), 1901, 350-85) adds that it inhabits Sierra Leone, on soils formed of decomposed granite or gneiss. Owing to its having been first made known from the Nunez river it is often called "Rio Nunez Coffee." In India and Ceylon this plant has so far failed to justify extended endeavours, but in Dominica the results have been most encouraging.

CULTIVATION.

Localities and Area.—In this work it is desirable to restrict observation to India, and consequently to allude only incidentally to the coffee-growing of other parts of the world. Particulars of cultivation in Java, Sumatra, Philippines, Ceylon, Queensland, Brazil, West Indies, Central America, Mexico, etc., will be found in the respective chapters of Thurber's Coffee from Plantation to Cup and other such works, to which the reader is referred. The actual area under the crop in India cannot be stated definitely, owing to the unwillingness of certain planters to furnish information. The error that exists, however, a relative one, and tends year after year to be lessened rather than increased. Taking the official returns as they stand, it has to be accepted that the area shown under coffee, during the past thirty years, has manifested severe fluctuations. With a perennial crop this can alone denote the following or abandonment of certain plots and the resuscitation of old plantations or the opening out of new lands, coincident with variations in the world's coffee necessities. Thus, for example, the revolutions that took place in Brazil in 1889, 1891 and 1893, followed as these were by small crops during one or two of the succeeding years, had a highly beneficial effect on the Indian coffee-planting industry. The area returned as under coffee in 1885 stood at 237,494 acres, but for the ten years ending 1895 the mean area in India was 274,000 acres; in 1903, 228,815 acres; and in 1904, 212,964 acres. The latest report of the Commercial Intelligence Department states the area at the end of 1906 to have been 210,688 acres. During the decade ending 1895 prices may also be said to have ruled high, so that the industry was very prosperous.

In addition to the absence of returns as to certain plantations, an estimate of yield to acre could hardly be accepted as even of general application. It accordingly follows that trade statistics almost invariably manifest higher exports than the agricultural data would show as produced. The relation of surveyed areas to actual returns of foreign exports is one of the most profitable aspects of study. Taking 100 to represent the area as also the exports in 1885, the following variations have oc-
**INDIAN AREAS OF PRODUCTION**

curred, every fifth year being selected:—1885, area 100, exports 100; 1890, 114 and 63; 1895, 120 and 78; 1900, 115 and 66; 1905, 90 and 97; and 1906, 89 and 61. (See prices, p. 391.)

*Production.*—The coffee produced in India is practically all exported, the most important markets being the United Kingdom and France, so that the returns of trade afford a useful check on the figures of production. The year of highest export was apparently 1885–6, when 41 million lb. were shipped, or about 6 million lb. in excess of the year’s production. Some ten years later (1895) (the record year of production) the exports came to 32½ million lb., or 7½ million lb. less than the recorded production.

The official year of trade returns being from March 1, and that of the agricultural statistics the calendar year, a certain overlapping of data of necessity occurs, and, moreover, reserve stocks over local consumption are usually drawn upon before the new crop comes into market. But taking it all round, the particulars of area and production are substantiated by the actual records of the trade.

Of the total area, 28,089 acres (according to the Report of the Commercial Intelligence Department) were under immature plants in 1906, so that in the future these will come into bearing and enhance the yield, very possibly to a greater extent than the reduction due to the age and disease of the plants presently returned as mature. In passing it may be here observed that in addition to the actual area under coffee, the planters own 108,581 acres, much of which is available for future expansion should such be found desirable. Analysing the area of production according to the report for 1906, we learn that out of the actual area recorded (196,318 acres), 89,202 are in British India and 107,116 in Native States. Of the former—42,646 acres are in the Madras Presidency; 46,393 acres in Coorg; 74 acres in Bombay Presidency (Kanara district mainly); 84 acres in Assam (South Sylhet mainly); and 5 acres in Burma. Of the latter—101,489 acres are in Mysore, and 5,627 acres in Travancore and Cochin collectively. If we disregard the isolation into British and Native we learn that the coffee outside the Madras Presidency is ordinarily only about 0·15 per cent. of the total Indian area. It would thus be quite safe to describe Indian coffee-planting as an industry confined to the Madras Presidency. The chief localities are Mysore, Coorg, the Wynaad, the Nilgiri, Pulney and Shevaroy hills. The most important districts are Kadur and Hassan, both in Mysore, Coorg, and the Madras Presidency proper.

*Yield.*—On December 31, 1906, there were in all India 31,827 plantations, which gave employment to 24,477 persons permanently and 46,044 temporarily. These figures show a considerable reduction on the previous year, when there were 43,233 plantations. Dividing the figure of area by that of production and striking the mean of all the returns for some years back, the Indian yield would appear to be a little over 100 lb. to the acre, but it fluctuates very greatly; thus in 1903 the yield would appear to have been 139 lb., while in 1901 it was only 65 lb. It is probable, however, that in all the larger and better-worked plantations an average yield of 2 to 3 cwt. is usually obtained, in European plantations, and ½ to 1 cwt. in Native. But even that average is misleading, since it is well known some of the better plantations may yield as much as 7 to 10 cwt. an acre. Hence the officially returned acreage divided by the declared production, since it involves a mean of good, bad and indifferent results, cannot

be accepted as a method of deriving the yield, though the figures thus produced are suggestive and have, therefore, a certain value.

*Climate and Situation.*—It has been said, and with much force, that a good deal of land at one time and another has been opened under coffee that was never suited to it. Of this nature are some of the Coorg estates (or portions of them) that have a southerly aspect and are exposed to the full force of the east winds. Situation and exposure are factors of prime importance. It seems to be the Indian experience that coffee prefers land standing from 1,500 to 5,500 feet above the sea-level, the exact altitude being controlled to a large extent by latitude. Far to the south higher altitudes would seem necessary than in the more northern tracts. The temperature best suited would appear to range from 55° to 80°. The total rainfall should not exceed 150 inches but about 100 is the amount most frequently commended, provided it be fairly evenly distributed throughout the year; but December to March may be dry. Coffee distinctly requires a humid atmosphere, and in the opinion of most planters the prevalence of heavy winds are more objectionable than a dry atmosphere or a low rainfall. The climate must be open and bracing and the sky not heavily overcast. With *C. arabica* low-lying and damp situations induce disease. As already mentioned, however, altitudes lower and warmer than those indicated for *C. arabica* are suited for *C. liberica*, but even with that species the higher limits of its production give the most valuable berry.

*Soil.*—Coffee, although very largely a surface feeder, has a long tap-root which it is most desirable should not be injured during transplanting. The success of the crop depends to a large extent on the depth of the soil. The best soil might be described as a well-drained, ferruginous loam, though certain clays mixed with sand give good results, especially if a fair amount of humus be present or be given as top-dressing. Very chalky soils, as also stiff clays, are useless. It is usually held that soils that contain a fair amount of iron give the best-flavoured berries. But below the subsoil there must rest a bed of very porous material so as to ensure ready drainage. In fact a rocky soil with pouches of loam between the outcropping rocks gives admirable results, as may be seen in many parts of the Shevaroys, the Nilgiris and the Wynaad. The rocks are constantly weathering and thus adding to the soil, while, according to the planters, they also transmit the heat and moisture. [Cf. Robinson, Fringle, Voelcker, Lehmann, Leather, etc.] It is, however, unfortunate that no record has been kept of the conditions of land opened out and of the same fifteen or twenty years afterwards, both in estates manured and in those not manured.

*PROPAGATION.*—*Nursery.*—Having selected the site for a plantation, cleared and burned (or piled up in ridges to await natural disintegration) all the trees not deemed necessary for shade purposes, laid out the roads and carried a water supply to the coffee-house, the next most urgent task is to select and prepare the site for the nursery. This must never be on an old coffee plantation, but on virgin ground of sufficient richness that manuring may not be necessary except to add sand with a view to securing its porous nature. But the soil of the seed-beds must be rich in vegetable mould, bear a gentle slope, be well drained, retentive of moisture, and liberally supplied with water for irrigation purposes, since for some time watering is necessary. If not already secured, provision
SPECIAL CULTIVATED STOCKS

should be made for shade against the severity of the sun, but drip from protecting trees must be avoided by seeing that they are at a sufficient distance from the seed-beds. The beds should be slightly raised and of a breadth to allow of hand dressing from the dividing paths. In many cases temporary shelters may have to be constructed over the beds. A deep trench had better also run along the top of the entire nursery so as to check the possibility of surface wash.

The reader should consult the Dictionary, and one or other of the technical reports, cited above, for details of the coffee industry. For example, the varying methods of sowing, transplanting, weeding, pruning, etc., which to some extent are peculiar to each locality, must be sought for elsewhere. All that can be attempted in this work is a review of the facts that are deemed likely to have a bearing on the stability and prosperity of coffee planting.

Selection of Stock.—One of the most important of all tasks is the decision as to the stock to be grown. Even if the choice has been made of Arabian in preference to Liberian, there still remains the selection of the race or hybrid desired, and the source of supply. The reputation of the seed estate, the age of the parent stock (seven to ten years preferably), the method of treatment of seed, etc., etc., are points of vital importance. The seed should be gathered from healthy plants, the cherries should be fully ripe before being plucked, then hand pulped after maturity, and lastly they should be washed and dried in the shade in such a fashion as to avoid both fermentation and undue drying of the kernels. In fact some planters believe that seeds fresh from the trees should be husked and instantly sown to obtain the best results. The talk of “male” plants and the discussion as to the value of peaberry as seed, are themes indulged in at the expense of infinitely more valuable topics, but the greatest mistake of all is to suppose that coffee is coffee and that both seed and seedlings may be picked up anyhow or anywhere.

Races and Hybrids.—M. Jumelle (Les Cult. Colon. (Aliment.), 1901, 352-3) mentions many forms of coffee (apparently all races of C. arabica) and his enumeration may be here quoted as suggestive, since some of the races mentioned are already known to the Indian coffee planters. He treats of Moka as the stock typical form of the species and adds:—

(a) Vermelho.—A red-fruited coffee much grown in Central America: it is more robust than the type.

(b) Amarello of Brazil.—A yellow-fruited plant rich in caffeine but rather bitter in taste.

(c) Maragogipe.—The Upland Brazilian coffee, which has seeds nearly as large as Liberian coffee and is very prolific. This form appears to have been introduced into South India and is often referred to by planters, but no one appears to have furnished a report of its special merits or of the success attained with it in India. According to some writers this is a hybrid between C. arabica and C. Laurentii. [Cf. Kew Bull., 1894, 163-4; L’Hort. Colon., 1900, 62-3; Agri. News W. Ind., 1903, ii, 316-7.]

(d) Leucocarpa.—A white-fruited plant found originally in Sierra Leone. Could this be one of the special species of that country and not a cultivated race of C. arabica?

(e) Sourriére.—A very hardy plant that resists insect pests: the leaves are like those of the type but the seeds much larger.

(f) Leroy of Reunion or Pointed Bourbon.—Is more hardy than Moka, has short branches crowded with leaves, and the seeds are pointed at one end.

(g) Mysore.—Commercially described as “Cannon’s high-priced Mysore.” Has round heavy seeds; the branches are ascending; but as the yield is irregular it is being replaced by the next form.
(h) Coorg Coffee.—This has large flat seeds and is propagated easily. There are several well-marked races such as the “Chick,” “Golden Drop,” “Nalknad,” etc.

(i) Java Coffee.—This bears branches less horizontal than Brazilian, and the two young leaves at the extremity of the shoots are greenish-yellow in the Javan, and brownish-yellow in the Brazilian plant.

The planters of India recognise many more distinct races, but as no one seems to have scientifically described these, and the writer’s personal acquaintance with the coffee plant was acquired during one or two very rapid tours of inspection, he is unable to attempt a description or classification of the special Indian races and hybrids. The reader would do well, however, to consult Mr. J. Cameron’s various reports on the experiments conducted at the Lal Bagh of Bangalore. He will discover that Cameron discusses the hybrids that have been produced naturally, and explains that their most remarkable feature is their immunity from leaf-disease. But he has apparently not been so successful in the production of crosses as has been the case in other parts of the world. All the same his conclusions on this issue are clear and definite. He is sanguine that hybridisation may be looked to as likely to afford much advantage. The renovation of coffee, he accordingly adds, is “not wholly a matter of soil enrichment.” “Next in importance to hybridisation and proper culture, the interchange and special selection of seed must take a high place.” It may be here added that much has been said regarding the value of plants formed by grafting, or by inarching, as for example C. arabica on to rooted plants of C. liberica. The seeds from such are said to be superior to pure stocks, and in some respects constitute forms nearly as distinct as the crosses and hybrids already mentioned. The Kew Bulletin (1898, 30) affords much useful information regarding the hybrid coffees now grown in South India—a subject very greatly developed subsequently by the Indian press. But the industry is much indebted to Mr. W. L. Crawford, Mr. J. W. Hockin, Mr. Brook Mockett and Mr. Graham Anderson—the last-named gentleman having read a paper of great merit before the South Mysore Planters’ Association that reviews all the practical results attained.

The importance of careful selection of stock cannot, in fact, be overstated, and it is probably not far from correct to affirm that the majority of Indian coffee plantations possess two or more widely different plants treated as if one and the same, the result being irregularity both in quality and yield. The difficulties of the industry preclude any risks being accepted that might be obviated by personal knowledge and care. Hence it is desirable that the nurseries be as near the planter’s house as possible, so as to ensure constant supervision, from sowing to picking out and final transplanting. Any departures from the desired type should be instantly removed from the seed-bed, though no opportunity should be lost of studying sports that may appear. Forms directly suited to the climate, soil, and method of treatment pursued in each plantation should be the aim of every planter. But these cannot as a rule be purchased. They must be acquired as local manifestations or crosses specially developed. The study of the seed-bed and the care of the seedlings should be the special charge of the manager himself, not of the overseer or foreman of works. [Cf. Lehmann, Lect. in Planting Opinion, August 8, 1903.]
much injury to the roots of the plants. When about a year old the
seedlings are planted out into their permanent positions, but if care be
taken to select dull weather for this operation, many planters prefer older
plants, say two years old. Much difference of opinion prevails as to
the distance apart that the plants should be lined in the estate. The
question hinges on the following considerations:—(a) the nature of the
stock selected; (b) the system of cultivation to be pursued, more especially
the size of plants desired; (c) the character of the soil; (d) the degree of
shade that exists naturally, or that it is contemplated to afford; and
(e) the nature of the climate. In cold countries, where the plants are
not likely to attain to any great size, close planting may be indicated, the
reverse being the case under influences that might be expected to cause
glorious growth. In India the distances apart usually adopted vary
from 4 to 8 feet each way, and 7 feet might be said to be common, or
6 feet between the plants and 7 feet between the rows. This would
give 1,037 plants to the acre, but in many estates a considerably larger
number exists—in some 5 by 5 feet, or 1,740 trees to the acre. On
the other hand, Mr. Leeming of Scotforth, in the Shevaroys, was induced
some few years ago to believe that a larger plant and more space would
give equal, if not better returns, at a much lower cost than the prevalent
system of many small plants. He accordingly removed each alternate
bush and reduced his estate to 600 plants to the acre. The result was so
very promising that he went still further, and reduced it to 300 or 325
plants to the acre. On the average his bushes now stand 12 feet apart
each way. In 1899 I had the pleasure of inspecting Scotforth plantation
in company with Leeming, as also most of the other coffee estates of
that neighbourhood. And I have to admit that Leeming's plants seemed
to me in a healthier condition, and to be fruiting more vigorously, than
any coffee seen elsewhere. The yield had been greatly increased, the cost
of cultivation lessened, the plants rendered better able to throw off disease,
and the produce recorded as fetching a higher price than had been the
case under former conditions. These are all powerful arguments. But
there may be other considerations and conditions that have to be borne
in mind. It does not follow, for example, that plants 12 feet apart each
way would give everywhere the same results as on the Shevaroys, nor
that each race of the coffee plant would do so. The subject is one, how-
ever, that is capable of definite verification, and one moreover that it
would seem should be solved by every planter for himself. It would
not be a very serious matter to place a plot of a few acres under trial, and
if the returns proved unsatisfactory the replanting of fresh stock in place
of the old and exhausted plants that had been removed would in time
repay the outlay.

Cultural Operations.—It is undesirable to give details of the varied
opinions and practices that prevail as to the best systems of "holing"
and "planting out." The size and depth of the holes depend very largely
on the nature of the soil, the lie of the land, and the amount of money
and time the planter is prepared to expend. Where money is not a
serious consideration, large holes are made, the removed earth being
deposited on the higher side, the holes left exposed for some time to the
sun and air, then filled in with surface soil, manure and green vegetation
(weeds), but with little or none of the earth previously removed. After
a time the fresh soil thus furnished will sink, and this depression must
be made up with fresh surface soil. Farm-yard manure may with advantage be also given until a little mound has been formed, on the top of which the seedling should be planted. Transplanting should if possible be made during cloudy days, and just before the commencement of the most copious season of rain. Temporary shade should be afforded to the seedlings, in the form of small pieces of crude bamboo matting, or simply leafy boughs or tufts of bracken fern. It is also a good plan, especially in exposed situations, to fix a stake to which the stem may be lightly tied. If exceptionally dry weather follow transplanting, it may be necessary to give one or two waterings. In some cases a nursery is dispensed with and two or three seeds are deposited on the specially prepared hole-mounds, the healthiest one being ultimately allowed to grow and the others cut out or transplanted.

Drains.—Weeding or removal of wild herbage from the plantation, so as to prevent the young coffee from being choked, now becomes an essential operation. If drains have not been provided at the time the estate was being laid out, by this stage they become imperatively necessary. Nothing is, in fact, more important than a good system of drainage. In the *Pests and Blights of the Tea Plant* (2nd ed., 45–66) it has been urged on the attention of tea planters that the objects of a system of drainage are to increase the depth and improve the condition of the arable soil. Every word of what has been said in that work on the drainage of tea is applicable to coffee. And I may further add that during my inspection of the coffee estates of South India I found few had been drained anything like to the extent practised with tea. I accordingly urged the coffee planters to reform this defect.

One of the great advantages of drainage is the admission of air (oxygen) into the soil. The drainage of agricultural lands differs thus essentially from that of the streets of a town. The removal of surplus water is undertaken with a definite object in view, the fulfilment of which determines the position and number of the drains. The water is drawn below the surface, and thus made to carry with it the materials that the combined action of the sun and the air have transformed into a soluble condition. To permit or encourage surface wash is to render the soil sterile, in fact to afford facilities for soil-removal. The deeper the drains the further apart they may be placed, and the deeper the resulting arable soil. But drains of some kind are indispensable for successful coffee planting. In many coffee estates that occupy steep, hilly slopes, a system of *trenching* or *contour catch draining* has come into general use, as a protection against severe and wasteful surface wash. The trenches to some extent answer the purpose of refuse pits for the accumulation of manure. In fact in most instances they assume the condition of parallel chains of pits. If used as pits into which the weeds may be thrown, it is customary to have them cleaned out before the setting in of the rains, so as to afford every means of intercepting the fine soil of the surface wash. The contour drains in the tea estates are usually laid out with a level and the earth removed in their formation thrown on the upper side. This is essential, since the slightest slope downhill would convert them into dangerous surface drains. So again *terracing* is an additional method practised with great advantage on some estates, though apt, when exposed to the south or south-west, to dry the soil unduly. But as with contour drains so with terraces, they must be laid out as nearly level as possible.
TILLAGE

But when slopes are not too great and the soil fairly light, bunding is a third method, superior to even trenching or terracing. Instead of cutting out a terrace, a bank of soil is laid across the slope, and the rain thus made to wash this into a natural wide terrace. In many parts of the country bamboos and prunings are used to form fan-like structures upon which the sitting-up process may be encouraged.

Digging and Mulching.—Lehmann (Bull. Dept. Agri. Mysore, 1902, ii.) has very properly pointed out that coffee is so very different from the majority of the plants cultivated in Europe and America, that it does not of necessity follow that approved Western methods are in every detail applicable to it. "For one thing," he observes, "coffee thrives under the shade of large trees, while in Europe, or at any rate in Canada, the cultivated crops invariably suffer near trees of any sort." He accordingly urges that under the climatic conditions and on the soils that prevail in Mysore, it is essential that knowledge of coffee cultivation should be acquired by direct experiment rather than deduced from general agricultural principles. And in that opinion he is assuredly correct. Coffee is as sensitive, Lehmann tells us, as most plants to the injuries caused by caking or baking of the soil. In Mysore, he continues, most soils after being dug and then exposed to heavy rain, followed by bright sunshine, become quite as hard on the surface as they were before having been dug. But surely that peculiarity is experienced throughout the world, and on the pure sands of the deserts of Rajputana as much so as on the rich loams of Northern Europe or the coffee lands of Mysore, wherever rainfall is followed by bright sunshine. It is to check the parching and baking action of the sun that gardeners mulch or litter certain crops as a temporary measure. It is with the same object in view that weeding at the commencement of the hot months is discouraged by the cultivators of most tropical countries. Cameron points out that the annual weed "Blumea" (Ageratum conyzoides) seen in established plantations can do comparatively little harm and that a light covering of weeds might even do good by preventing the surface becoming overheated. To guard against severe baking and overdrying of the soil is a legitimate and rational aspect of all agriculture. But to advance from that position to the condemnation of tillage and the rejection of the fully demonstrated fact that the breaking-up of the surface soil and its exposure to the action of heat, light, air and water has the effect of reducing non-soluble to soluble compounds and the production thereby of plant food, seems utterly unwarrantable. The protection of the soil against surface wash and surface baking by a natural litter of leaves (mulching) is very admirable and may be very useful as an occasional process of fallowing, but to expect that any lands, however admirably drained, weeded and mulched, could continue indefinitely to yield coffee or any other crop without tillage or manure, is to carry a natural law to a perilous and unjustifiable extreme. Lehmann, by his studies of the manures of coffee, has shown that he never contemplated his recommendations for mulching to be the one and only method of treatment of the soil that was desirable. It would indeed be an unwarrantable assumption to affirm that what may be true with a wild plant must be true universally with the same plant under the abnormal demands of cultivation. It is beside the issue to say that mulching has actually been the system with a group of coffee gardens in Coorg for many years (Madras Weekly Mail, March 20, 1902). It might be fairly be, and in fact

COFFEA ARABICA
Cultivation

To guard against severe baking and overdrying of the soil is a legitimate and rational aspect of all agriculture. But to advance from that position to the condemnation of tillage and the rejection of the fully demonstrated fact that the breaking-up of the surface soil and its exposure to the action of heat, light, air and water has the effect of reducing non-soluble to soluble compounds and the production thereby of plant food, seems utterly unwarrantable. The protection of the soil against surface wash and surface baking by a natural litter of leaves (mulching) is very admirable and may be very useful as an occasional process of fallowing, but to expect that any lands, however admirably drained, weeded and mulched, could continue indefinitely to yield coffee or any other crop without tillage or manure, is to carry a natural law to a perilous and unjustifiable extreme. Lehmann, by his studies of the manures of coffee, has shown that he never contemplated his recommendations for mulching to be the one and only method of treatment of the soil that was desirable. It would indeed be an unwarrantable assumption to affirm that what may be true with a wild plant must be true universally with the same plant under the abnormal demands of cultivation. It is beside the issue to say that mulching has actually been the system with a group of coffee gardens in Coorg for many years (Madras Weekly Mail, March 20, 1902). It might be fairly be, and in fact
has been asked:—“Can it be proved that these very plantations could not have done better during the past?” or, “May they not, even now, be approaching the exhaustion that led to the abandonment of many similar and once fertile estates in that very province?” It is doubtless true that with rich primeval forest land, if well drained and carefully mulched, exhaustion may not become manifest for many years. But it is equally true that with indifferent soils or exhausted lands, mulching can never take the place of tillage and manure.

Lehmann concludes his very suggestive report—a most valuable paper even though its main contention may not be accepted as constantly and universally applicable—by the following statement of the advantages of mulching:—“The careful preservation of the natural mulch on pieces on which the coffee has ‘closed in’;—(a) saves the digging: (b) leaves the soil in a better mechanical condition than the usual amount of digging could do: (c) probably prolongs the life on an estate and increases its general vigour and productiveness after the first year or two: (d) will save a large portion, possibly all the expense of applying bulk manure. Not digging an estate may have the following disadvantages:—(a) it is liable to reduce the crop for a year or two: (b) it has the tendency to increase the risk of fire.”

A volume might be written in an attempt to review all the opinions that have been published for and against the tillage of coffee lands. A correspondent, for example, wrote to a Madras paper in 1895 regarding South Coorg—“The change that is worked in a sickly piece of coffee by deep digging is little short of marvellous; in a couple of weeks’ time one would hardly know it for the same piece of coffee.” That sentence is fully expressive of the opinions of the vast majority of planters.

**Manuring and Manures.**—Cameron (Rept. Offic. Visit to Coffee Dist., Coorg, 1898) has much to say on the necessity for high cultivation and the manures best suited for coffee. He discusses farm-yard manure; bone; oilcake; nitrogenous manures, and the fixation of free nitrogen by the aid of leguminous catch crops; lime; phosphates; potash; green manures, etc., etc., and commends the use of bracken fern for the litter of cattle on account of its subsequent value as a manure. In his concluding observations he remarks: “The application of proper manure in correct quantity and at the most serviceable time, are things which should be assiduously learned from practical experience.” So again, one of the most valuable contributions to our knowledge of the art of manuring coffee is the series of studies conducted by the late Mr. William Pringle, and published in pamphlet form by Messrs. Matheson & Co., of Madras. While we have many similar technical reports, some of which will be briefly mentioned below, very little of a practical nature has transpired of the accumulated experience gained during the seventy odd years of Indian coffee cultivation. The planters prefer, as a rule, farm-yard, or bulk manure, as it is called, and are restricted in its use by the difficulty of procuring enough. Lehmann has recently pointed out that the first and foremost consideration is to see that all the essentials in soil-composition are present, in the right proportion and right condition. Fertilisers may then be given in the direction of crop requirements. He, for example, remarks that “the potash fertilisers have, I fear, not received the attention they require. Judging from the analytical results I have seen, most of your soils are rich in nitrogen but relatively poor in potash,
phosphoric acid and lime, and, although much more potash than phosphoric acid is carried off in your crop, potash is but seldom added.” So again, many writers have shown, and most conclusively, that if the soil does not possess enough lime, bone and other expensive manures may be worse than useless. Voelcker (Improv. Ind. Agril., 1893, 270), for example, some years ago observed that the differences of practice occur in the manner of applying manures, some planters preferring to throw manure broadcast and to fork it in, others thinking it better to dig a trench round the bush, about a foot or a foot and a half from the stem, and to put back the soil mixed with whatever manure it is intended to apply. “Manures such as bones, oilcakes, etc., are too generally used, because they have always been used, and because there is a general belief in their utility, but it is more than probable that in some cases large sums are needlessly expended on them, while in others lack of lime, potash, or other soil-constituent may be responsible for a diminishing yield.”

The manures and the methods of applying them to one plantation are not always applicable to another, so that no general rule can be laid down, and the indications afforded by the soil itself must be closely followed. In some parts of the coffee area, fish manure is much appreciated as a crop fertiliser, cow-dung being viewed as strengthening the wood. Mixed bone and fish manure produce an abnormally heavy crop. Oilcake (poonae) is believed to strengthen the leaves against blight. [Cf. Voelcker, l.c. 104–5.]

The season for applying manure is also a subject of much difference of opinion, but is possibly best solved by a careful study of the particular manure that it is contemplated to be given. Stem and leaf-forming manure should naturally be given just after the crop has been gathered; those supposed to increase the yield would, on the other hand, best be supplied just before the flowers appear, say in February and March. So again, bone and other manures that take some time to decompose require to be given early and soluble manures much later. Many writers seem, however, to condemn immediate or chemical manures and regard these as possessing few, if any, advantages for coffee.

Assimilation of Free Nitrogen.—So much has been said of the advantage of growing (as a sort of rotation) leguminous crops along with coffee, that a volume might be written on that topic alone. The subject is by no means new nor confined in its applicability to coffee. A rotation of clover with grain crops became a principle of all early European agriculture, long before the correct explanation of that system had been discovered. Its application to coffee has been urged by all writers, more especially by Mr. B. Nelson. The use of leguminous shade-trees such as the sau of the Assam tea planters (Albizzia stipulata) and the Erythrina lithosperma of coffee planters are good examples of both shade and nitrogen assimilation. (See below the para. on Shade-trees.) [Cf. Pests and Blights of the Tea Plant, 136–47.]

Nitrification.—Allied to the study of free nitrogen, though perfectly distinct, are the methods by which the combined nitrogen of the soil or of manures is prepared for plant use and the processes or vehicles of its transmission into the roots. This is defined as the nitrification of the soil. Nitrogenous matter is oxidised and the nitrogen developed into a nitrate chiefly of lime or of potash. Until quite recently it was believed to be a simple chemical process. But it has been ascertained to be a consequence
of the vital activity of certain organisms, chiefly bacteria. Ammonia compounds are found by the agency of uro-bacteria and other putrefactive organisms before the nitrates are produced. Dr. A. B. Frank (Lehrb. der Botanik, 1892, i., 259–75) gives details of some studies of symbiotic fungi found on the roots of certain plants, such as on a few species of Cupulifera and Orchidaceae. These would seem to aid in nitrification. A long series of articles from the pen of Mr. H. B. Evans will be found in Planting Opinion of 1900, in which he advocates that “Nitrogen Hunger” is one of the chief maladies of the coffee plant. He seems to have assumed that the nitrogen of the soil and of the manures of coffee estates does not exist in an assimilable condition. In other words, that the agents of nitrification are absent to a ruinous extent. This, he would further believe, proceeds from the deficiency of a necessary symbiotic fungus, the function of which (Evans affirms) is the transmission of nitrogen from the soil to the roots of the coffee. Should the existence of a symbiotic fungus be actually established for coffee, the conditions that would favour its extended production might become of supreme importance. But the issue, so far as present knowledge goes, is a pure hypothesis. The presence of a fungus on the superficial roots of the coffee was discovered by Janse in Java. [Cf. Ann. du Jard. Bot. de Buiten., xiv, 113–8.] That fungus was most prevalent in soils rich in humus, and was also found on the roots ramifying among the litter of dead leaves on the surface. But no one has as yet proved that Janse’s fungus is actually beneficial to the coffee plant, and Janse himself, like all other investigators, failed to specially cultivate it. Although there are possibilities in this direction, the subject is infinitely less known than the action of the bacteria contained in the root tubercles of the leguminous plants indicated above. [Cf. Percival, Agri. Bot., 1902, 764–6.]

Concluding this brief review of coffee manures, it may be remarked that Voelcker observes very truly that “a sure sign of the land being too highly manured is the appearance of shoots all up the stem. The indication of a good bush is, on the contrary, the healthy growth of new wood on the branches.” [Cf. Wall, Manuring of Coffee Estates; Burgess-Brown, Coffee Planting (17 years’ experience in Ceylon), 1877; Hughes, Ceylon Coffee Soils and Manures, 1879; Munro, Soils and Manures; Lawes, Corresp. regarding Coffee Manures, in Planting Opinion, Aug. 1896; Kramer, Mededelingen Pl. Java, 1899, 3, 73; 1900, 64; 1901, 1, 56; Clarke, Prize Essay, Management of Soils under Coffee, 1883; Elliot, l.c. 350–82; Pringle, Madras Mail, 1891; Revue des Cult. Colon., 1901, viii., 198, 294; Lehmann, Lect. before N. Mysore Planters’ Assoc. (reprinted in Planting Opinion), Nov. 1900; also subsequent lecture in Planting Opinion, Aug. 1903; Cultura Rational du Caffeiro, in Journ. dos Agri. Rio., 1902, ii., 57; São Paulo, Boletin da Agri., Jan. 1902.]

Pruning.—Within the past few years, thanks to the enlightened energy of Mr. Leeming of Scotforth, Shevaroys, there has come into existence two diametrically opposite schools. These may be characterised as the non-pruning and the severe-pruning systems. Having studied the latter for some time, and formed the opinion that certain departures were urgently needed, I became a partial convert to the non-pruning system so ably advocated by Leeming. It would seem, at all events, very possibly preferable to the system of severe pruning that presently prevails. Judged of from the purely botanical standard of the state of health and vigour of
HANDLING AND PRUNING

the plants, the non-pruning system seemed superior to the customary form
of severe pruning. But I am disposed to add that I can easily conceive
of climatic conditions and stock plants where a pruning system would
be indispensable, so that I by no means think non-pruning is of uni-
versal application. It is, moreover, not new but has for many years
been followed in other countries, and even in India has been the practice
in vogue with most Native coffee-growers. Leeming would, however,
appear to be the first European planter in India who has had the courage
of his convictions, and who has not only uprooted two-thirds of the plants
on his estate, but allowed those that remained to grow in obedience to soil
and atmospheric conditions.

It is customary to speak of coffee-pruning as consisting of three stages,
or operations—viz. :-—Topping, Handling, and Pruning (proper). The first
consists in nipping off the top shoot, so as to check the upward growth.
This is done at various stages, usually when the plants are 3 years old,
the shoots being then cut at a height of 5 feet; at other times the nipping
off is done much earlier, at 18 months to 2 years, the stem being left at
from 2 to 3 feet in height. When the short process is pursued, a sucker
(as it is called) soon arises near the top pair of branches and renews the
upward growth. This is allowed to continue for a foot more and is then
in turn nipped off. A second sucker in consequence rises up and is in
like manner checked, when the desired ultimate height of the main stem
is attained, namely 4 to 6 feet (usually 5).

In the first instance (3-year-old stems) there is a terminal snag pro-
duced. The topmost pair of branches, below the snag, having the best
advantage as to light and air, lengthen horizontally and in due course
become so weighted with fruit that the terminal snag of dead wood is split
open, and this cleavage increases year after year until many bushes become
literally eleft in twain. Admission is thereby given to damp and weather
action, also to disease and vermin of all kinds. The aim of the planter in
this system of "topping" is to produce a crown or umbrella of primary
branches. By what is called "handling," all undesirable suckers and
"gormandisers" are systematically removed and every effort made to
restrain the bush severely on fixed lines of growth supposed to favour
fruiting and be most convenient to the pluckers. [Cf. Pi errot, Cult. Prat.

In the second system (largely followed in Coorg), in addition to the
terminal snag, with all its possibilities of evil, the growth of the stem is
twice checked and snags of dead wood thereby interposed within the stem,
which must have the immediate consequence of disarranging and inter-
cepting the circulation of the sap. Nothing could be conceived less ad-
Vantageous. Moreover, the effort is made by the growth of the secondary
branches, ultimately produced, to convert the topmost three or four pairs
of primaries into a completely ramified umbrella, that must of necessity
render the branches below a useless burden on the resources of the plant.
M. Edouard Pierrot recommends a system of pruning that does not
seem to me to differ from that followed by the Indian planters. His
account of coffee-planting is, however, most instructive, and should be
consulted by all interested in the industry.

So far as could be learned from personal observation, few subjects
are perhaps more urgently calling for reformation, both as an aid against
THE COFFEE PLANT

disease and as a means of enhancing returns, than the system of pruning. Any pruning seemed accordingly preferable to that usually practised. By encouraging a vertical rather than a horizontal growth, the fruiting area of the estate is (if one may so express it) immensely increased. But where, from the nature of the soil, the peculiarities of the climate or the character of stock grown, "coffee trees" could not usually be produced (such as those of Scotforth), it would seem that a pyramidal bush might nevertheless, and with advantage, be aimed at rather than a fruiting umbrella. This might be accomplished in various ways that doubtless would instantly occur to the practical planter.

Without desiring to dictate, one method that suggested itself to me while inspecting the coffee estates of the Wynaad may be here mentioned. Plants 4 feet in height, or when they possess 6 or 7 pairs of branches, might be taken in hand. In some plantations, however, bushes only 2½ to 3 years old were seen to possess 15 to 20 horizontal branches, within a height of 4 feet. It is very unlikely that these could all bear fruit, hence perhaps half may have to be removed. But when the approved number of primaries had been secured, the green terminal shoot, containing a pair of leaves and a bud, might be clipped off, and at the same time the terminal buds of the topmost three or four primaries similarly destroyed. Care would have to be taken, however, that this plucking off of the terminal buds was done on green not woody shoots. Delay till wood is formed almost invariably involves a snag, and moreover the cutting back of finally matured shoots requires great care and a study of the best age and most favourable season for each locality. The object aimed at by the system suggested would be the production of a pyramidal bush, and if sufficient space were allowed such might ultimately be expected to fruit from the ground to the topmost twig. The check given to the growth of the upper primaries would prevent their attaining the size and weight sufficient to split the stem (in the way already mentioned). The secondaries borne by each primary would in time become fan-shaped, and through the regulation of the lengths of these fans the bush would become completely pyramidal. It is the secondaries borne on the primaries that are the fruiting shoots, and the purpose of the recommendation here offered would be to produce a maximum of such, fully exposed to light and air. Similarly a vertical pyramidal bush might be formed by the development of upward-growing suckers in place of horizontal branches, the main branches being trained to ascend from the stem or its primaries, like those of a poplar. But I need not enlarge on this theme. What seems imperatively necessary is greater spacing, a better-shaped and a more healthy bush. Mr. Leeming's "coffee trees" in these respects, at all events, are as nearly perfect as seems likely to be attained; and where trees are not possible, bushes of a tree shape might be secured in preference to that of an umbrella. (See the remarks above on the tendencies of certain races to produce ascending and of others spreading branches.)

To conclude these observations, it may be said that pruning as presently practised is done about March after the crop has been collected, and consists in removing all shoots that have borne fruit and in selecting and protecting those that are intended for next year's crop. But the pruning must be completed before the flowers begin to form, and in pruning it is often recommended to leave alternately the opposite laterals. All tertiaries, as also diseased branches, are usually cut off. A handling is often given just after the flowers appear, in order to remove useless flushing. During a second handling suckers and crosswise shoots are rubbed off, without injuring the bark, and, in carefully worked estates, even a third handling is often given. It seems to be an accepted rule that September and October shoots should be preserved, and that as many of those formed in February as can be spared should be removed; but during fruiting the plants are never interfered with. In many estates removal of moss and cleaning the bark is regarded as of great service to the plant and obviates the harbourage of pests and blights.
SHADE-TREES

Shade-trees.—When Arabian coffee is grown upon lands of low altitude, shade becomes imperatively necessary, but in these positions Libenian may be successfully grown without any shade. As the upper limits of Arabian coffee cultivation are reached, shade may be largely dispensed with. Much difference of opinion prevails as to the extent and nature of the shade best suited to each region. Cameron (Rept. Tours in Coorg, 1898) very properly urges that a mixture of different shade-trees is preferable to one particular tree all over an estate. The balance of soil is thereby secured and a better shade attained. In Mysore tall original trees are generally preferred to the leafy bushes specially resorted to in other localities such as the Shevaroys. If protection from wind be the object aimed at, shelter belts of strong densely branched trees are indicated, but if shade from the sun be the object, much will depend on the severity of the sun and the liability to boror. It is the accepted belief that shade gives a certain protection from that pest, and this circumstance, more than protection from the sun, often determines the nature and extent of the shade-trees desirable. As little shade as possible is necessary during the rainy months, and the maximum shade during the hotter months. The study of the season of new leaf in shade-trees is, therefore, all-important.

Dal (Cajanus indicus) would make an excellent shade-bush for young coffee, and by its root tubercles and copious supply of leaves it would enrich the soil at the same time, but its liability to fungal disease (see p. 198) might be viewed as rendering it undesirable. Another Leguminous plant has been much appreciated by coffee planters—viz. one or other of the species of Erythrina such as indicia, lithosperma and suberosa. Mr. B. N. Nelson (Planting Opinion, 1896 to 1899) wrote a series of articles and showed that the use of E. lithosperna as a shade-tree gave a material increase to the yield of coffee. The Silver Oak (Grevillea) is much commended by many planters, but while useful for shade it can have no manurial value. The other trees, fairly extensively employed, may be here mentioned in alphabetical sequence, viz.:—Acrocarpus fraxinifolius; Albizzia lebbeck, molucana, procera and stipulata; Arelcarpus Chaplasha, integrifolia and Lukocha; Bischofia javanica; Cedrela Tomii; Dalbergia latifolia; Ficus asprima, glomerata, hispida, infectoria, and mirysensis; Grevillea robusta; Pithecolobium samii; Pterocarpus Marsupium; and Treme orientalis. Many other trees might also be mentioned, such as one or two exotic plants, for example India-rubber (Manihit glaziovii) and Eucalyptus. As catch crops Indian corn has also been tried, and with fair success; and in Coorg, pepper and cardamons are much resorted to, especially by native cultivators. [Of. Kew Bull., 1895, 306; Graham Anderson, For. Trees in Coffee Lands Mysore, 1885; Rept. Agri. Chem. Mysore, 1901–2, 29–35; Journ. d’Agri. Trop., 1902, ii. 124–5; Trop. Agrist. Planter; Madras Mail, etc.]

ENEMIES—PESTS AND BLIGHTS.—To give even the most general outline of this subject would occupy many pages. Having studied with some care the enemies of the tea plant, the first impression left on my mind, in visiting the coffee plantations, was the comparative absence of pests. An ordinary tea garden when compared with a coffee plantation would afford the entomologist ten to every one for his special study. Even the blights or fungal diseases are far less numerous, though one is very much more prevalent and widespread than any of the blights of tea. At the lowest possible estimate there are 200 insect pests on the Indian tea plant, and perhaps not twenty all told on the coffee. But the few that are present are often disastrous to the industry, and thus make up for their specific panacity by their individual voracity. In fact it may be said that two or three insect pests and one or two fungal blights have practically baffled both planter and scientist and have proved so disastrous as to have
ruined the industry over large tracts of country. This is significantly true of Ceylon, the leaf-blight having there proved so completely incurable as to have caused the planters to substitute tea for coffee, as their only escape from ruin. Numerous reports and monographs have been published by Morris, Marshall Ward, Nietner, Bidie, Harman, Cooke, Massee, Barber, etc., so that it cannot be said the subject has been neglected, but so far little progress has been made of a practical nature.

The more important diseases of the coffee plant are the following:—

It has been assumed as probable that *M. caudata*—a parasite found on *Cajanus cajan*—was the parent source of *H. vastatrix*, the differences observable between the two fungi being in all probability the result of growing on slightly different hosts. So in the same way leaf-blight, seen in Natal and other African plantations, may have originated from *H. woodii*—a parasite found on two species of *Vangueria* and even on *Coffea zambesiaca*. Massee accordingly writes: "It is not at all necessary to assume that the coffee disease has been imported along with the coffee plant from one country to another, taking into consideration the wide distribution of different species of plants attacked by *Hemileia, vastatrix* or *H. woodii*, both of which are capable of infecting species of *Coffee*." In India there are some six or seven species of *Cajanus*, fairly abundant wild plants in the coffee area, also a species of *Vangueria* both in Kanara and the coffee tracts of Burma. If, therefore (as pointed out by Massee), a practical lesson is to be drawn from these considerations, to start a plantation in a district where these and other allied plants to the coffee are abundant would probably mean disaster. To grow for the purpose of shade, plants belonging to that family would also very possibly be dangerous. All rubiaceous plants should therefore be watched for any appearance of leaf-blight, and exterminated as far as possible from proximity to coffee.

The leaves of coffee are the parts most frequently attacked by *Hemileia*, though spots are sometimes present on the young shoots as well as on the fruit. These expand in size irregularly, are at first pale yellow, but in time become bright yellow and orange coloured. Though showing through on both surfaces, the spores appear on the under-surface only. These are formed in dense clusters, and emerge from the tissue by the breathing mouths (stomata) of the leaves.

While touring through the coffee districts of South India I observed the grub of a minute insect feeding on the spores of this fungus. I was told this had been seen by the planters for some years. It would appear of importance that the life history of that little creature should be worked out, since it may be the planters' greatest friend. When leaf disease is at all serious it is so prevalent as to render most of the methods of treatment, that have as yet been suggested, quite impracticable. Syringing with fungicides, such as the Bordeaux mixture, sulphuring the leaves, removing and burning the leaves, tearing off or punching out the diseased portions, have each and all been advocated and tried with varying, though never with complete, success. The best results as yet recorded have been attained by producing a stronger, more vigorous plant, through increasing the spacing, lessening the shade, improving the drainage, manuring liberally, and restraining the pruning knife. Under some such treatment

384
LEAF-BLIGHT

liability to borer may be increased, but leaf-blight brought under control. On some soils, under certain climates, or with particular exposures, leaf-blight never has been serious, and, moreover, either the plants are now better able to withstand the disease or its virulence is being attenuated, because in South India coffee-planting is by no means impossible, in spite of blight and borer. The low prices, through overproduction in South America, are far more serious than all the blights at present known. There would seem little doubt that had the Ceylon planters cultivated and manured their estates more thoroughly and systematically than they did their industry might have been saved. When the disease appeared both soil and plant were exhausted. The rapidity of the destruction that ensued may be thus demonstrated: average yield for the years 1866–8, all over the island (that is, before *Hemileia* appeared), was 4.28 cwt. per acre; in 1872–4 it had fallen to 2.93 cwt. per acre, and in 1878 to 2 cwt. per acre.

2. American Coffee Disease, *Stilbum flavidum*, Cooke; Massle, l.c. 445; Lecomte, l.c. 204; Jumelle, l.c. 377.

"This disease is almost as destructive to the coffee industry in the New World as *Hemileia vastatrix* is in the Old World." "The symptoms of the disease are unmistakable: circular whitish blotches occur on the leaves, often in considerable numbers, and are equally marked on both surfaces. Using a pocket-lens, very minute fungi resembling a miniature pin in shape, and of a clear yellow colour, can be seen grouped on the spots on the upper surface of the leaf. The berries are also sometimes attacked, being marked with circular spots. On the young shoots the pale diseased spots are elongated" (Massse). As this disease has not appeared, so far as is known, on the coffee of Asia, we have the somewhat significant fact of two coffee blights, the one confined to the Old and the other to the New World. *A species of Stilbum* does considerable injury to the tea, being the Thread Blight of tea planters. [Cf. *Pests and Blights of Tea*, 392.]

3. Leaf-rot.—This leaf-blight was described by Cooke under the name Pelticularia koleroga, the specific name being the vernacular for the disease. [Cf. also Tabeuf, l.c. 518; Lecomte, l.c. 203.] It is said to be prevalent in Mysore during July; the leaves, flowers and berries become covered with a shiny gelatinous substance which turns black about the time that the affected parts fall from the plant.

Cameron thinks that continuous or heavy rainfall, dense shade, drip, and stagnation of drains favour the development of this blight. Improvements to combat these defects are beneficial. All affected leaves should be burned or dusted with flowers of sulphur. As seen in the Kew Herbarium the leaves are covered with a simple mycelium much as in *Stilbum*, but without any fructifications. Samples of it have come from the coffee plantations in Venezuela, Costa Rica and Jamaica, as well as Mysore, so that it is fairly widespread and should it commence to assume its complete form, may become a serious pest. It should therefore be kept under control and carefully studied.

4. Coffee-twig Disease, *Necator deceretus*, Massse, l.c. 327. This Twig Disease is said to be a destructive parasite on coffee trees at Selangor. It commences at the tips of the young branches and extends downwards. Bursting through the epidermis of the shoots are minute white spots, which soon become orange-red in colour and gelatinous in texture. The twigs thereafter turn black and thus appear as if syringed with acid, while at the same time the bark splits as in canker.

During my tour through Coorg and the Wynaad I was shown a disease that brings to mind the Malay twig disease or canker just described. The tips of the fruiting shoots, including a large number of leaves and berries, become withered and dried up, and in due course turn black. I was unable to discover on these any fungus, but obviously should have visited the plantations at a much earlier season of the year in order to study the distressing disease indicated. The withered fruits, if gathered along with the ripe cherries, greatly lower the value of the crop, so that they are not only a serious loss but a source of danger through their being inadvertently collected. The Indian planters regard the blackened and withered shoots as a consequence of a want of general tone and vigour, and as proceeding from poverty of soil rather than being due to any specific disease. An inspection of the specimens preserved at Kew leads me, however, to suspect...
that it is due either to the self-same species, or an allied fungus to that just described as the coffee-twig disease of Solangor.

5. Borer: Ind. Mus. Notes, ii., 153. This pest used to be known as "Worm" or "Coffee Fly." It is most troublesome in Mysore, South Coorg and the Wynad, where in 1865-6 it destroyed whole estates. It has also appeared in the small coffee gardens of Assam and Burma. It is the grub of a beetle, Xylotrechus quadrupes, Chevr., and is yellowish-red with black transverse lines. It damages the tree by boring holes into the stem, usually a few inches from the ground. These passages are at first transverse, but soon ascend spirally to the growing tip, where the larvae are matured. The plant early shows signs of death and ultimately withers down to the point where the beetle entered.

This pest is most prevalent in hot, exposed gardens, and may be kept in check by free irrigation, good tillage and the growth of large shade-trees. Cameron speaks of nimb oil, poured into the openings made by the borer, as being useful in either expelling or killing the grub. As a preventative it is believed also desirable to encourage rather than interfere with the nesting of insectivorous birds in the plantation. If the stems of injured trees are collar pruned, new suckers are thrown out and the plants thus renewed, while the borers with the channelled stems are destroyed.

Another borer is the larve of the moth Zeuzera coffeae, Niether. [Cf. Ind. Mus. Notes, ii., 157; Watt and Mann, Pests and Blights of Tea, 200-1.]

6. Bugs.—Various insects are by planters all called bugs. They belong for the most part to the family known as the Coccidae or Scale Insects. There are four chief pests of this kind, known as Brown, Green, Black and White Bug.

Brown Bug, Lecanium hemisphaericum, Larg.; Green, Coccidias of Ceylon, 232-4, pl. 85; Ind. Mus. Notes, ii., 198. "This insect was formerly known as the "Brown Bug" of the coffee plant, and before the advent of the "Coffee Bug" was considered the most serious insect pest of that plant." "For some years before the coffee failed, the bug—as a pest—had practically disappeared." It is met with now and again all over the coffee area of India, but nowhere to a very serious extent. It is perhaps most harmful in the Shevaroy, Nilgiri and Mysore plantations. [Cf. Agri. Journ. Ind., 1906, i., pt. i., 77-8.]

Green Bug, L. viridis, Green; l.c. 199-203, pl. 69; Ind. Mus. Notes, ii., 198. This proved such a scourge in Ceylon that it was practically responsible for the final abandonment of coffee cultivation over the greater part of the planting districts. It first attracted attention in 1882, and by 1886 had been dispersed all over the coffee districts of Ceylon. It attacks weakly trees and almost completely denudes them all but the two or three terminal leaves. On healthy plants the leaves become black through the attendant fungus, but do not fall off, and the bushes make a vigorous effort to grow. In Ceylon the plants had been weakened by Hemileia when they became infested with green bug. In 1881 the exports were 452,000 cwt., but ten years later they had fallen to 88,780 cwt., and in 1902 were only 10,000 cwt. [Cf. Agri. Journ. Ind., 1906, i., pt. i., 78.]

Black Bug, L. nigrum, Niether; Green, l.c. 229-31, pl. 84; Ind. Mus. Notes, ii., 198. This bug, though found on coffee, is not so serious a pest as either the brown or green bug.

Mealy Bug, Pseudococcus austiimidum, Linna.; Ind. Mus. Notes, ii., 198. This is a flat oval creature covered with white down arranged in parallel ridges and running across its back. It prefers hot, dry plantations and would seem to be harboured by the species of Erythrina now so largely grown for shade purposes. In a plantation in the Wynad where the trees had been cut down, I observed white bug very prevalent on the underground portions of the stems, as also on the roots, and swarming to the neighbouring coffee. Whether or not this observation is of invariable application cannot at present be affirmed, but plants seem to favour the growth of any species of bug should be discouraged in coffee plantations even although the present species has not been recorded as doing serious damage.

Every effort has been made to exterminate these pests. But in the case of green bug, the insect, being green in colour and small in size, was not noticed
until it had been established in Ceylon in such force as to defy all subsequent efforts at extermination. It usually decreases during both very wet and very dry weather. The most hopeful method of dealing with it, as also with all other scale insects, is through their natural enemies. The larvae of certain ladybird beetles (Chilocorus circumdatum for brown bug, and Scyphus rotundatus for white bug) live on them, and a minute chalcid wasp breeds within the body of the mature Leccanum. So also a parasite fungus (Cephalosporium lecanii) kills these insects by living on their bodies.

7. **Grub.**—The larvae of the moth *Agrotis ypsilon*, Rott.; *Ind. Mus. Notes*, ii., 161; iii., 21; Watt and Mann, *Pests and Blights of the Tea Plant*, 1903, 220–3; Maxwell-Lefroy, *Memoirs, Dept. Agr. Ind.*, 1907, i., 169. The Cutworm, Black Grub or Ringer are very destructive to the seedlings of coffee, as much as 25 per cent. being often found destroyed by this pest. It seems to have been specially destructive in Mysore.

The larvae of the cockchafer, *Lachnosterna pinguis*, Walk., often do much damage by eating the roots of the young coffee plants. [Cf. *Ind. Mus. Notes*, ii., 149; Watt and Mann, *l.c. 167–9.]

8. **Other Insects** that occasionally attack the coffee may be here enumerated:—

Architecta destructor, Nieter, a weevil that eats the leaves *P. avusis tepida*, Cramer; a moth that defoliates the bushes; *Narasura conspersa*, Walker; *Alou laetinea*, Cramer; *Euprocclus virgatus*, Walk.; *Trichia seligii*, Fed. ; *Calleistoma variegata*, Fedd.; *Euphyes lecoustignaria*, Fed.; *Bournia lecostignaria*, Fed., and *B. zygumaria*, Fed.; *Tortrix coffearia*, Fed.; *Cupua coffearia*, Nieter [cf. *Ind. Mus. Notes*, v., 187], and *Gracillaria coffeifolia*, Motsch. (recalling *Eutrichia coffeella*, G.M., in Jardin, *l.c. 258–9 and pl.), are all moths reported to have been occasionally met with on coffee in Ceylon. So also *Anthomyia coffee*, Nieter, is the coffee-leaf borer; *Stachia geinitziana*, Motsch., a species of *Rhynchota* that attacks the coffee-cherries; *Apis coffee*, Nieter, the coffee-louse (parasitised by *Microtus australis*); and *Aevius coffea*, Nieter, the coffee-mite. So far as presently known, none of these pests have given any cause for anxiety to the Indian planters.

9. **Other Pests.—Locusts, Weevils, Rats, Squirrels, Monkeys and Jackals** often do much injury—the animals mentioned being very fond of the ripe cherries.

**Life of the Estate.**—The late Mr. William Pringle very rightly observed that "no matter how healthy a coffee tree may be, no matter how carefully pruned, handled, tended and nourished, its life will end sooner or later. Under favourable conditions, the tree may live for fifty or sixty years; as a rule, it will seldom last thirty. It will, under favourable conditions, be in full bearing in the fifth or sixth year, and may go on for twenty to twenty-five years giving paying crops. Many trees are exhausted in ten to fifteen years by unskilful treatment, borer, and attacks of *Hemileia vastatrix*, etc., and must make room for a new generation. If the vacancies can be successfully supplied and the plants developed in a healthy and vigorous manner, there is no reason why an estate should be limited as to age. If we can so arrange matters as to have a continual succession of young plants coming on and developing into healthy trees to replace those taken out, a coffee estate may be considered as a permanent investment. In suitable localities efficiently drained and manured this can be done: and an estate may be considered to be working under the best possible conditions of perpetuation where from 4 to 5 per cent. of vacancies occur every year that are successfully supplied. It is upon the success of the supplying that the life of the estate depends, and practical planters consider this question one of the first importance in Southern India. It is only when supplies cannot be got to grow that there is a necessity to abandon the estate. With many aspects and under some conditions the plants cannot be raised, except at a ruinous cost."

MANUFACTURE.

Terms Employed.—The ripe coffee fruit is called the "Cherry"; the contained twin seeds are the "Berries." When only one seed is developed it is spoken of as "Pea-berry." This is often upheld to be richer in flavour, and accordingly much has been said about the possibility of producing a plant that would yield mainly, if not entirely, pea-berries. The succulent outer coat of the fruit is the "Pulp," and the inner adhesive layer is known as the "Parchment." The seed-coat within the parchment which adheres closely to the seed is called the "Silver-skin." The pulp is commonly removed at the plantation, but it is frequently the case that the berries are sold in parchment and either submitted to treatment in the coast towns or exported in that condition to Europe, where they are hulled and finally prepared for the market. The machinery for this purpose is expensive, and the operation of final cleaning can be as effectually if not better accomplished in Europe than at the plantation. It is believed moreover that the coffee carries best in parchment, so that the extra freight charges are more than compensated for by the quality of the coffee turned out in Europe. [Cf. Kew Bull., 1893, 128-33.]

The preparation of the berry from the cherry is effected by certain distinct operations that may be here indicated very briefly. It would, however, be impossible to describe all the methods and appliances used without devoting many pages to this subject.

Seasons and Crops.—The blossoms as a rule appear in March and the fruits commence to ripen in October and continue till January. The more gradually the blossom fades the better; a superabundance of flowers is not considered a good prognostication, since only a small percentage form fruits. Rain during flowering is unfavourable, but after the fruit has set a shower or two is beneficial. It is usually advocated that none but fully ripe fruits should be collected. In Arabia a cloth is placed below and the bushes shaken, when the ripe cherries fall into the cloth. In India they are hand-picked, and it is believed not necessary that they should be pink-coloured all round; the slightest tinge is sufficient, and in fact with the appearance of colour the sooner picked the better. The berry (seed) inside will be found to be of a fine dark-greenish or bluish-green colour. It is the endeavour of the planters to preserve this greenish tint as much as possible. Berries that have dried into a reddish or chocolate colour are spoken of as "foxy," and the presence of such lowers very greatly the price. Berries that have fallen to the ground are collected at the end of the season and are known as "Jackal Coffee."

Pulping.—The operation known by this name is the removal of the pulp which surrounds the "berries" (seeds). This is best done day by day on the collections being brought to the factory. If unavoidably delayed it may be necessary to produce fermentation before the cherries can be pulped. There are two chief forms of the pulper, viz. the disc or the cylinder, but a long list of special machines, mostly developments of these, might be given. The principle in both is a grater, working against a smooth chop, adjusted according to the size of cherries. The disc-pulper is the simplest contrivance, and this may be either single or double and worked by hand or steam. A single pulper will accomplish 20 to 25 bushels an hour, a double one 40 bushels, or twice that amount if driven by steam. In design it is somewhat like a cotton-gin: it tears off the pulp and drops the seeds through a sieve kept in position so as to carry forward the pulp
HULLING AND MILLING

or tails. The best design for a factory is a three-storied building placed against the hillside and so arranged that the cherries are conveyed to the top story without requiring a lift. From there a hopper carries the cherries and water, in a continuous stream, on to the grater. Space cannot be afforded to discuss the other numerous inventions that exist for pulping; suffice it to say that most Indian factories are behind the standard of those in other countries, and that the defects of much of the Indian coffee are due mainly to the imperfections of the factory.

Native coffee is mostly dried with the pulp attached, then pounded in a mortar. It is thus practically the system followed in Arabia in ancient times, and which is still to some extent pursued in that country.

Fermentation and Washing.—On the beans (seeds or berries) passing through the sieve they are found to be covered with a sticky mucilaginous material. If the contained saccharine matter be not removed it is difficult to dry the berries. This is accomplished either by washing or fermenting, or more generally by both. The period necessary for fermentation depends greatly on the temperature of the atmosphere, but from 12 to 18 hours usually suffice. Mr. Graham Anderson has shown that the amount of saccharine matter depends on the exposure, and that the produce of young trees will not ferment as readily as that of mature plants. The berries, after thorough washing, are spread out to dry on specially prepared platforms which constitute the lowermost portions of the factory.

Hulling or Milling.—This consists of the removal of the parchment and silver skin from the beans. As already stated, this operation is usually performed by the traders and not by the planters. Many firms, especially at the coast towns, do the milling, such as Staines & Co. of Coimbatore, but a large proportion of Indian coffee is milled in London. The Indian planters seem to be of opinion that this operation might be much improved by better machinery than exists in India. [Of Planting Opinion, Aug. 1899.] A bushel of parchment coffee will usually give half the quantity of clean beans. The coffee is then assorted into various grades according to size of berries. This not only meets the necessities of various markets, but has the effect of furnishing a uniform berry and one that will roast to the same extent throughout. Nothing injures coffee more than a percentage of small berries that become charred before the others are sufficiently roasted. Charcoal absorbs completely the aroma of coffee, hence charred berries are positively destructive of merit.

Packing.—It is of the greatest consequence also that attention be given to the art of packing. If berries be exposed to the drying action of the atmosphere beyond a certain extent, their value may be thereby greatly depreciated. All the best coffee is accordingly packed in casks, the utmost care being taken that the wood used may not taint the coffee. Packing in sacks or bags is much inferior, and if shipped with mixed cargoes, coffee in bag may be so tainted as to be next to useless.

Adulteration and Substitutes.—This subject has attracted much attention for many years. It may be confidently affirmed that although much difference exists between the coffee of one estate and another, dependent very largely on the process of manufacture and the care bestowed in drying, assorting and packing, direct adulteration never takes place at the plantation. While that is so, there is perhaps no other dietary article so much and so persistently adulterated as coffee. This is very largely a consequence of the legislative measures that prevail in the countries of

Trade

consumption. When taxed abnormally high, adulteration prevails. But this is often safeguarded by special legislation such as the French enactments that prohibit the vendor from mixing. In England, on the other hand, mixing is so much in vogue that it is often difficult to procure pure coffee. "Our Coffee Mixture" may contain any adulteration conceivable, with perhaps not more than 5 per cent. of coffee. This is the natural consequence of legalising mixtures. Criminality consists alone in selling as "pure coffee" an article that contains anything but coffee. Legally "Chicory" may be the roasted chicory root itself, or the root of an allied plant or other vegetable substance applied for the same purpose.

The substances mostly employed in adulteration of coffee are the roots of chicory, dandelion, mangold-wurzel, turnips, parsnips, and carrots. The seeds of beans, peas, date-stones, malt rye, burnt sugar, biscuits, locust-beans, figs, etc., are all used. Roasted flour coloured with ferruginous earth and flavoured with the grounds of exhausted coffee or of other even more objectionable substances are often sold as coffee. There seems every reason for believing that the decline of the demand for coffee throughout the world is largely a consequence of the difficulty in obtaining the pure article. For further particulars regarding coffee adulteration confer Chicory and Coffee, a lithographed report by J. D. Hooker, John Lindley, Thomas Graham, John Stenhouse, Dugald Campbell, William B. Carpenter and A. S. Taylor, issued by the Inland Revenue office in 1853. This gives the microscopic structure and chemical tests by which the adulterants of coffee may be recognised, and although more recent publications exist on this subject, hardly any are more accurate and authoritative. [Cf. Food Journal, March 1870, Dec. 1873; Clifford, Journ. Soc. Arts; and Hanousek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 271-4.]

Negro Coffee.

The seeds of several species of Cissia are used as coffee substitutes under the name of Negro Coffee. [Cf. Hooper, Rept. Labor. Ind. Mus., 1900-1, 23-4.] For "Malt Coffee," consult Hanousek (l.c. 354).

TRADE IN INDIAN COFFEE.

Commercial Tests.—The value of coffee depends upon many circumstances, such as form of the berry, its size, colour, smell, flavour, age, and uniformity. One of the greatest difficulties is to discover a standard by which merit may be definitely determined. Were it possible to fix a standard, the planters could aim at a definite article. Much has been done in India by Mr. Leeming, Dr. Lehmann and others in this direction, and it is believed their efforts may soon be rewarded. Lehmann found that the quantity of the alkaloid Caffeine was no evidence of quality. Caffeine (as shown by M. Bertrand) varies greatly. In Coffea arabica it ranges from 0·83 to 1·60 per cent.; in C. liberica between 1·06 and 1·45 per cent.; and in C. stenophylla between 1·52 and 1·70 per cent. In a series of specimens specially analysed, those that had the highest specific gravity and contained the most nitrogen and phosphoric acid brought the highest price. Colour seems to depend more on the degree of ripeness when collected, and the care taken in manufacture, than on the nature of the soil or the class of plant grown. As a general rule the Old World coffees are inclined to turn yellow, and the New World green. Weight decreases with age and by over-drying. Odour is perhaps the most important criterion, and apparently it can alone be determined by expert opinion.

Yield and Cost of Production and Price Realised.—Under the paragraph devoted above to "Localities and Area" will be found all the.

390
PRICES

particulars on these topics for which space can be afforded in this work. The regions of Indian cultivation, the average production, and the estimates of yield per acre have thus been exhibited. These facts have to be re-read in connection with the returns of trade that have presently to be furnished. It has been shown that an average of 3 rising to 7 cwt. an acre would fairly express the better-class European plantations, but there is a large number of small native concerns that lower both the average yield and the quality of Indian coffee. It is believed that the Native plantations yield from \( \frac{1}{4} \) to 1 cwt. an acre. The cost of cultivation has been variously put, but it seems probable that Rs. 120 per acre for the best European and Rs. 40 for native coffee would be safe estimates. The former would include manuring, as also all factory charges. It is generally stated that the lowest cost of production on European plantations is Rs. 80 yielding 2½ to 3 cwt. an acre.

The net cost of coffee has been taken as Rs. 27 a cwt., and since the cost of production is 60 to 70 per cent. wages paid, a fair computation of the value of the industry to the inhabitants of the coffee area may be arrived at by multiplying the European and native acreage by the estimated cost of production. The mean of all the figures usually published shows one person to be employed on every 2½ acres of coffee. But such calculations are tentative in value only; as there is perhaps no other Indian industry more obscure and misleading, so far as its statistics are concerned, than that of coffee-planting. There are, however, three fairly certain aspects, viz. that the cultivation (see p. 370), production and price have all three seriously declined within recent years. Thus taking the price obtained in 1874 as being 100, we have the following relative prices for Indian coffee down to 1902:

During the past five years the actual prices realised were:—1901-2, Rs. 49-0-4 (variation 65); 1902-3, Rs. 49-1-5 (65); 1903-4, Rs. 46-15-2 (62); 1904-5, Rs. 50-6-2 (67); 1905-6, Rs. 48-12-4 (65); 1906-7, Rs. 43-11 (58) per cwt. As with estimates of average yield, so with prices: the average may be quite misleading as a factor of possible results. But, as already observed, competition with the cheap production of Brazil has proved the most alarming feature of the Indian industry.

Foreign Transactions.—In Milburn’s Oriental Commerce is given a statement of “the East Indies” coffee imported into England from 1802 to 1810. The total was in 1807, 2,721 cwt. "Company’s" and nil "Private," while in 1809 there was nil Company’s and 213 cwt. Private. Throughout the years indicated the imports fluctuated so greatly that the returns are of little value. It is, however, explained that it came from Moka, Java, Bourbon and Ceylon. No mention of India. About ten years later we read of a charter granted for an Indian plantation, and
by 1853-4 coffee figured among the standard exports from India. In that year the supplies drawn by the United Kingdom from India were valued at Rs. 4,75,980. Ten years later (1863-4) they were Rs. 38,43,910; in 1873-4 they were Rs. 73,98,530; in 1883-4 they were Rs. 1,06,21,380; by still another decade (1893-4) they had begun to shrink, being then valued at Rs. 99,61,631. Turning now to the returns of the total trade for the past six years: the exports in 1901-2 were 255,042 cwt., Rs. 1,25,02,200; in 1902-3, 269,165 cwt., Rs. 1,32,12,628; in 1903-4, 291,254 cwt., Rs. 1,36,74,757; in 1904-5, 329,647 cwt., Rs. 1,66,09,757; in 1905-6, 360,182 cwt., Rs. 1,75,67,240; and in 1906-7, 228,094 cwt., Rs. 99,64,778. The Madras ports furnished the entire amounts, less a fluctuating quantity from 1,000 to 10,000 cwt. exported mainly from Bombay. Of the receiving countries the United Kingdom heads the list, the consignments thence having been in 1901-2, 116,584 cwt., Rs. 64,25,838; in 1902-3, 155,501 cwt., Rs. 83,10,903; in 1903-4, 152,452 cwt., Rs. 82,71,186; in 1904-5, 187,344 cwt., Rs. 1,05,02,674; in 1905-6, 172,384 cwt., Rs. 96,74,780; and in 1906-7, 82,358 cwt., Rs. 41,22,420—a valuation about equal to that of the supply taken by the United Kingdom in 1883-4. These returns thus allow a comparison to be made with the valuations quoted above of the Indian exports since 1853. After the United Kingdom, France has to be mentioned as the next most important receiving country of Indian coffee; during the past five years the exports to that country have averaged a little over 100,000 cwt. And after France comes Ceylon, which during the same period has taken on an average over 20,000 cwt. of Indian coffee a year.

The world's production of coffee has been estimated as close on 15 million bags (132 lb. each), of which 11½ million bags are furnished by Brazil. The greatest coffee-consuming countries are Holland (18-82 lb. per head, calculated on population of 1900), Belgium (10-53 lb.), and the United States of America (10-60 lb.). After these come Germany (6-6 lb.), France (4-79 lb.), Austria-Hungary (2-17 lb.), and the United Kingdom (0-90 lb.).

**Conclusion.**—For further details of the Medicinal Properties, the Chemical Composition, the Fiscal Regulations (in India and England) and other such topics, the reader is referred to the library of technical works that exists on these and kindred subjects. Practically every report or book of importance has been consulted in preparing the present brief account, and the citation of publications, paragraph by paragraph, should therefore prove helpful to those who desire fuller details.

**COIX, Linn.:** *Agri. Ledg.*, 1904, No. 13; *Fl. Br. Ind.*, vii., 99-100; *Gramineae.* Job's Tears, gurqur, jargadi, sankru, jhonki, ka-si, kessi, kesoi, etc., etc.

**History.**—So much attention was given by the early botanical writers to the subject of *Coix* that the inference might be drawn that it must formerly have been a plant more extensively cultivated than at the present day. It is generally believed to be the *Lithospermum* of Pliny (bk. 27, ch. xi. (Holland, transl.), 1601, ii., 284). In most of the early works *Lithospermum* or *Coix* is spoken of, however, as a wild plant, or one cultivated as a curiosity only. Gerarde, Parkinson, Miller, etc., all allude to the use of the seeds as beads (bedes). The circumstance mentioned by some of the more directly botanical authors, such as Rumphius and Loureiro, that coix was regularly cultivated in Eastern countries as an article of food, seems to have escaped consideration.

One of the most beautiful of the early drawings of this plant is that given...
**SPEdIES AND VARIETIES**

by Besler (Hort. Eystett., 1613, i., 13, fol. 6, f. 1). So accurate, in fact, is Besler’s picture that it might be reproduced as a modern sketch. But this is not the only interest in it, for in the text the grain is described as striated, a peculiarity, it may be added, that is possessed alone by the cultivated edible forms of the plant, although no mention is made of its being edible. The plant is also figured by Jacobus Bontius under the name of *Milium Solis* (Hist. Nat. et Med. Ind. Or., 1629, in *Proc. Ind. Utr. re Nat. et Med.*, 1658, 162). Turning from these European records to those of the East, we are informed by the authors of the *Pharmacographia Indica* that the seeds are “mentioned in Vedic literature and appear to have been one of the cereals which were cultivated by the Aryans on the hill slopes of the Himalaya.” “The Arab travellers in the East became acquainted with the seeds and named them *Damas Daud*—‘David’s tears,’” and afterwards *Dama Ayib*—“Job’s tears.” Es-Saghami, who died about the year 1260, mentions them in the *Obib* as a well-known strengthening and diuretic medicine. The Arabs introduced the plant into the West, and it has become naturalised in Spain and Portugal, where it is still known as *Lagrima de Job*.

It is significant that the word *kasi* (or some very similar word) should appear and reappear all over India as the vernacular name for one or other of the forms of this plant. Thus we have the *ka-si* of the Nágás on the north-east frontier of India, *kasi* in the Central Provinces, *kasi* in Gujerat, *kessai* in Berar, and the cheik or kyeik, kulees, and kalinsë of Burma, and *køsen* in Japan. The word *ka-si* or *kessai* in India most frequently denotes a cultivated edible form. The cultivation as an edible grain is at the present day closely associated with the Mongolians, and its introduction and distribution in India may have been a consequence of the influence of that people; hence very possibly the explanation of the name *ka-si*. [Cf. Joret, *Lea Pl. dans L’Antiq.*, 1904, ii., 247.]

Habitat and Distribution.—There are two undoubtedly wild forms of this plant and several cultivated states. By far the most widely distributed is *Coix Lacryma-Jobi* proper. This is met with in the Himalaya, Rajputana, the Central Provinces, Bombay, South India, Bengal, Assam, Burma and the Shan States. But its area extends to China, Japan, the Malayas, the American Continent (North, Central and South), the West Indies, Polynesia, the Mascarene Islands and Tropical as also Northern Africa, and it is cultivated as a garden curiosity in South Europe. It is thus met with throughout the tropics and in all warm temperate countries. The other wild species, *C. gigantea* (and its variety *C. aquatilis*), has a much narrower distribution, is a distinctly tropical plant, and is practically confined to India and Burma. Of the cultivated (or semi-cultivated) special forms of *C. Lacryma-Jobi* the cylindrical-fruited *stenocarpa* has been recorded as met with in the Naga hills, Burma, the Shan States, Tonkin and New Guinea. The flattened—spheroidal—form, the connecting link between *C. Lacryma-Jobi* and var. *stenocarpa*, is the special bead form. It is a wild plant met with chiefly in Burma, the Malayas, China and Japan, and has been named by me var. *monitifer*. Lastly, the fully cultivated and edible form, *C. tuberosus*, is grown (so far as India is concerned) in the Central Provinces, Sikikim, the Khasia hills, Burma and the Shan States, and outside India it appears to be cultivated in Tonkin, China and the Malayas, but apparently nowhere else. Grisebach in his review of *Botanical Geography* (*Roy. Soc.*, 1846, 86) refers to the edible coix as a special feature in the most important area of production of that grain, viz. Eastern Bengal, Assam, Burma and the Malayas. In fact were a statement prepared of the geographical features of interest in the cultivated plants of British India, *Coix* would have to be commented on as characteristic of the tract of country that stretches east by south from Nagpur to Sikikim, Assam, Burma, the Malayas, and China, and be regarded as an important food grain with some of the most ancient aboriginal inhabitants, especially those of Mongolian origin.

Species and Varieties—In the *Flora of British India*, *Coix gigantea* has been treated as a variety of *C. Lacryma-Jobi*, while *C. aquatilis* has been regarded as a form imperfectly known. It seems probable, however, that all three are fairly distinct plants, separable from each other by constant characters. Whether they should be treated as but one species, with several fairly well-marked varieties, or two or more distinct species, may be open to doubt. It would seem the safer course, however, to accept them as constituting two species with several varieties under each. The best names, if not the most ancient ones (as already indicated), would be *C. Lacryma-Jobi* for the one and *C. gigantea* for the other. The latter is preferable to *C. aquatilis* since it has become better known. The
species thus isolated are certainly very distinct. They differ in structure of leaf, flower and fruit, etc., as well as in habitat and economic properties. The wild states of *C. Laevigata-Jobi* have the capsular-spathe generally more or less spherical, and only slightly drawn out at the apex into a pyriform shape and obscurely angled and universally bluish-white (never chalky-white). The leaves are broad, often distinctly auriculate, quite glabrous, except for the double row of ascending teeth, along each of the veinlets of the upper surface—a peculiarity that gives the texture of the leaf the appearance of being embroidered and makes it backwardly hispid.

The *gigantea-aquatica* series of coix are always wild plants; *gigantea* is found on the lower hills—dry soils—a robust erect plant, the *equation* in swamps and most frequently as a floating weed, 20 to 100 feet in length. The capsular-spathe is invariably pyriform, much drawn out on the apex, the actual mouth cut obliquely into an elongated lip, which is often somewhat serrulate, ripe fruit prominently angled, and having two or three furrows along its flattened face, of a dull greyish-white to brown colour and very hard. The leaves are much shorter than in *C. Laevigata-Jobi*, most frequently only faintly auriculate, and the upper (inner) surface is often marked by curious transparent glands, which in the young leaves are tipped with hairs; on the outside the leaves are quite glabrous except near the extremity of the sheath, where a few glands of an exceptionally large size are generally present.

The forms of *C. Laevigata-Jobi* in the wild state have the capsular-spathe invariably bluish-white, a colour which rapidly disappears under cultivation. In the variety known as *stenoecarpa* the capsular-spathe is elongated until it becomes cylindrical, but when cultivated the tubes (so formed) change in colour to chalky-white or become almost straw-coloured. In other forms, instead of elongating, the capsular-spathe becomes flat and spherical, until fruits often not more than one-eighth of an inch long are found and others more than double that size, but always broader than long; hence the development in these examples may be said to be in the opposite direction to that in *stenoecarpa*.

When they exist as wild plants the shell in all forms of *C. Laevigata-Jobi* remains hard and polished, and, while it may darken in colour and become pink, brown or even black, is never found soft in texture nor chalky-white in colour. But under cultivation the spathe loses the bluish-white colour, becomes soft-shelled, and of a chalky-white or straw-colour to deep blue, brown or black; but in all these cultivated states it assumes a new character—viz. the leaf-sheath, on being transformed into what I have called the capsular-spathe, retains its veins as pronounced striations, so much so as to give the grain (in husk) a striped appearance. In the elongated semi-pyriform states of cultivated *C. Laevigata-Jobi* there is also a further peculiarity—viz. that a portion at the base of the fruit-spathe becomes constricted into a well-marked annular disc. The condition with a soft and striated shell and basal annulus appears to constitute the variety known to botanists as *Ma-yuen*—a name given in honour of the Chinese General who is supposed to have first pointedly directed attention to the plant.

**Cultivation as Food.**—This curious edible grain might almost be said to be unknown to the inhabitants of India generally, except as a weed of cultivation. To many of the aboriginal tribes, however, such as those of the Central Provinces, Sikkim, Assam and Burma, it is an important article of diet. The plant grown as a regular field crop is invariably one or other of the many forms of the variety *Ma-yuen* already sufficiently described. But in times of scarcity the wild forms of these plants are (all over India) resorted to as articles of food. The grain is held to be sweet and wholesome, the only objections to it being the smallness of the supply and the hardness of the shell. In the forms specially cultivated the shell is soft and amenable to ordinary methods of milling.

Roxburgh was apparently unaware that coix had to be included among the edible cereals of India, though doubtless he had read Rumphius's description (1750) of its cultivation in the islands of the Malaya, also Loureiro's account of it in Cochin-China. In the *Agr.-Horticultural Society of India* (Trans., 1841, viii., 348) mention is made of the grain being sent from Amherst. Mr. Riley, who presented the sample, said the
REGULAR FOOD GRAIN

plant was of a "very hardy nature, and thrives upon almost any kind of soil, yielding a good amount of produce and in taste resembling wheat." Wallich identified the plant as C. Laevyma. J. D. Hooker, in his Himalayan Journals (1848, ii., 289), gives some interesting particulars regarding its cultivation in the Khasia hills. "Each plant," he tells us, "branches two or three times from the base, and from 7 to 9 plants grow in each square yard of soil; the produce is small, not above 30 or 40 fold." Mason, in his Burma and Its People (1860), published much useful information, and this has been brought up to date in the new edition by Theobald (1883, ii., 107). We there read that "Coix affords a good example of the results of cultivation of a wild plant the seed of which is of a stony hardness, but which is soft in the cultivated form and the kernel sweet. It is much cultivated by the Red Karens, and may be often seen for sale piled in the bazaars."

In the article published in The Agricultural Ledger I have given a full account of the collections recently furnished to the Reporter on Economic Products from very nearly every important locality of India; I have quoted, under the special forms, the practical observations of the local authorities. This course was deemed preferable to a compilation of data into a common paragraph on cultivation, of facts and opinions that would seem in many cases only applicable to the individual forms of the plant. It may, therefore, be accepted as undesirable to republish that information in order to support the statement that there exists in India a fairly extensive and certainly a widely dispersed cultivation of the plant. There are great diversities in size, shape and colour of the grain, as also in quality and purpose to which put. These diversities, confirmed by the existence of many vernacular names, establish belief in an ancient knowledge, as possessed by the aboriginal (especially Mongolian) tribes of India. It has been affirmed that very possibly the pastoral Aryan invaders grew this grain on the slopes of the Himalaya, anterior to their becoming localised and assuming cultivation as a craft. But it is much more probable that the grain was distributed over the plains of India in close association with the Mongolian conquests. From Darjeeling and through Bhutan to the mountains of Upper and Eastern Assam, the Khasia, Garo and Naga hills, etc., to Burma and the Shan States, coix might be described as not only a fairly plentiful crop but an exceedingly important article of diet. Certain forms of the grain are roasted, then husked and eaten whole, being either parched (as with Indian corn) or boiled as with rice. Other forms are so very different that the grain may be milled and ground to flour (átá), and thereafter baked into bread. It seems probable that the properties that necessitate so very different methods of treatment and preparation involve a diversity chemically and structurally quite as great as that which exists between the hard and the soft wheats or the glutinous and the starchy rices.

Romanet du Caillaud (Bull. Soc. d’Acclimat., 1881, viii., 442-4) tells us that in the 1st century A.D. the Chinese General Ma-yuen conquered Tonkin and became so fond of the Annamite grain bo-bo (the y-dzi of the Chinese) that he carried away several cart-loads of seed, and thus introduced its cultivation into China. Bretschneider (Bot. Sin., 1895, pt. iii., 384) says of coix that it is cultivated near Peking under the name ts’ao-tss’th. He then adds that there are two varieties, one with white, the other with grey coverings to the fruits. "I have also observed," he adds, "in
the druggists' shops a variety (or species) with small oblong, pointed fruits.” The oblong, pointed fruit might be *C. giganteus*, and, if so, it would be most interesting to find that species in China. Many writers have given their opinions on the coix grain of China. It is often spoken of as the ee-jin or ee-yin, and is reputed to be one of the most remarkable of foods. Dr. Smith wrote that it is larger and coarser than pearl barley but equally good for making gruel.

In a small book on the *Useful Plants of Japan* (issued by the Agricultural Society of that country) it is called the *tomago* or *hatomago*. “It is an annual cereal grass cultivated on common dry land. The stalks grow to a height of 4 to 5 feet. The grain, pounded in a mortar and cleaned, is consumed as meal and mochi. An infusion of the parched and ground grain is used instead of tea and is called *kosen*. A Chinese variety of larger grains, greyish brown in colour, with thinner shells is more easily crushed and cleaned.” A gruel of the flour is specially commended by Du Caillaud for use in hospitals. The Chinese use the grain in soup, as pearl barley is employed in Europe.

Manufacture of Beer. — The references to the Japanese habit of drinking a decoction of the grain, and to the preparation of gruel and tea from it, necessarily suggest the more extended use in the manufacture of a kind of malted beer which in the Naga hills is called *duu* (p. 758). But a surprising feature may be said to be the circumstance that the *duu* made from one grain is of a much superior flavour to that from another, and, further, that the *duu* of one grain may be kept for months, while that from another goes bad in a few weeks. I have personally experienced much pleasure, while travelling in the Naga hills, in partaking of the fresh *duu* offered in friendly salutation. It is something in flavour between that of butter-milk and cider, and on a hot day at the termination of a long march is most acceptable. Some of the forms of coix (like many rices) have a rich perfume, and such grains when used in the preparation of beer are said to give it a fruity flavour and delicate aroma (see *Eleusine*, p. 520).

Medicinal Properties. — A missionary, writing of Tonkin to M. Du Caillaud, said that “Job’s tears” made a refreshing drink, was a good blood-purifier and excellent diuretic. The gruel prepared from the ground seed, he observed, as also *Eau de Larme-de-Job*, was extensively employed in the summer to cool the body. By the Tonkin people it is spoken of as the “grass of life and health,” is believed to neutralise the miasma of the air, and to purify water when boiled like tea with a quantity of coix flour and set by to cool before being used. In India coix can hardly be said to enjoy any reputation for medicinal virtues. The Rev. Dr. Campbell tells that among the Santals the root is given in strangury and in the menstrual complaint known as *silka*. Dymock (*Veg. Mat. Med.*, 1885, 853) says the seeds are sold in the drug-shops of Bombay under the name of *kassai-bij*. The authors of *Pharmacographia Indica* add that the wild form only is used medicinally, and that it is considered strengthening and diuretic.

Chemical Properties. — The grain of coix, both wild and cultivated, has been subjected to chemical tests, and the somewhat conflicting results obtained are possibly due to the botanical position of the particular plant under examination not having been previously ascertained. In Church’s *Food-Grains of India* (1886, 60) occurs the following remark: “In the sample of this grain which gave” the under-mentioned “analytical
INDUSTRIAL AND DOMESTIC USES

figures it was found that the edible seed after the removal of the hard and shining grey husk did not weigh more than one for every four parts by weight of the whole grain operated upon.” In the Kew Bulletin (1888, 267) is published Church’s second examination—and this a specimen, admittedly, of the cultivated grain. “From four parts by weight of the sample,” he says, “three parts of husked grain were obtained—three times the quantity yielded by C. Lacryma” (presumably the comparison drawn is to the sample reported on in the Food-Grains, which I have assumed may have been a wild grain). Subsequently Church gave his third analysis in the Supplement to the Food-Grains (1901, 3), the grain examined having been cultivated coix of the Khasia hills. The following sets forth the practical results of the first and third of these examinations:

<table>
<thead>
<tr>
<th></th>
<th>NUTRIENT RATIO</th>
<th>NUTRIENT VALUE</th>

<td>Wild Coix (presumably)</td>
<td>1:3:8</td>
<td>89</td>
</tr>
<tr>
<td>Cultivated, Khasia hills</td>
<td>1:4:4</td>
<td>90</td>
</tr>
</tbody>
</table>

Commenting on his final results, Church says that the quantity of albuminoids approaches to that of some kinds of pulse, and that the proportion of oil or fat is larger than that present in the great majority of cereals. In The Agricultural Ledger will be found the chemical results obtained by several other investigators.

Industrial and Domestic Uses.—From a remote antiquity both in Europe and in India, the grains or seeds, especially of the wild plant, have been used as the beads of rosaries. By the aboriginal tribes of India and Burma they are employed in personal adornment. Necklaces, earrings, head-dresses, etc., are often largely composed of them, and dresses, bags, baskets, etc., extensively ornamented with them. For these purposes a semi-cultivation has been pursued, possibly for centuries, that has resulted in the development of special grains, in cylindrical or spheroidal forms, and in a rich variety of colours. In Nepal, Oudh, and among the hill-tribes of the central tableland of India generally, they are employed either by themselves or in conjunction with cowrie-shells in the decoration of baskets, agricultural implements and cattle. By the Karens of Burma the cylindrical grains cover certain portions of dress, and are elaborated in designs that simulate (or perhaps may have suggested) some of the patterns seen in embroidery. With the Angami Nagaas, earrings are constructed that consist of a rosette of the elongated seeds surrounding the metallic green wing-cases of a beetle.

Trade.—The possibility of a profitable expansion of the industrial uses of these seeds to a large extent suggested the inquiry, the practical results of which have already been set forth. A fairly large trade exists in the seeds, and they are used in the construction of Japanese bead door-curtains. An exceptionally large kind—a form of C. aquatica—was discovered by me in Poona, utilised in the construction of such curtains. It seems probable that C. gigantea and C. aquatica, together with some of the larger forms of monilifer, are most likely to be worked up in that manner. But in discussing possible future industrial developments it is essential that the separation indicated into the forms of C. Lacryma-Jobi that are cultivated and those that are wild should be clearly kept in mind. Cultivation destroys very rapidly the hard pearly shell, upon which to a very large extent the industrial demand depends. It also changes the colour of the grain and produces dull chalky whites and straw-colours, utterly devoid of the rich glossiness of the wild grains. By the selection and partial cultivation of spontaneous varietal forms or sports (such as those named stenocarpa and monilifer) these dangers are ever present. This fact is fully appreciated by the Burmese experts, and the cultivation, partial though it be, is abandoned for a time or fresh stock secured from the jungles, when regression has been observed. It is thus difficult, if not impossible, to guarantee a continuous supply of any one shape, size, or colour of grain, and this may at once be admitted as (from the European point of view) a serious obstacle to a
COLOCASIA ANTQUORUM
Kachú

greatly increased demand. The smaller and more gracefully formed examples of monilifer and of stenocarpa, it would seem, stand a fair chance of coming into use in Europe as beads, especially in the construction of bugle-trimmings and as buds and other special portions of artificial flowers. They would be cheaper, more durable, than the glass at present used, and since they may be dyed any desired shade of colour, they might be extensively employed in dress-trimmings. And doubtless the difficulty of producing and maintaining certain sizes and shapes of grain would soon be overcome, were a profitable demand to arise for a larger production than at present exists.

Jacobus Bontius, Hist. Nat. et Med. Ind. Or., 1629, in Piso, Ind. Utri. re Nat. et Med., 1658, 144; Rumphius, Herb. Amb., 1750, v., 313, t. 109; Forster, Pl. Esc., 1786, 57; Arum Colocasia, Roxb., Fl. Ind., iii., 494-5; Taleef Shereef (Playfair, transl.), 1833, 12-3; Nicholls, Textbook Trop. Agr., 290-3; Dutchie and Fuller, Field and Garden Crops, iii., 8, t. lxxv.; Mollison, Textbook Ind. Agr., iii., 191-3; Rec. Bot. Surv. Ind., i., 86, 277; ii., 25, 147; 1905, iii., 296; Prain, Beng. Plants, ii., 1112; Wiesner, Die Rohst. des Pflanzens., i., 566; Aroidée. The Taro, Eddoes, Scratch-coco, Tania, Egyptian Arum; in the vernaculars kachú or kachó, kachhí, aví, avós; dzu (cultivated) and kirth (wild) Naga hills; ráb (Pb.); álá, terem (Bombay); shámd-þúmpa (Tel.); Tahitian tallo or tarro, Malayen tallas, etc.

Habitat.—A tall, coarse, tuberous herb, wild and cultivated both in moist and dry situations over the greater part of tropical India and Ceylon up to 8,000 feet (in the Himalaya); cultivated, in fact, in all tropical countries. The plant has large heart-shaped leaves, borne on long footstalks which arise from a short farinaceous underground stem or corm. The corm constitutes an important article of food with the Natives of India, and the young leaves are often eaten in the form of spinach. The plant is in consequence fairly extensively cultivated, and special races have been evolved to suit every condition of soil and climate, from the swamps of Lower Bengal to the moist hills of Assam and Madras, to the dry uplands and lower hills of the Deccan and Rajputana and even to the temperate tracts of the Himalaya.

Wild and Cultivated Forms.—The wild plant, which is extremely plentiful in the moist tropical regions, produces but rarely an edible tuber though its leaves are often eaten. Roxburgh describes three special wild forms:—kaila kachu, a plant with purple leaves found on the edge of ditches—the leaves and leaf-stalks are eaten; the char-kachu, which has the leaves clouted with bluish-black; and the ban-kachu with green leaves. These are found on roadsides and homestead lands, but above inundation level.

Roxburgh also mentions two cultivated forms, the guri-kachú and the asu-kachú (or early kachú). Small corms of these are planted in May or June, the asu being reaped towards the end of the year and the guri not until February or March. Lastly Roxburgh mentions, as a distinct species, a special form of
INDIAN UTILISATION

COLOCASIA

ANTIQUORUM

Kachú

c. antiquorum, viz. nymphaisfolium, the sur-kachu, which frequents aquatic situations and produces corms that attain the length and thickness of a man's arm. Engler (in DC., Monog. Phaner., ii., 491) refers the forms of c. antiquorum to seven varieties, three of which are met with in India. Duthie and Fuller say that two varieties appear to be grown and distinguished by their roots, viz. dhokki gaqitti, the white- and kāli ki gaqitti, the dark-coloured. The word gaqitti, they observe, refers strictly to the young off-sets, the main root being known as denu. Nicholls (i.e. 292) says that there are two principal varieties, one with green stems and leaves and the other with purplish ones, but that the tubers are identical in both kinds. Numerous vernacular names are given to cultivated races of this plant all over India, but in the present state of knowledge it is impossible to assign them any more distinctive positions than those indicated above.

Cultivation.—The following account of the method of propagation usually adopted is given by Nicholls:—"The best soil is a sandy loam with an abundance of organic matter in it. The plant does not do so well on clayey soils, and it does not thrive on pure sands. . . . The plants are propagated in the same way as are yams. That is, when the crops are reaped, the head of the tuberous rhizome is cut off and the leaves are detached, leaving a few inches of the lower part of the leaf-stalks. These heads are then planted, and soon a number of plants bud forth from the top of the head and produce a crop of tānias. The heads may be kept some time before planting without suffering any harm, and thus they may be carried to long distances." Nicholls also observes that the tubers may be left in the ground without deterioration for a considerable time after they are ripe, so that they can be dug up as they are required. Mollison, speaking of Bombay, says that the crop is rarely grown over a large area. Patches are raised in the back yards of houses, and in the garden lands of Gujarāt it is common to find a patch near a well, with single plants at the corners of beds of other irrigated crops. "When grown alone," he continues, "the land is carefully prepared as for other garden crops, and laid out into beds 12 feet by 6 feet for irrigation. Forty plants occupy each bed. The crop should be freely manured and watered, also weeded as required. Off-sets should be removed before they root, unless it is desired that the whole surface should be covered with plants. This is, perhaps, advisable when the crop is grown under sewage irrigation for the value of its leaves and leaf-stalks. If grown for its corms, the plants should be 12 inches apart. It takes ten months for the corm to reach maturity. When the crop is planted four or five months, the leaves and stalks may be gathered every three or four days. They should be cut off close to the ground whilst young and tender. A few older leaves should always be left to preserve healthy, vigorous growth." Duthie and Fuller state that in the Cawnpore district the average outturn is only 50 maunds (less than 2,000 lb.) per acre. In Coimbatore, however, the yield has been recorded as 6,250 lb. per acre.

Utilisation.—The corms contain much starch and constitute an important article of food throughout the country, especially with the lower classes, and in some districts, such as Travancore, the corms are of very special value. They are usually scraped or partially peeled, cut up into small pieces, and boiled like potatoes. After boiling, the soft pieces are often fried in oil (ghi) or oil and the usual Native condiments added. Sometimes also they are pounded into a paste, and in New Guinea they are said to be ground into flour and made into biscuits. A pickle prepared from the main root (denu) with chillies, salt and lime-juice is sold in the bazāras. The bazār rate for the vegetable is said to be about 14 maunds for one rupee. Mollison observes that the stalks and leaves are cooked either separately or together. If separately, the fibrous cuticle of the stalk is removed and the inner part cut into short pieces and cooked with condiments and gud.
COMMIPHORA
Indian Bdellium

INDIAN AND IMPORTED BALSAMS

To this preparation is added boiling oil (phodni) in which mustard, turmeric and spices have been mixed. The prepared dish is a sweet curry. The leaves are used as a ság or are chopped fine with the stalks and made into a curry. There are numerous other preparations of kachú leaves and stalks. Nicholls says that the mature leaves and stalks are an excellent fodder for cattle and food for pigs.

All parts of the plant contain an acid principle which is commonly supposed to be extracted by boiling. Thus on account of this acidity the juice of the petioles is often employed as a domestic remedy, being regarded as styptic and astringent. But this acrid principle was investigated in 1888 by Pedder and Warden in the case of the species C. Hirven, Kunth. (bush kachú), which alone is regarded by the Natives as poisonous and never eaten. The results of the above investigation were recorded in the Dictionary, and it may suffice to say that the poisonous principle was discovered to be due to very numerous bundles of crystals of oxalate of lime, and thus to mechanical irritation similar to that produced by cowhage (N生素pha pruriens) or chopped hairs administered in food. The crystals, it may be observed, are indissoluble in boiling water, but are rendered inert by water slightly acidulated with hydrochloric or nitric acid, and to a less extent with acetic acid. Hence in preparing Arum tubers for food the Natives almost always add an acid vegetable or fruit such as tamarind.

D.E.P., i., 365-70.

Myrrh.

COMMIPHORA, Jacq. (Balsamodendron, Kunth.); Fl. Br. Ind., i., 529-30; Engler in DC., Monog. Phaner., iv., 7-29; Engler and Prantl, Pflanzenfam., iii., pt. 4, 251-6; Index Kew., i., 593, suppl. i., 103; ii., 46; BURSE RACEE. A genus of small spiny, balsamiferous trees containing some 80 species, of which 60 are African and only 5 Indian. Some yield Bdellium, others Balsam, and others Myrrh.

Assam Bdellium.

C. Agallocha, Engl.: Amyris Commiphora, Rozb., Fl. Ind., ii., 245; B. Roxbughii, Arn.: gugala, gugal, mashaśaboka, gugar, gukul, etc. It bears, in fact, the same names as the next species. A native of Eastern Bengal, Sylhet and Assam. It was formerly supposed to yield Indian bdellium or gugul, but its gum is now said to be used only as an adulterant of, and not as a substitute for, myrrh.

Indian Bdellium.

C. Mukul, Engl.: Indian Bdellium, gugula, gugul, gugul, gukul, mukul, maišākṣi or maiśāči, koushikaha, etc. A tree found in the arid zones of Sind, Kathiawar, Rajputana, Berar and Khandes. A gum exudes from incisions on the bark made in the cold season. It occurs in verniform pieces of a brown or greenish colour, and is put on the market as a substitute for African bdellium. The Indian supply comes very largely from Amraoti and is used in Bombay, mixed with mortar, as a fine cement (p. 293). It is employed medicinally in leprous, rheumatism, etc. Dutt (Mat. Med. Hind., 1900, 132-5) says that “old guggul is dry and without flavour or colour, and should not be used in medicine.” Moodeen Sheriff (Mat. Med. Mad., 1891, 93) remarks that the wholesale price is Rs. 4 per maund and retail 3 annas per lb.

The commercial interest in the products of this genus centres on the foreign supply largely imported into Bombay. Of these mention may be made of Bdellium and Bysabul from Africa; Balsam of Mecca (mor, baldśìm), an aromatic oleo-resin from Arabia; and Myrrh, both that which comes from Africa (Somali-land) and that from Arabia. The best is the karam or banda karam, and the second quality the meetiya or chenai-bol. Recently Europe has begun to import these products direct instead of via Bombay. The value of banda karam at Bombay is given as Rs. 34 per maund of 37½ lb., meetiya Rs. 16 to 25, refuse Rs. 8. In 1808 the East India Co. imported into England 53 cwt. of myrrh valued at £1,014 = £19 2s. 7d. per cwt. The present-day price is about £5 per cwt., but exact particulars of the import and re-export trade are not available. It is possible that some portion of the transactions mentioned under Boswellia (p. 174) belong in reality to Commiphora. [Cf. Kew Bull., 1896, 91-4; Kew Mus. Guide, 1907, 39-40.]

The London direct from Arabia and Abyssinia. When it comes from Bombay it is called Red Zanzibar. He has also urged that it would be preferable to retain the name Balsamodendron in preference to substituting Commiphora. [Cf. Tschirch, Die Harze und die Harzbehälter, 1906, i., 391-410.]

COPPER METAL: Occurrence and Production.—For detailed information regarding the Indian mines and sources of copper ore, the reader is referred to the publications mentioned above. The indigenous industry of copper smelting may be said to have been dormant in India for many years, though some short time ago expectations of its revival were entertained in connection with two localities in Bengal, viz. Singhbhum and Darbhun. More recently discoveries of some value have been made in Darjeeling, Chanda, Garhwal, Assam and Baluchistan, etc. An elaborate historical account of the Chota Nagpur copper-fields is given by King and Pope in the work cited above, and will repay perusal. Holland says that copper was formerly smelted in considerable quantities in South India, Rajputana, and at various parts of the outer Himalaya, where a kilns-like rock persists along the whole range and is known to be copper-bearing in Kullu, Garhwal, Nepal, Sikkim and Bhutan. He adds that all attempts by European companies to open up the deposits have proved unsuccessful and the Natives no longer work the ore themselves. Nevertheless mining leases are still held and prospecting licenses are frequently granted for copper-ore. It will be seen from the statistics of the imports of foreign copper and brass that if a paying deposit could be opened there is a large annual demand in India which might be contested. It may be said of the ancient workings that they very rarely reached the pyritic ore because with their simple and inefficient appliances they were unable to cope with the flow of water which followed their mining operations. Hence the ore smelted was principally oxides and carbonates.

Indian Copper and Brass Workers.—There may be said to be three classes of operatives concerned in the copper and brass trade, viz. smelters, foundrymen, and coppersmiths. Every village has its trade in copper vessels, and most have, in addition, their coppersmiths. The iron and brass foundries are often treated conjointly, so that separate statistical returns cannot be furnished. Thus in the Moral and Material Progress of India (1905-6, 178) the number of workers for 1905 is stated to have been 24,300. It has been repeatedly pointed out that there is a tendency for the copper and brass industry to become more and more concentrated in the towns, a movement which must contribute to its better organisation. Certain centres having become famous for their copper and brass manufactures are securing a large proportion of the total trade and drawing the best workers away from the villages. Nevertheless the industry as a whole is said to be in a secure state compared with many of the other indigenous crafts, and this result is largely a consequence of the essentially hand-labour character of much of the goods turned out.

Statistics of the Indian outturn of copper are not available, but in the
COPPER AND BRASS

INDIAN COPPER AND BRASS

concluding paragraph will be found full particulars of the foreign trade, and these give the most accurate conception possible of the Indian copper-smith's craft.

Copper and Brass Wares.—The tambó (Copper), pital (Brass), jasta (Zinc), rangá ( Tin and Pewter), and sisa (Lead).

Each province has two or more centres noted for copper and brass works, hence the diversity of art designs in the ornamentation of these metals. Brass is an alloy of copper and zinc usually in the proportion of 2 to 1 or 4 to 3, but it is rarely made in India, being generally imported as sheet-brass. A cheaper but inferior alloy of copper, zinc and tin is called bharat, kaskut, or kansú. But phil or kansi is the most constant of Indian alloys and corresponds to the bell-metal or white brass of Europe. It is a bright metal, takes a high polish, and is composed of copper and tin in the proportion of 7 to 2. Hoey mentions the kasiharas are the vendors (not themselves the manufacturers) of ornaments made from an amalgam of copper and zinc. The actual manufacturers are dhaliyas or bhariyas, the former casting in stone moulds, the latter in clay.

In the Hindu order of purity gold is followed by copper, sliver, brass and iron. Brass is detestable (makrühl) to the Muhammadans, who prefer earthenware, but copper may be tinned and approved in that form. The Hindu ceremonial law prohibits phil or bell-metal as containing pewter (rangá). This is unfortunate, since phil is by far the most sanitary metal in India, and in it acid materials may be cooked and milk and curds kept, whereas such is not the case with copper or brass.

Casting.

Indian craftsmen manifest a wide knowledge of the technique and utilisation of these metals and their alloys. The huge brass idols of Burma are cast with appliances and by a staff of operators absurdly inadequate when judged by European standards. Chain bangles and anklets (santh), often worn by the peasants, are moulded in Rajputana and elsewhere and sold at a few annas a pair that could not be manufactured in Europe or America at so small a price. [Cf. Textile Journ., 1891, i., 78.] Between these extremes in magnitude and intricacy may be said to lie the long range of domestic and sacred utensils, in the production of which the craft has drawn to its ranks men of nearly every caste in addition to the hereditary workers, the kasers and thathera.

Domestic vessels are rarely ornamented because, by ceremonial law, they must be secured with mud before being washed with water. The commonest copper or brass vessel of the Hindus is the globular melon-shaped lotá, which is flattened from the top and possessed of an elegantly reflexed rim. It is doubtless modelled after the expanding lotus-flower (Nelumbium speciosum). The Muhammadans have given the lota (or, as they call it, the tonji) a spout, in order to secure an approach to the running water ordained by the Koran for their ablutions. The spouted water-pot has given rise to a totally different series of metal-work, both domestic and decorative, from those connected with the Hindu lota. And perhaps this may also be traced the broader (transverse) developments of Hindu and the narrower (more longitudinal) designs of Muhammadan art.

Artistic and Ceremonial.

Ceremonial implements and the vessels elaborated from these are richly varied in shape and ornamentation. Examples are the kosa or panch-patr, a spade-like vessel used in raising water; the kusi or achhans or spoon used by the priests in sprinkling holy water; the dhupandam or censer; the ezhahan or idol-throne of lotus-leaf pattern; the hanging lamps (arti); the bells (ghantá), and in particular the chains by which these are suspended in the temples; and the designs usually adopted for idols, especially those portraying the youth and pastoral existences of Krishna, are all highly artistic and have contributed very greatly to Indian conventional art. The following publications will be found useful as reviewing the chief centres and styles of Indian copper and brass work:

PANJAB AND NORTHERN INDIA: Kipling, Journ. Ind. Art, 1884, i., pt. 1.; Old Kashmir Copper Ware, L.C. pt. iv.; also Copper and Brass, Delhi, L.C. 1887, Amritsar, and Lahore, 1888; Johnstone, Monog. Brass and Copper Pd., 1888; C. H. B. in Civil and Military Gaz., Jan, 5. 1902. UNITED PROVINCES: Benares Ware, Journ. Ind. Art, 1885, i., pt. 7; Moradabad Ware, L.C. BOMBAY: Hammered Copper in School of Art, Journ. Ind. Art, 1886, i., No. 11; Brass and Copper Bom-
COPPER SALTS.—The most important is the Sulphate—Blue-stone, nila-thiitlia (nila-tutia), mor-tutia, mayil-tuttam, turicu, galqand, doutha, etc., etc. Speaking of this salt, Holland observes: “For many years pyritic deposits in India have been turned to account for the manufacture of soluble sulphates of iron and copper,” as also in the manufacture of alum—the double sulphate of alumina and potash. He then discusses the importance of the manufacture of sulphuric acid (see pp. 50-1) as a link in the chain of production of many of the most important chemical and metallurgical industries—such as soap, glass, paper, oils, dyes, etc. He further points out that it is a by-product of such value as to admit of the smelting of ores which it would be impossible otherwise to undertake. But in Europe the price of sulphuric acid has been reduced, during the past 100 years, from £30 to £2 a ton, and in consequence this originated such activity and far-reaching competition as to have all but exterminated the ancient Indian manufacture of alum, cupperas, blue-stone and the alkalies and alkaline earths, reduced the export trade in nitre, rendered the smelting of copper and several other metals no longer profitable, robbed the country every year of nearly 100,000 tons of phosphatic fertilisers, and compelled India to pay ten million sterling for products obtained in Europe from minerals identical with those lying idle in India. Under the account of Alkalis and Alkaline Earths (pp. 50, 55) it will be found that this subject has been incidentally discussed already. So again under Coal and the Manufacture of Coke (p. 347) mention will be found of the loss to India of a valuable manure. Hence it may fairly be said that a more important and more immediate direction for developing India’s productive resources could hardly be mentioned than the utilisation of her pyritic deposits by the modern economical methods pursued in Europe. As exemplifying this contention it may be pointed out that the production of sulphuric acid from iron pyrites was in Germany 358,149 tons in 1882 and 754,151 tons in 1898. Of that large quantity only 25,000 tons were exported; the balance was used up in the German chemical industries which within the past three-quarters of a century have expanded from a mere nominal value to a capitalisation of £50,000,000.

The manufacture of copper sulphate as pursued in India at the present day is on a very small scale. The knowledge of its possible production from pyrites has been possessed by the people of India from a remote antiquity. The pure salt is, however, imported extensively from Europe. Medical writers, such as Dutt, give particulars of the methods of refinement pursued with the salt that is to be used for medicinal purposes. These are very possibly of questionable advantage. Blue-stone is extensively used in medicine, in dyeing, and as an ingredient in one of the best-known and most valuable fungicides—the “Bordeaux Mixture.” (See Camellia, p. 229.)

Copper Acetate, Verdigris (zamyar), is manufactured by the sirkaksh or vinegar makers. They buy up copper filings from the coppersmiths. These are put into a jar and covered with distilled vinegar (arag). The pot
COPPER and BRASS

INDIAN COPPER AND BRASS

is closed at night but open during the day. After twenty-four hours the araq is poured off and mixed with water and left to evaporate until only the zangdr remains. Copper acetate and the arsenite of copper are used as insecticides and as colouring reagents. Zangdr yields a blue-green of great beauty. [Cf. Hoey, Monog. Trade and Manuf. N. Ind., 1880, 195.]

TRADE IN COPPER, etc.—O’Conor (Rev. Trade Ind., 1898–9, 15) says, “The trade in this metal follows closely the fluctuations in its price and in the material condition of the people. In a time of scarcity and famine the imports fall in a marked degree, the copper utensils of the household being the first articles parted with in the pinch of distress. For the time earthen utensils are substituted, and the stock of copper in the braziers’ shops accumulates. When plenty reigns again, copper pots are in active demand and the import trade is lively.” The instability of price owing to the operation of speculators is another factor which adversely affects the Indian market. Any rise of price has an immediate effect in decreasing the demand for copper and throwing the people back to earthenware (Rev., i.e. 1901–2, 9.) O’Conor returns to this subject and observes, “So much, however, is this trade a sort of economic barometer measuring the presence or absence of pressure on the people, that the figures of the trade merit attention:—

To the returns quoted by O’Conor have been added (as a matter of convenience) the figures for the years 1902 to 1906.

Robertson (Rev. Trade Ind., 1904–5, 8) remarks, “After five years of steady progress the imports of copper have fallen by 1-3 per cent. in quantity and 2.7 per cent. in value.” “Owing to the rise of prices in Europe, caused by large demands for America and China, imports of both unwrought and wrought copper were greatly restricted during the last quarter of the year. The sensitiveness of the Indian demand to price changes is always noticeable, for besides its increasing use for industrial purposes, copper as the material for household utensils is an article of great importance in the domestic economy of the people, and their ability to satisfy their requirements is regulated first by their material prosperity, which is principally a question of good or bad crops, and secondly, by the commodity being cheap or dear.” The ominous decline thus briefly indicated became even more marked in 1905–6, when it amounted to 36.5 per cent. of the quantity and 32 per cent. of the value. [Cf. Noël-Paton, Rev. Trade Ind., 1905–6, 10.]

But to obtain a full conception of the traffic it is necessary to add to the above imports of copper those in brass of all kinds. These fluctuated from 10,000 to 12,000 cwt., valued at from 6 to 8 lakhs of rupees. The grand totals for the years 1902–7 thus became:—1902–3, 407,494 cwt., valued at Rs. 2,03,28,458 ; 1903–4, 444,188 cwt., Rs. 2,23,37,805 ; 1904–5, 437,043 cwt., Rs. 2,16,65,708 ; 1906–7, 223,097 cwt., Rs. 1,46,88,046.

The major portion of the imports come from the United Kingdom. Of the supply (copper only), 433,091 cwt., secured by India in 1903–4,
the largest quantity imported in the last five years, the United Kingdom supplied 293,555 and each of the following countries furnished from 18,000 to 25,000 cwt., viz. Ceylon, Hongkong, Belgium, Germany and Japan. Bombay takes by far the largest share (228,874 cwt. in 1903-4), followed by Bengal (163,908 cwt.) and by Madras, a long way third (34,501 cwt.).

COPTIS TEETE, Wall. ; Fl. Br. Ind., i., 23; Hobson-Jobson, (ed. Crooke), 1903, 548-9; Ranunculaceae. Coptis or Gold Thread, titá, mámirá (ˈmámíran), mahmirá, pita-karosana. A small stemless herb, with perennial root-stock, met with in the temperate regions of the Mishmí hills, east of Assam. The plants are said to grow on the ground among the moss around the stems of trees.

Very little, if any, additional information is available since the publication of the Dictionary, and the original article should therefore be consulted. Four reasons, it will there be found, were given for questioning the absolute identification of the tonic drug prepared from this plant with the "mámíra" of early European writers.

The Bengal supply comes through Assam, but a Chinese root, the identity of which must be regarded as uncertain, is also imported into India. The latter may possibly be a different species of Coptis, for it is to be observed that C. anemonoides affords a medicinal root in Japan, whilst C. trifolia, Salisb., yields both a medicinal root and a yellow dye in North America. [ Cf. Wiener, Die Rohst. des Pflanzen., ii., 477.] But the thicker Chinese rhizome as described by Dymock seems to recall some of the forms of katki or kuru, such as Pierovisia Kurrou, Gentiana Kurrou, Casenia fenestriatum, Sceurta Chirara, etc. It is just possible also that one or other of these roots may be sold as titá in the Upper and Western Provinces. Indeed J. D. Hooker was actually presented in Sikkim with a handful of the so-called "teeta," which he identified as Pierovisia. It would thus seem highly likely that that, being the most abundant Indian equivalent, may have been at an early date identified with the classical mámirá, and called mámirá. At all events it is largely sold throughout India and is frequently mentioned in The Bower Manuscript of date 5th century. Moreover it is worth noting that Coptis, Berberis, and doubtless many other yellow bitter drugs contain berberines, which it would seem, constitutes their efficacy as eye-salves. For example, from Mussourie and other localities on the N.W. Himalaya the roots of Thalictrum foliolatum are collected and sold under the name momíri. Aitchison speaks of the roots of both a Corydalis and a Geranium being used in Afghanistan as a drug, which is there called mámirá. Two samples were examined by Mr. Bhaduri and found to contain 6.85 and 6.5 per cent. berberine respectively (Rept. Labor. Ind. Mus., 1902-3, 29). In conclusion it may be noted that C. Teeta and the use of mámirá as an eye-salve were unknown to the Sanskrit medical writers—they are doubtless of Muhammadan introduction. (See Berberis, p. 130.)

Apart from the utilisation of Coptis as a collyrium or eye-salve, the root makes a valuable tonic in the dobiety following fevers, etc., but it is not a fabrication. There appears, however, to be a considerable demand for it in India, and it might be found profitable as a cultivated plant. But it may be here added that the Mishmí poison consists of a mixture of powdered titá with the pulp of an acid glutinous fruit such as Dillenia equecula. It is generally employed by hunters for killing wild animals. [Cf. Pharmacog. Ind., iii. (app.), 92-3.]

The Mishmís gather the roots of the titá, towards the end of the rainy season, and carry them, packed in tiny wicker-work baskets, to Sadiya, where they are bought by Assamese and Bengali merchants, apparently at about 3d. per oz. The drug found in Bombay comes from China via Singapore in bulk, the better and thinner root fetching about Rs. 3½ per lb. and the second kind Rs. 2.

CORCHORUS, Linn. ; Fl. Br. Ind., i., 396-8; Tiliaceae. The Jute Fibre of commerce, Jew's Mallow; the patta, júta, jata, káladosa of Sanskrit authors (according to Skeat, Dutt and others). It is, however, by no means very clearly nor fully indicated in the classic literature of

India. In the vernaculars it is the pát, jhut, jhoto, jhuto, etc. When specially used as a vegetable it is nalita or nadika—the molochia or melochia of the Arabs. The fibre is pát, koshta, etc., the coarse sackcloth of it and formerly used by the very poor in Bengal is tát, and the bags made of it are choti or goni.

Species and Varieties.—It may be said that there are two important cultivated forms of this genus and many wild species which are distributed throughout the tropics of Asia, Africa, and America. Geographical evidence is thus very nearly unavailing in any effort that may be desired to trace out the origin and history of the chief cultivated forms:—

Description.

This is the ghi nalita pát of Roxburgh (Fl. Ind., ii., 581) and the narchá of Dutt (Mat. Med. Hind., 1900, 302). The fibre is the true pát or koshta, the latter name being possibly derived from the Sanskrit kosha a sheath and given in allusion to the fibres around the stem beneath the bark. It is recognised by its glabrous leaves, small flowers and sub-globose, not beaked, but warted fruits. As pointed out in the Dictionary, however (l.c. 536), the fruit in the cultivated species of the genus Corchorus, as in Brassicae, is very variable. It seems, in fact, probable that the peculiarities of the seed are much more constant than the shape of the fruit or the number of its carpels and valves. It is thus highly likely that this, as also the next form, are but cultivated conditions unworthy of the specific positions usually assigned to them. They are at all events each representative of groups of cultivated races that vary in colour of stem, shape of leaf, degree of hairiness, size of flower, shape and number of valves of fruit, etc., etc., until a panorama of specimens might be assimilated that would not only break down the separation of capsularis from olitorius but might even endanger the positions of C. trilocularis and C. acutangulus. This much is certain, namely that if specimens be furnished in flower but not in fruit, the two chief jute plants can with difficulty be separately distinguished.

Races.

Mr. Burkhill in a report submitted on November 7, 1903, to the Director of Land Records and Agriculture, Bengal, as the result of his critical study of the races of this species, has pointed out that when grown in proximity to each other all those become crossed so freely that in a remarkably short time the progeny cannot be recognised as anything more than mongrels. The flowers are freely visited by bees and appear to be most readily cross-fertilised, though a certain percentage of self-pollination also occurs. Burkhill remarks, moreover, that there are hardly any naked-eye features that one can seize on whereby to distinguish the races of jute, except the colour of the stems and leaf-stalks, the time of flowering and the height that the plants attain. The only one of these characters serviceable at thinning time is the first, and this in Burkhill's opinion may have led to the development of the special red or green races that are characteristic of certain districts. N. G. Mukerji and R. S. Finlow, who wrote a note on explorations conducted by them in 1904, say there are three
chrij forms of *C. capsularis*. These are the *Tarla*, the Bombay and the *Desval*. The first grows the tallest (10 to 12 feet) while the last attains to only 7 feet, and the Bombay to 9 feet. The *tarla* stands waterlogging better, i.e. it does not get so “rooty” if late in the season there is an accumulation of 4 or 5 feet of water in the field. The Bombay and *desval* both get rooty under these circumstances. The *desval* comes to maturity early in July or even late in June, and has not, therefore, much time to get rooty, but it branches freely. The Bombay, though it gets rooty does not branch much, and bears very little fruit. The *tarla* is the form preferred where there is liability to much inundation.

**Habitat.**—Bretschneider (l.c. 441) observes that a species of *Corchorus* is grown to a large extent in the plain of Ning-po. In China this fibre is used in the manufacture of sacks and bags for holding rice and other grains. So again, he says, jute (*Corchorus sp.*) is the most important fibre plant of the plain of Tientsin. It grows to a great height. The *Board of Trade Journal* (Oct. 29, 1903) speaks of the exports of 40,000 cwt. of jute from Tientsin. The specimens in the Kew Herbarium show that the *Corchorus* of Tientsin is the present species. Further, Roxburgh tells us that a reddish-stemmed form of *C. capsularis* had been successfully acclimatised in Bengal, the seeds of which came from Canton. This, he adds, yields a better quality fibre than the *C. capsularis* of Bengal.

So far as India is concerned to-day, *C. capsularis* is grown mainly in Eastern and Northern Bengal and Assam, and thus in a country that possesses many strongly Chinese peculiarities: seen in the people who inhabit it, in their articles of food and nature of some of their social customs, as also in the climate and soil of their country (see *Bommeria nivea*, p. 149). If, therefore, one were pressed to give an opinion, based on botanical data, as to whether or not jute was indigenus to India, that position might have to be conceded for *C. olitorius*—the least important of the two jute plants, but very possibly would have to be refused for *C. capsularis*, unless an exception were made in favour of Eastern and Northern Bengal, a tract of India with strong Chinese characteristics. In fact at least one of the best varieties, *C. capsularis*, has already been indicated as derived from China, though in connection with the earliest published drawing of that species the author (Pluketnet) speaks of it as the American plant with long leaves and striated sub-rotund fruits.

I have in the *Dictionary* (l.c. 536) discussed the specimens of this species seen by me in the Calcutta Herbarium. It may be useful to give here some particulars of the examples in the Kew Herbarium. No specimen in either collection is stated to be contributed by the botanist to have been wild in India, in the Malayas, China, or in Japan. With the exception of a specimen from Natal (of which little is known) there are no examples of this plant from Africa, Arabia or America. The following may be specially mentioned:—From *India*—Upper Assam (by Jenkins); Bengal; Sikkim *Tarai*, a remarkable example collected by Hooker and which has long narrow leaf, deeply and uniformly serrate leaves; other examples of the typical form from Moradabad; Saharanpur; Kannara, and Mysore. From *Ceylon*—a few sheets. Many examples from *China*, most of them stated to be cultivated and one accompanied with samples of the fibre and fragments of the textiles made of it, viz. that from Ningpo (Hossie's collection); Foochow (Carles); Kiu kiang (Shearer); Yangtze-kiang (Faber); Hongkong (Champion, cultivated). [Cf. Hematley, *Journ. Linn. Soc.* (Bot.), 1886, xxiii., 94.] From *Japan*—two samples, one said to be cultivated, the other no record. Lastly from *Perak*, Tonkin (Balansa's collection); Sarawak and the Celebes—fairly complete sets, but none of them stated to have been found in a wild condition.

Not a few authors have, however, affirmed that this plant is wild in China, the Malayas and India. I repeat there are no botanical specimens either in the Calcutta or the Kew Herbaria to support the opinion that it is indigenous to India, and in my personal experience it nowhere exists there, even in a state of acclimatisation. It is a cultivated plant of a very restricted area, and one subject to greater racial modification than the next form.

OLITORIUS

Jute

f. 2810 (but fruit a little too pointed); Richter, Codex Bot. Linn., 1840, 525 (shows that Linn. first included Pluk., t. 127, f. 3, under this species and subsequently placed it under C. acutans, Sp. Pl., 1762, 746; but Linn. cites in addition Browne, Triumflattia, in Nat. Hist. Jam., 232, t. 25, f. 1—a plate that in my opinion is rather C. acutangulus); Martius, Fl. Bras., 1842, xii., pt. iii., 126; Prain, Beng. Plants, i., 286; etc., etc.

The vernacular names usually given to this species cannot be accepted as separately distinguishing it, though ban-pât is its most general name—a circumstance indicative of its frequency as a weed of cultivation. So also the fibre of this form is perhaps that very generally designated as desi pât or tosha. Moreover the plant is (even in India) the edible species of authors, and it is just possible that it corresponds with the Jew's Mallow and even the melochia of the early writers. Mukerji (Handbook Ind. Agri., 1901, 298) would, however, seem to think C. capsularis is the vegetable and C. olitorius the medicinal form. It is thus possible that the tender shoots of both species are eaten. The Indian names—nâdita (a corruption of the Sanskrit nādika), nutia, narich, sag, etc.—may, however, be accepted as mainly denoting the present species. It is, therefore, somewhat surprising that the plant figured by Rumphius as the sag of Bengal should have been C. capsularis. This was most probably a mistake due to his not having personally investigated the Bengal plant. The Ganja sativa of Rumphius (his cultivated species) is undoubtedly, however, C. capsularis, while his Ganja agrestis (or the wild form) is not a species of Corchorus at all. It would thus seem fairly certain that Linnaeus was in error when he identified the latter as C. olitorius, and to this error very possibly is attributable the statement, made perhaps more emphatic than the facts justify, viz. that C. olitorius is indigenous to India. But it is curious that Rumphius should have regarded C. capsularis as the special cultivated form, since in Egypt, Africa, America and India, C. olitorius is the edible and hence the cultivated plant of most non-Indian authors. Sir William Jones while discussing the kanâ (Crotalaria juncea) incidentally speaks of the "Capsular Corchorus," so that by 1795 the two forms may be assumed to have been accepted by Indian botanical authors as distinct.

The leaves of C. olitorius are usually glabrous, except on the petioles and veins of the undersurface; the flowers are seemingly larger than in C. capsularis; the capsule is elongate, cylindrical, usually not materially tapered at either end, glabrous, smooth, beak long, straight, cells and valves generally four but five not uncommon. It would seem that the fruits are longer, thicker and smoother in the African than in the Indian forms, though apparently the fruit is smooth when collected mature and warty when immature. Some of the African and Egyptian forms have the fruit tapered at both ends; this is not true of the Indian plant.

Habitat.—In the Flora of British India (i.e. 397) it is observed of this species that it is indigenous in many parts of India, and distributed by cultivation to all tropical countries. The chief centres of its Indian cultivation are the districts of Bardwan, Khulna, 24-Parganas, Hugli, etc., but it is met with here and there completely acclimatised on roadsides and margins of fields all over India and Burma. Its claim to being strictly speaking indigenous, however, rests on doubtful evidence. It is certainly more frequently and more widely met with in India than is C. capsularis. It seems also fairly certain that in India it is a much less variable plant than the "Capsular Corchorus." But it may be said that while all the forms met with in the Indian jute area do not (on the botanical standard) amount to more than cultivated races, there are numerous allied forms met with in Africa, Egypt and America that perhaps deserve to be recognised as definite varieties. But on the other hand several plants described by botanists
INdian Pot-herb

**Corchorus**

Jute

as species might very possibly be more accurately treated as varieties of the present. But it is barely matter for surprise that a pot-herb, met with throughout the tropical regions of the globe, and which has existed at least in centuries under garden cultivation, should have assumed a multiplicity of varieties and races; in fact the comparative paucity of Indian forms is a significant circumstance. In India it is invariably found on high and dry land, hardly ever under the inundation indispensable with *C. capsularis*. It is admittedly inferior as a source of jute, and is never cultivated where *C. capsularis* is possible. But it occasionally grows taller than even some of the forms of *C. capsularis*, such as the *desviol*; it prefers sandy loams, and takes a longer time to come to maturity (September and October, the *desviol* season being July).

In the Kew Herbarnium there are numerous interesting samples of this species, the labels of which occasionally bear instructive notes, a few of which may be here quoted:—From India—Madras, cultivated in gardens; Mysore (Rottler's specimen has the note that paper is made from it in Bengal); Lower Bengal, many; Bombay, Ava (Wet. herb.); Belgium, Ritchie's, said to be eaten but not cultivated, though always found near cultivation; Moradabad; Amballa, in cornfields; Kumaon, up to 4,000 feet; Nepal; Simla, up to 4,000 feet in fields. Afghanistan, road-sides and fields; Sind, occasionally. From China—Yunnan. From Ceylon, up to 3,000 feet. From Africa and Egypt—Liberia (Sir H. H. Johnston contributes a plant with very large smooth fruits, and narrow, thick, and sharply serrate leaves); Angola; Sonogambia; Sierra Leone, cultivated; Zambesi (vernacular name *terere* = eaten); Niger river, in fields; Kordofan, edges of fields; Khartoum; Lako Nyassa; Cross River, Old Calabar. From Madagascar. In the West Indies—Cuba and Jamaica, cultivated from Calcutta seed. From Mauritius, introduced before 1864, now a weed. From Java, Philippine, etc. From Australia—Alligator River (leaves very narrow), etc., etc.

**Cultivation in India.**

**History.**—The history of the modern jute industry is exceedingly interesting and at the same time closely associated with the British rule in India. There can be little doubt jute fibre has been known in India from comparatively ancient times, but the confusion that existed, almost down to the middle of the 19th century, in the use of the words *san*, *banga*, *pát*, *goni*, *ganía* (gunny), hemp, etc., renders it often a matter of supreme uncertainty what particular fibre may have been indicated by the majority of writers who use one or other of these names. It would seem more than probable that *san*-hemp (the fibre of *CrotaLaria juncea*, see pp. 430–7) was better or earlier known to the ancient Hindus than were jute or even the true hemp (*Cannabis sativa*, see pp. 251–5). Moreover, it is almost safe to assume that for many centuries the names mentioned were used almost synonymously, just as in modern commerce there are perhaps a dozen widely different fibres all called hemp. Hence also the expression, frequently met with in Indian modern trade returns, of "*hemp other than jute," which shows that jute was viewed as but a form of hemp that it had been found desirable to record under a separate heading. The first commercial mention of the word "jute" occurs apparently in the returns for 1823, and it seems fairly certain the vernacular name *pát* had by then been fixed as the equivalent of jute. In the Bengal Board of Trade, consultations for January 14, 1793, for example, we read of the continued efforts made to establish Indian hemp as a recognised trade fibre. This is reproduced by Robert Wissott (Treatise on Hemp, 1808, 23) and again in Milburn's *Oriental Commerce* (1813, i., 283; ii., 209–11). The returns quoted in the last-mentioned work are for the years 1786 to 1803. It is pointed out that there were various qualities of hemp such as *sann*, *shore-sann* and the *paut*, which last, as it "does not grow to the height of above 4 feet... is not a profitable article to the landholder." "The leaves and tender shoots are used as an article of food." The plant in question was in all probability *C. ovalis*. But, farther on, allusion is made to "cooch-morden-paut and amleeh-paut"; the former may have been *C. capsularis*, and the latter no doubt was *Mibicus cannabinus*. About the period indicated the East India Company made a great effort to discover a good substitute for Russian hemp, to be employed in the manufacture of ropes and sail canvas. This led to many practical and useful discoveries. Boxchurch wrote in the *Transactions of the Society of Arts* on the culture, properties and comparative strength of hemp and other vegetable fibres, the growth of the East Indies (1804, xxii., 363–96; 1806, xxiv., 143–56). In a letter to the Court of Directors of the Company (dated 1795) he used the word "jute."
CORCHORUS
History

Col. Sir R. Temple has pointed out (Ind. Antiq., 1901) that that name occurs, however, in the log of a voyage made in 1746. It has been suggested that the gardeners employed at the Botanic Gardens, Calcutta, were in Roxburgh's time, as they are to-day, natives of Orissa, and hence that the word "jute" may have been an Angleised form of their name for it—viz. jhut. But the incident mentioned by Temple carries the word back forty years before the date of the foundation of the Royal Botanic Gardens, though it is quite likely all the same that it came from jhut. The origin of the word gunny is curious. It no doubt comes direct from the Sanskrit gôni, "a sack," but in modern usage, in the form of ganja, it denotes the narcotic of Cannabis sativa, and has thus been transferred from a fibre to a resin. Whether or not gôni exclusively denoted the baking of the true hemp (Cannabis sativa) need hardly be discussed in this place. It was early applied to sack-making of Crotalaria fibre and even to that of Corchorus, hence Rumphius (l.c. 212) gave the jute plant the name of ganja (ganja) sativa.

The early references to the jute plant down to the middle of the 18th century may be said to be very largely concerned with identifying the pot-herb which Pliny (79 A.D.) describes as being used by the Egyptians. Considerable uncertainty prevails as to its being the melochia (melokyeh) of the Arabs. Simon Januensis (1473), for example, speaks of the leaves as being hawked in the streets of Babylon. Runolf (1553) was apparently the first traveller who critically examined the melochia, which he found being cultivated on the banks of the Euphrates, and which he says was largely eaten by the Jews near Aleppo. Camerarius (l.c. 47) was perhaps the first botanist who figured it, and his engraving is an excellent representation of one of the African forms identical with or closely allied to C. olltorius. It had been prepared by Gesner but never published, and he lays stress on the fact that it shows the bearded base of the leaf and the cylindrical fruit—characters which had not been previously made known. Corchorus, as accepted by modern botanists, was thus in the sixteenth century definitely determined to be melochia. But although this pot-herb of the Arab writers and Eastern travellers (from perhaps 1000 A.D. onwards) was unquestionably an edible Corchorus, it is fairly certain that the melochia cloths of Greek and Latin authors (Arrian, Pausanias, Pollux, Nervius, etc.) were not jute textiles. Yates (Text. Antiq., 303-4 et seq.) is of opinion that the melochia cloths brought from India were made of Hibiscus fibre. In the Peripius the melochia were said to be procured from localities identified as Ujjain and Junnar. The fibre of the former locality could hardly have been other than Hibiscus cannabinus, while the latter most probably was Crotalaria juncea, if guessed at purely and simply on modern experience of the distribution of the fibrous plants of India.

In the Ain-i-Akbari (1590, Jarrett, transl., ii., 123) mention is made of sackcloth ( jái ), but whether of jute, san-hemp, or even of the true hemp cannot be ascertained; but Jarrett, in a footnote, identifies it with jute and the district of Rangpur. That textile was, however, made at Ghoraghat in Eastern Bengal, and thus in the very heart of the jute country, so that it may perhaps be assumed to be the true jute textile in which, according to the tikul, the old tāt, or tāt, was the poorer people were clad. For two centuries after the date of the Ain no mention is made of any fibre or textile that could with certainty be taken as having been jute, though all coarse textiles appear by that time at any rate to have been spoken of as gunnies. W. Foster, for example, has drawn my attention to a passage (in Engl. Factories Ind., 340) of date Surat 1621 in which packages are spoken of as "gunned." This could not have been jute cloth, but more probably was a textile of Crotalaria or Hibiscus, since even to the present time jute is not produced in the Bombay Presidency. Curiously enough the coarse textiles made in England, about the time here indicated, were characterised in Persia as "Sackcloth Londre" (Fryer, New Acc. E. Ind. and Pers., 1672-81, 224), and it is thus even questionable how far the simple use of the word "sackcloth," or its vernacular equivalent "tāt" can be accepted as denoting jute fibre. Frequent mention is made by Foster (l.c. 76) of "gunny" among the articles to be sent from Surat to Persia.

In this connection also it may be regarded as significant that Rhodee (India's earliest scientific botanist) is silent regarding the species of Corchorus, although both C. capsularis and C. olltorius have been repeatedly collected subsequent to his time on roadsides and as weeds of cultivation, not only in Rhodee's special country—Malabar—but here and there throughout both Southern and Western India. On the other hand, Rumphius, as already pointed out, gives a most
Early Production.—It is a somewhat curious circumstance that Buchan-Hamilton, in the first decade of the 19th century (Stat. Acc. Dinaj., 198-9), should have expressed the hope that jute (or, as he called it, pad) fibre should under no circumstances be allowed to divert the attention of the public until a fair trial had been made with san-hemp. At that time both Roxburgh and Hamilton were engaged in the search after useful substitutes for hemp, to be employed for the ropes and cordage of the Company’s ships. For this purpose Hamilton deprecated an extended utilisation of jute. It was not, however, till 1833 that his account of the jute cultivation of Dinajpur was published, and he there mentions that large quantities of the cloth called tat or chota were being produced. With the enhancement of manufacturing enterprise in Europe came the demand for foreign food supplies. This necessitated an increasing provision of sacking and packing materials, which it was early recognised could be best met by an extended production of jute. In consequence, a foreign demand for this, the cheapest and most easily manufactured of all fibres, was created and responded to by the cultivators in Eastern and Northern Bengal. The production of gunny-bags thus rapidly became a recognised part of the Bengali peasant’s work. By and by, however, European machinery began to compete with manual labour, and, as in all other parts of the world, in due time gained the day. Practically every homestead in the jute tracts may be seen to have a few bundles of jute suspended from a beam in the roof of the verandah. That amount of the fibre is annually spun into yarn and worked up, as required, into string and rope, or is woven into gunny cloth or bags. Year by year, however, this domestic craft has decreased, and it may safely be affirmed that the decline in hand-loom jute-weaving is far greater than of cotton-weaving. In fact, at the present day hand-loom gunnies have practically disappeared from the markets of the world, and yet so late as 1880–1 the returns of foreign exports from India had to be divided into two sections: (a) power-loom; and (b) hand-loom. But that the loss of the hand-loom industry has not impoverished the jute districts may be inferred from the fact that in no part of Bengal are the poor now clad in coarse jute sackcloth—all are able to procure cotton garments.

Area.—It is impossible to give exact particulars of the total area under

Present Area.

New Areas.

jute at the beginning of the 19th century. Hamilton estimated that there were approximately 30,000 acres under the crop in Dinajpur. At the present time that district possesses about three times that area; but what is far more to the point, it is one of the unimportant districts in jute production. Unfortunately early statistics do not exist for the important districts of Bengal. In 1872-3 Mr. Hem Chunder Kerr estimated that there were one million acres under the crop, distributed over an area of 37 million acres, and further, that should the demand be doubled, the production of that amount would absorb only one-eighteenth of the available and suitable land. It has since been more than doubled. The total cultivated area of Bengal in 1902-3 was close on 60 million acres, with, in addition, something like 14 million acres returned as culturable waste. All Bengal land is of course not suitable for jute, but these figures nevertheless give a tangible conception of the possibilities of the future, or rather of the adjustments possible on a still further increased production of jute being called for and responded to. In 1903-4 the returns of Bengal jute cultivation manifested 2,275,050 acres (including 32,250 acres in Assam) as under the crop. This may be taken as about 3½ per cent. of the cultivated area of the province. It gave a yield of 7,241,000 bales (of 400 lb.) valued at 12 crores of rupees. Similarly, in 1904-5, the area was estimated at 2,899,700 acres, and the yield at 7,400,000 bales; in 1905-6 at 3,181,600 acres, and the yield 8,384,000 bales. The final forecast for 1906, issued by the Department of Land Records and Agriculture, showed the total area for the two provinces of Bengal and Eastern Bengal and Assam to have been 3,482,900 acres and the outturn 8,843,000 bales, and the estimate for 1906-7 to be 3,883,200 acres and the outturn 9,127,400 bales. Of that estimate the district of Mymensing was calculated to have had 847,100 acres; Rangpur 455,800 acres; Dacca 312,000 acres; Tippera 310,000 acres; and Bogra 200,000 acres; while Faridpur, Pabna, Dinajpur, Rajshahi, and Jalpaiguri each had exchanges of 120,000 to 150,000 acres. The balance was accounted for by some four districts that have usually from 20,000 to 60,000 acres each, and a like number of districts each with less than 10,000 acres under this fibre plant. Lastly it may be here added the portion of the jute area comprised within the province of Bengal proper was in 1906-7 estimated to be 931,100 acres, of which Purnea was supposed to have had 264,900 acres; Jessore 142,800 acres; Murshidabad 95,000 acres; Nadia 93,000 acres; 24-Parganas 86,000 acres; and Hughli 65,000 acres—all other districts much smaller areas. Within the past few years two new Indian areas of production have begun to attract attention, namely Assam (proper) and Nepal. From the lower valleys and terai of the last-mentioned, fibre is exported and conveyed into the United Provinces and Bengal. It has been ascertained that this is mainly baboi grass, for the use of the Lucknow paper-mills, but to some extent jute is also supplied and enters Bengal through the district of Purnea. The Assam production (say 90,000 bales—i.e. 330,000 cwt.) does not seem to have materially increased for some time past. The Nepal jute, though at present relatively unimportant, has manifested a distinct power of expansion. In 1899-1900 it was 70,889 maunds, valued at Rs. 2,80,341; in 1902-3 it had become 149,518 maunds, valued at Rs. 5,08,898; and in 1904-5, 205,114 maunds, valued at Rs. 9,01,154. At the same time it may be safely added that no indication has as yet been given that, should occasion arise, Bengal might not even now materially increase its jute
production. Complaints have been heard of the expansion not being as rapid as could be desired. If this be the case it seems possible there may be some other causes than the indifference of the cultivators. In fact with improved rail and river facilities of transport the expansions of the past stand every chance of being not only maintained but even enhanced materially.

Soil.—Jute seems to be capable of cultivation on almost any kind of soil. It is least successful and almost unprofitable, however, on laterite and open gravelly soils, and most productive on loamy soils or rich clays mixed with sand. As already observed, C. olitorius requires higher land than C. capsularis, but there is something as yet unexplained that controls the production of these two forms of jute and restricts them to their respective areas. Speaking generally, the finest qualities of C. capsularis are produced on homestead lands (suna) such as that required for aus-rice, pulse and tobacco, which crops are accordingly rotated with the finer qualities of jute. The coarser and larger kinds are grown chiefly on salt lands, that is to say the char or mudbanks and islands formed by the rivers, and on completely submerged (bil) lands or even salt-impregnated soils, such as those of the Sundribans, but most of such inferior lands are better suited for C. olitorius than for C. capsularis. It has been said that the best quality of jute is obtained from loamy soils. Clay soils give the heaviest yield, but the plants of such soils do not ret uniformly. Sandy soils produce coarse fibre. Plants grown on inundation lands produce surface roots that injure the fibre of the portion of the stem from which they arise. Leather is disposed to think geographical and climatic influences are possibly of more value than the composition of the soil.

NEW AREAS.—A hot damp climate, in which there is not too much actual rain, especially in the early part of the season, seems the most advantageous meteorological requirement. Both climates and soils apparently identical with those of the Gangetic and Brahmaputra valleys have on more than one occasion been pointed to as hopeful new Indian areas, but still failure has so far resulted from the efforts made to extend cultivation into these. Mr. R. S. Finlow (Jute specialist to the Government of Eastern Bengal and Assam, to whom reference has been made above) has published an account of a tour conducted with a view to investigate the possibility of extending the cultivation of jute in India to new areas. Bihar, he thinks, holds out the best prospects of success. But the efforts in this direction have passed beyond the experimental stage, as the crops obtained have been good and the area an expanding one. Outside Bengal, the climatic conditions in Madras he thought more favourable than in other parts of India. The Malabar coast, South Kanara, and the deltas of the three great rivers, the Godavari, Kistna and Kauveri, were ideal centres. Bombay was less favourably situated but the experiments with the irrigated fields of Sind would be looked to with interest, and it was possible that the irrigated districts of Poona, the most westerly portions of the Deccan, and the Karnatak, and the higher lands in the Konkan might be found suitable. Lastly, in the Central Provinces, experiments made at Nagpur had given indications of success and were well worth persevering with. [Cf. Bull. Agri. Research, Inst. Pusa, 1906, No. 3.] Jute has been and is being tried in America (Dodge, Useful Fibre Plants of the World, 1897, 125-33), in Mexico (see below under Trade), in Africa, Algeria, Formosa, etc., among many other countries, with but indifferent results. Of Persia, Lord Curzon (Persia and the Persian Question, 1899, ii., 497) says that it is cultivated and used for making sacks, but the amount of fibre available, he adds, is insufficient, hence a steady import from India takes place. Fresh efforts are, it is understood, being contemplated in the Congo valley and in the Gold Coast, and these may be successful if able labour with the required knowledge and indispensable perseverance can be ensured. The alarm recently expressed regarding commercial production of jute in Hongkong may possibly be explained through the supplies
of Tonkin and Annam being exported via Hongkong. But it may be added that perhaps the foreign areas of which India need have any serious anxiety are China and Cochín-China. [Cf. Sly, Extension of Jute Cult., in Agrí. Journ. Ind., i., pt. iii., 251; Finlow, in Rept. Agri. Dept. E. Beng. and Assam, July 25, 1907, app. ii.]

Preparation of Soil.—It may be stated that, when the crop is to be raised on low lands, where there is danger of flooding, ploughing commences earlier than on the high lands. The more clay in the soil, the more frequently is it ploughed before sowing. The preparation thus commences in November or December, or not till February or even March. The soil is generally ploughed from four to six times, the clods are broken and pulverised, and at the final ploughing the weeds collected, dried and burned.

Seed and Sowing.—It would appear that no special attention is paid either to the selection of superior fibre-yielding seed or to the attainment of stock specially suited to the fields on which it is to be raised. The cultivators, as a rule, neither buy nor sell seed, and there is consequently little or no exchange of stock. In the corner of a field a few plants are left to ripen seed, and the supply thus obtained is sown broadcast. The sowings, according to the position and nature of the soil, commence about the middle of March and extend to the end of June, but bids land is usually sown in February to March. About 8 lb. of seed to the acre is the amount generally employed. Broadcasted sowings would appear to be the rule, but Mukerji recommends drill sowings, the lines being 9 inches apart, thus allowing of wheel or bullock hoeing. Thin sowing gives better yield but coarser fibre. The spacing most approved is when the plants are 4 to 6 inches apart. Irregular branching shortens the length of the fibre. Long cultivation on the same soil results in the plants becoming much branched. For results of experiments in thin and thick sowing, consult the Experimental Farm Report Sibpur (1901–2).

Rotation.—Since passing to press the present review of information on the subject of jute, an instructive report has come to hand on certain experiments performed at the farms of Bardwan and Cutta. This has been written by F. Smith (Agri. Journ. Ind., 1907, ii., pt. ii., 140–60), and deals with the results obtained during the past three years in Bardwan and the past year in Cutta. He tells us that the following experiments were carried out: (a) manure tests; (b) cutting at different stages; (c) variety experiments; (d) spacing experiments; (e) thick versus thin sowing in the production of seed; (f) drill versus broadcast sowing; and (g) rotation experiments with paddy. Space cannot now be made available to deal with the details exemplified, but it may be useful to furnish Smith's general conclusions (l.c. 160) regarding the rotation of jute with paddy:

"1. On aman paddy land, both jute and paddy can be grown in rotation with each other on the same land in the same year.

"2. For the Bardwan district, the third week of April should see the jute sown to enable the jute crop to be harvested in the last week of July and the aman paddy to be transplanted in the first week of August. The land should be cultivated for eight to ten days between the harvesting of the jute and the transplanting of the aman paddy.

"3. For the Cutta district, the jute seed should be sown in the last week of March and the jute crop harvested in the end of July.

"4. The jute seed-bed can be well prepared by eight ploughings with the ordinary country plough, and by three ladderings with the ordinary country ladder."
"5. For paddy the land is well prepared with three or four ploughings with the ordinary country plough, and one or two ladderings.

"6. An application of 100 maunds of cowdung per acre to the land before sowing jute, and a top-dressing of one or two maunds of saltpetre per acre to the paddy crop when the land is just moist (i.e. when the soil is beginning to dry), will be found very efficacious.

"7. The raiyat's food-supply is not only assured, but the extra jute crop gives a handsome profit.

Hoeling and Weeding.—In about fifteen days after sowing the weeds should be uprooted and the unduly thick sowings counteracted by the less healthy plants being removed and the desired spacing secured. This is repeated three or four times at intervals of two or three days, the soil being at the same time loosened.

Manuring.—Very little manure is given to jute, especially where silt deposits take place. In fact the superiority of certain districts over others is largely a consequence of the heavy annual deposit of silt. When available the cultivators employ farmyard manure at the rate of 150 maunds per acre (the maund = 82-3 lb.). It is freely admitted this produces fine glossy and strong fibre. In fact, conversely, seed of the finest stock when grown on poor soil, especially if not manured, yields very inferior fibre. Under such conditions the plants, moreover, flower early, and it is a maxim that whatever will prolong growth and retard flowering will improve the quality of the fibre. But there are practical difficulties: in many cases there are no carts available to carry manure to the fields, and no roads along which heavy loads could be conveyed. Bonemeal, castor-cake, saltpetre and superphosphates have all been tested at the Government farms, but cowdung gave by far the best result. For experiments in manuring jute at Bardwan and Cuttack, the reader should consult the account published by Smith.

Harvest.—The time for reaping the crop depends entirely on the date of sowing; the season commences with the earliest crop about the end of June and extends to the beginning of October, the average season being thus from middle of August to end of September. The crop is considered as coming into season (as is the case with most fibres) whenever the flowers appear, and as past season when the fruits are all formed. The fibre from plants that have not flowered is weaker than from those in fruit; the latter is coarse and wanting in gloss, through strong. Success lies in the mean between these extremes, namely when the plants are in full flower and beginning to set fruit. Late harvest gives a high weight, and advantage being taken of this fact might account to some extent for the complaints of deterioration, though it seems that avaricious buying, either from necessity or on purpose, has taught the cultivators that rejections formerly deemed worthless have now a distinct market value.

Crop.—The average crop per acre is a little over 12 maunds, but the yield varies considerably, being as high as 36 in some localities and as low as 6 to 9 in others. It is probable, therefore, that 14 might be a safer figure to accept as the average, and it is one borne out by last year's officially recorded area and yield. The yield is much dependent, however, on the season and the class of cultivation pursued—hence the severe fluctuations in supply characteristic of the transactions in this fibre. It has been estimated that with high-class cultivation costing as much as Rs. 30 an acre (or Rs. 2 a maund) the net profit should be from Rs. 20 to Rs. 30 an acre or more, according to the prices ruling, but
CORCHORUS

Separation of Fibre

it is feared that the actual amount expended is very frequently much below that figure.

Diseases. Diseases and Pests.—In a paper on the Insect Pests of Jute, Maxwell-Lefroy (Agri. Journ. Ind., 1907, ii., pt. ii., 109-15; also Memoirs Dept. Agri. Ind., 1907, i., 160, etc.) says that our knowledge of these pests, though not extensive, has been considerably enlarged and, while there was reason to believe that this crop, grown on a large scale, suffered little from pests, there is now abundant proof that this does not hold good for small areas of jute or for jute grown in new localities. He then proceeds to describe the insects hereafter recorded as pests, viz. the Indigo Caterpillar, the Jute Semi-looper, and the Jute Weevil.

Retention. Separation of Fibre.—The process pursued in Bengal may be described as one of simple and inexpensive retting. But it is modified here and there to such an extent as very possibly to originate, at least in some measure, the various qualities of fibre recognised in trade. Sweet water is essential and stagnant is preferable to running, presumably because in the latter the germs necessary for the decomposition of the tissue are not developed so copiously. The most general practice may be thus briefly described—the stems are cut near the ground, tied into bundles, and carried off to a tank or roadside pool of clear, not muddy water. The bundles are laid one on the top of another, and if need be are weighted to cause all to be submerged. In that position they are left until the decomposition of the connecting tissue has been accomplished and the fibres liberated. The period required for this purpose depends upon the nature of the water, the kind of fibre, and the condition of the atmosphere. The germ concerned in the fermentation (corresponding with that for hemp and flax) does not appear to have been as yet studied in connection with jute, and it seems, therefore, probable that great improvements are possible in this direction. So far as present practice and experience go, the retting period may be said to vary from ten to twenty-five days, but is largely dependent on whether or not the bundles of stems have been stacked to allow of drying before being retted. It would seem to be the case that partly dried stems ret more expeditiously, and, moreover, the removal of the leaves during the dying process is believed to prevent the discoloration of the fibre. It would also appear that in some localities the stems are even left on the fields for three or four days, being covered up with leaves, weeds and earth. They are then shaken out, the tips removed and thrown away, tied into bundles and carried off to the retting-pools. The use of sods and mud to cause the bundles to sink into the retting water is doubtless a fruitful cause of the dark colour often seen in certain parcels of fibre. It is on this account that logs of timber are used as weights, when at all procurable.

It has also been affirmed that the red colour, often seen in the fibre, is due to the retting water having contained iron, but by others this is held to be a peculiarity of the race of jute plant (altapati), the colour being possibly imparted from the decomposing red pulpy tissues of the stems and leaf-stalks or inherent in the fibre itself. Mukerji does not think that a red-stemmed plant need necessarily afford a red-coloured fibre. He may be right, but this point needs confirmation. In many of the experiments conducted by chemists it has been found that the fibre manifests a tendency to assume a red colour under certain reagents. And it is sometimes affirmed that the red-stemmed forms give inferior fibre to the green-stemmed. It is essential that the operator should visit the retting-

Retting must not be prolonged.

**Separation of Fibre.**—The cultivator then proceeds to separate and clean the fibre. Standing up to his waist in the now fetid water, he seizes a handful of stems and beats the thick ends of these with a mallet. This assists in the separation. He then strips one after the other from end to end, and thus withdraws the canes entire. Taking up a large bundle of these ribbons, he now lashes them on the surface of the water and draws them towards himself by a sharp jerking motion which causes the adhering particles of tissue to be brushed off. Lastly with a dexterous action he spreads out the handful of cleaned fibre on the surface and thus exposes the still adhering particles, which he picks off by hand. The water is finally wrung out, and the clean fibre thrown over a bamboo which has been fixed near by as a drying-rack. During the drying process (which lasts for two or three days) the fibre is also bleached in the sun.

There are numerous minor modifications of this operation that need not be here detailed. But Leather (Agri. Ledg., 1896, No. 37, 384–9) has pointed out that in Seraiganj district a modification of this process is in his opinion of special value. "A bundle," he says, "of about twenty stems is taken in the left hand and most of the adventitious root removed with the right hand. Then the man takes a small wooden "beater" about a foot long with a 6-inch handle and flat sides, and after striking the bottom ends of stems until they are all level, he beats the lower portion of the bundle so as to loosen the fibre, turning it in the left hand at the same time. He next breaks the bundle at about the centre, first one way, then the other. Then clasping it, still in the left hand, just above the point of fracture, he strikes at the stems, with the beater, just below the fracture in a downward sort of way, and this knocks the wood stem outwards, so that after a few sharp strokes, and a little violent agitation in the water up and down, he can take hold of the stems and pull them out from the fibre, leaving it almost free from wood" (ib. 388). The subsequent cleaning is the same as that detailed above. In fact the only difference between the description given by Leather and that of all other writers appears to be the more liberal use of the mallet as a first operation. He does not make it sufficiently clear that the stems are retted before the special treatment he has described is begun, but that doubtless is the case. Were it affirmed that less retting was pursued where beating was practised, there might be an advantage in the Seraiganj system, but this does not seem to be the case. Still, the method of treatment is said to be the cause of the superior quality of the fibre for which Seraiganj is noted. Banerjei (Agri. Cuttack, 1893, 83–6) says that in Orissa the stalks are often beaten against a platform until the pith within is removed. But he adds, "this mode is not to be recommended as the pith sticks get broken and mixed up with the fibre, which itself gets knotted so that the whole fibre has to be repicked." Machinery has also been frequently suggested and tried, but the retted fibre, if carefully prepared, is held to be softer and better than the machine-separated. Moreover, the retting process costs only the labour it entails. It involves no expenditure of capital—an all-important consideration with poor cultivators. Primitive it may be, but the retting process is eminently suited to the people and
to the country, and is moreover quite sufficient for the majority of the purposes for which the fibre is required. On these and many other such considerations, machinery does not seem likely to come readily into use in Bengal. Colour, lustre, length, softness, uniformity and cleanliness are the attributes of superior jute.

**Grading, Baling and Qualities, etc.**—The produce is gathered together at various local centres; is sorted, packed and pressed for shipment. The sorting resolves itself into “cuttings,” which consist of the woody and hard ends; “rejections,” the lowest quality of fibre; and “jute” proper. But of jute there are trade qualities, denoted for the most part by the traders’ marks more than by any special properties. These are chiefly characterised by colour, glossiness and softness. It is generally held that late flowering forms (e.g. those flowering in September) give finer and stronger fibres than the early races (those that flower about July), but the figures of yield that have been published would seem to point to environment exercising a powerful influence. It would appear, as Mr. Burkhill has pointed out, that there is a tendency for jute to become early in the northern and late in the southern districts. This tendency, if confirmed, should be seized upon as one of value in seed-selecting. But the late flowering forms of one district do not apparently yield as much as the early flowering forms of another. Whilst that may be so, within any one district, the late forms are distinctly superior to the early ones. The variation in prices obtained is remarkable. Some of the forms of *C. olitorius* yield as much and fetch as high prices as some of the forms of *C. capsularis*. But when all is said there is a distinct advantage in the late forms, namely that the cultivators are then free to devote the required time for harvesting operations.

According to the reports currently issued, the finest grade is said to be the “Utariya,” which is strong, long and easily spun, brilliant in colour and of fine texture. In point of softness, however, it does not compare with “DeswáI,” the next most valuable grade. The quality classed as “Desi” (Daisee) is that most generally used in the gunny trade, and “Deora” (Dowrah) in rope manufacture. Other qualities that may be specially mentioned are *Narainganji*, an excellent fibre, being long and soft, and the *Serajganji*, which comes from Pabna and Maimensingh. The geographic value is one, therefore, that demands close study. Prain, referring apparently to this subject, observes that a strain natural to or acclimatised in a particular district gives better results in that district than any freshly imported seed. At present there are districts that would seem to produce very much better jute than others even when the same seed is used and identical methods of treatment are pursued. The bales of jute consist of 400 lb., and are made up at the jute presses ready for export.

**Prices.**—These are subject to very considerable fluctuations, as may be seen from the following prices ruling in Calcutta during January for the years 1900–1906:

**Deterioration of Fibre.**—Much has been heard recently of the supposed deterioration of the fibre, though the subject is by no means a new one. It was discussed by Mr. Hem Chunder Kerr thirty years ago. The conclusion he arrived at closely corresponds with the particulars adduced
DETERIORATION OF THE FIBRE

Corchorus

Investigations

to-day. The cry of deterioration, as already hinted at, is largely, in fact, a scapegoat. Kerr remarked: "I believe I am justified in inferring that in proportion to the increase of the cultivation, the quantity of medium and inferior jute has been greater season after season. When the demand is great and the price high, as they have been for some time, people find a ready market for whatever they can produce; and naturally become careless; whereas a glutted market leads to the rejection of inferior articles, and consequently cultivators are driven to the necessity of care in improving the quality of their goods." There would seem very little more to be said to-day on this subject except to make the commonplace observation (true of all branches of trade) that, whenever an attempt is made to "corner" a particular article, a rise of price must be closely accompanied by a fall in quality. Some few years ago (1887-8) my attention was specially directed to the subject of jute deterioration, and I accordingly took steps to have samples of the jute plant collected from all the districts of India where the plant was grown for its fibre. These came to hand during 1901-3, and may be now regarded as fairly complete. My object was primarily to discover if the recognised trade qualities could be traced to racial forms of the plant, or to climatic and soil conditions, or to methods of separation and drying of the fibre. It seemed probable there were two explanations of deterioration, assuming for the moment that the trade is correct in affirming deterioration, viz. (a) substitution of a prolific though poor stock plant, and (b) actual deterioration through exhaustion of soil. Since my departure from India many experiments and investigations have been continued by the Inspector-General of Agriculture, by the Superintendent of the Royal Botanic Gardens, by the Agricultural Chemist, by the Director of Agriculture, Bengal, and by the Reporter on Economic Products, in co-operation with the Committee of the Baled Jute Association. There have been brought together in consequence an extensive series of botanical specimens, of fibres, of soils on which the plant is grown and of waters used in retting, and these have all been critically examined and analysed, with the result that no direct confirmation has been obtained of a deterioration attributable to the cultivators. Moreover, the existence of botanical varieties under C. capsularis and C. olitorius has also been denied: the distinctive features based on colour of stems, etc. (upheld by agriculturists) have been viewed as alone justifying their acceptance as crosses, sports or races, not varieties. In passing it may be here repeated that Roxburgh says the reddish-stemmed forms of C. capsularis were imported from Canton, and then gave a superior fibre to the Bengal forms of that plant.

A feature of considerable importance in the controversy of deterioration has been established, namely that over and above occasional flooding of the markets with waste (that formerly would have been regarded as having no market value), the fibre is often nowadays deliberately damped in order to increase its weight. This would seem to be done by the middlemen (beparis), and not by the cultivators. N. G. Mukerji and R. S. Finlow, in a joint note on a tour of inspection, say "the raiyat produced good dry jute, but the article never reached Calcutta or Dundee as it was produced. The bepari would not buy damp jute." Nothing could be more injurious; for, once dried, if subsequently moistened, the fibre rapidly loses both strength and colour and has its value thus materially lowered, besides necessitating its having to be opened out and dried before it can be baled with any
safety. It has been reported that the traders often add as much as 20 per cent. to the normal moisture of good clean fibre, as also a large quantity of sand, and thus are able to sell at less than they purchased, and still make a good profit. It has been urged by the Committee of the Baled Jute Association that so serious has this practice become that it would be advantageous to have a law passed that would penalise the sale of jute containing more than an accepted percentage of moisture. This matter was discussed at a meeting of the Bengal Chamber of Commerce, and it is understood steps are being taken that may result in the passing of a Bengal Jute Frauds Act.

The cumbersome nature of the channel of jute sales and the difficulties that exist in checking this criminal moistening of the fibre, may be learned from the following extract from a note on Fraudulent Watering by D. N. Mookerji:

"Between the raiyats at one end and the home market at the other there are the following middlemen:—beparis or dealers, mahajans or aratdars, buyers, balers, and shippers. Sometimes the last three functions are combined by the same firm that bale and ship off at Calcutta what their agents buy in the country. But the business at Serajganj may be said to be practically in the hands of the mahajans or brokers. They are well-to-do people, being mostly Marwaris. They advance money to the beparis or sellers, the condition being that the latter must bring to the mahajans all the jute they can get from the raiyats. The money is not realised from season to season, but is allowed to be in the hands of the beparis, one bepari sometimes having an advance of Rs. 5,000 or Rs. 10,000, and occasionally no less than Rs. 20,000. When the jute is brought to the mahajan he settles the price with the buyer secretly, the bepari having nothing to do with it and often not knowing at all what his jute sells for. He has only a general idea of the state of the market from the price other beparis receive for their jute. I witnessed, on several occasions, the way the price is settled between the mahajan and the buyer. The mahajan throws a corner of his dhuti over the hand of Mr. X. and makes a sign on his palm. The latter exclaims in surprise it is far too high and he cannot possibly pay more than so much, making an answering sign on the palm of the mahajan, still under the dhuti. After some haggling the negotiations terminate. The mahajan now at once settles with the bepari, who goes home with his money, he (the mahajan) being paid by the buyer a few weeks (generally three weeks) later. The mahajan gets a brokerage of 2 to 4 annas per maund, but over and above this we may be sure he leaves a margin between what he pays the bepari and what he himself gets from the buyers. Plainly he is entitled to some discount for the ready cash he pays in advance, but the rate might be definitely settled, and the transaction might be aboveboard. The price of jute is subject to violent fluctuations. Probably there is no other article the price of which varies so much in the course of a few days in the same season. Both the buyers and the mahajans have daily wires from all the important jute marts, telling them of the state of the market, but the information is carefully kept to themselves. It might be an advantage to have some agency for making it public. At Chandpur there are no mahajans, but the beparis deal directly with the buyers. The raiyats also to some extent sell their own jute to the purchasing firms, without the intervention even of the beparis."

This remarkable story illustrates but one aspect, though a striking one, of the jute market.

THE JUTE FIBRE AND JUTE MANUFACTURES.

Industrial Properties.—Jute is a bast fibre. As found in commerce it consists of fibro-vascular bundles. These contain six to twenty ultimate fibres firmly coherent along their contiguous walls. The ultimate fibres are of the normal fusiform type and 1½ to 3 mm. in length. In section they are seen to be thick-walled and polygonal. Jute is, moreover, an aggregate fibre and consists chemically of two substances, cellulose and non-cellulose. Cotton is pure cellulose, a substance that withstands very considerably the action of heat and moisture, and is even little affected by the ordinary chemical agents employed in the treatment of textiles. Jute, on the other hand, is highly susceptible, and is readily acted on by water and by even feeble chemical agents. It is the type of the fibres now spoken of as consisting of lignified-cellulose or, as it has been called, bastose. Dunstan (Imp. Inst. Tech. Repts., 1903, 60–8), while contrasting pure cellulose with ligno-cellulose, says the most generally accepted view is to regard the latter as resulting “from the overlaying of normal cellulose by non-cellulose matters.” He then explains that this overlaying weakens the cellulose. Another theory, however, is that ligno-cellulose is not encrusted cellulose but a distinct compound. Cross and Bevan (Journ. Chem. Soc., 1889) were the first authorities to study jute critically. Their experiments and conclusions are too technical to be fully discussed here, but it may be said that they resulted in certain practical experiments having been conducted in India with a view to ascertain:—(a) the stage of growth at which the fibre was in its best condition, and (b) to discover whether by chemical treatment it was possible to ward off the tendency possessed by the fibre for a continuance of the retting, or rather rotting, process within the bales. It was admitted freely that the fibre as produced by the cultivator was very much superior to the same when delivered at the factory, more especially if it had passed through the damp heat to which it is unavoidably subjected in the hold of a ship during the voyage from India to Europe or America. It was felt, in other words, that if the fibre could be put through some simple chemical process, the effect of which would be to protect it against incipient fermentation, much would thereby be accomplished towards placing jute on a more certain and higher platform in the textile world than it at present occupies. It was, in fact, just possible some such treatment might even improve the quality as well as the durability of the fibre, without adding materially to its cost of production. Unfortunately, however, the treatment recommended proved unavailing, and Dunstan was thereby led to affirm that “the logical conclusion is, that attempts at special treatment of the fibre in India, before being supplied to the jute mills, or before shipment, are not to be advocated. The most hopeful directions for further experimental inquiry are these:—(1) of improving the stock by selection, and (2) of determining the most suitable time for reaping, the object being to secure that the fibre is cut at the best time.”

From the brief account already given, it may have been discovered that for some years past the scientific officers of the Government of India

421
CORCHORUS
Watering Fibre

have been studying the plant botanically, chemically and agriculturally, so that it is just possible improvements may yet be effected that will give a greatly extended interest to the fibre. Meantime a destructive tendency seems to have been established within the trade, namely fraudulent sprinkling of the cleaned fibre with water and sand in order to increase its weight. And it may well be said that if an enhanced price was the only consequence of this practice, the matter might not be more serious and vexatious than would be involved through having to impose rules of "refraction," but unfortunately the watering directly facilitates the injurious tendencies of the fibre, so that the commodity not only requires to be dried and rehaled before it can be shipped, but may have been seriously injured if not utterly ruined. In the opinion of some of the best-informed persons, this new phase is so serious as to threaten the very existence of the industry. The merchants and manufacturers are helpless.

It cannot be said that the last word has been uttered in favour of machinery as a process of jute-fibre separation. If the weakening consequences of retting could be removed, that alone might prove of much value. No experiments of a satisfactory nature have as yet been undertaken with mechanical methods of jute production. But it is quite true, as often urged, that the Indian raigat is too poor to purchase machinery, and that the inundated tracts of jute cultivation are not the most hopeful localities in which to anticipate the establishment of a complex mechanical and technical industry. Still, if by a mechanical or chemical process a greatly improved fibre were secured, the possibilities might be considerable. The Natives of India have by no means shown themselves averse to material departures from their time-honoured systems, whenever personal advantage is involved. But this has to be fully demonstrated before they will advance into new phases of old industries.

**Batching and Spinning.**—An important feature of jute fabrication is the fact that in an initial stage it is crushed by special machinery, and sprinkled the while with water and oil—"batching," as this is called. This lessens the harshness and brittleness of the fibre and thus prepares it for spinning. In the *Anglo-Indian Review* (Oct. 1903) there will be found an instructive article on the Indian Jute Industry, from which the following may be abstracted:—"The three main purposes for which jute is used are:—(a) for making cloth of different qualities, ranging from substitutes for silk to shirtings, curtains, carpets, or gunnies; (b) for paper, which is chiefly prepared from the "rejections" and "cuttings"; and (c) for cordage, which is made from the coarser and stronger qualities. The methods employed in spinning are in the main identical with those used in dealing with the heavy manufactures of flax, the fibre being either hackled or submitted to the breaker and the finishing card, thence passing through the roving frame on to the spinning frame in the ordinary way, though in certain very coarse yarns the material is spun direct on the roving frame."

In this connection it may be explained that in China, it would seem, lime is largely used in certain stages of the separation and cleaning of jute. No one appears to have described, with any degree of care, the method pursued, so that I am unable to furnish the particulars that would likely prove suggestive to the Indian cultivator and manufacturer. The subject is, in fact, alluded to here very largely in the hope that the admission of defective knowledge may call forth a fuller account
than we at present possess. It may be mentioned, however, that there are samples of jute cloth from China, in the Kew Herbarium, that seem so different from the Indian article that they might be mistaken for linen. These, it is stated, have been treated with lime-water, but whether as an after-bleaching process or during the retting has not transpired. The fibre seems, moreover, to have been spun into much higher counts than the twenties customary in Indian high-class jute textiles; accordingly it appears finer and more beautiful than in the Indian fabrics. Every aspect, therefore, of the Chinese and Cochin-Chinese jute production and manufacture are well worthy of careful consideration by those interested in the Indian industry.

Indian Jute Mills.—In 1820 jute fibre was first experimented with by Europeans, the result being a most unfavourable opinion—so much so that the brokers were for some years subsequently required to give a guarantee that sales of fibre effected by them were free from adulteration with jute. In 1828, 364 cwt. of raw jute, valued at Rs. 620, were exported to Europe. The manufacture of gunny bags and cloth was at that time entirely in the hands of the Bengal peasants, but the traffic could not have been extensive since there is no record of exports. In 1832 an enterprising Dundee manufacturer experimented once more with the fibre, with the result that he was able to show that it might be used as a substitute for hemp. This success, it is understood, was largely a consequence of the use of whale-oil to soften the fibre. From that date, however, jute gained rapidly in popular favour. It was recognised as capable of the most minute separation or subdivision, but only within the past few years has this fact been utilised for the finer textile purposes. In time the difficulties of bleaching and dyeing the fibre disappeared, and the success of jute was assured. Thus was the foundation laid of the manufacturing enterprise both of Calcutta and Dundee.

With the establishment of the jute mills in Dundee, a large export traffic in the raw fibre from Calcutta sprang into existence. But until the year 1854 little or no effort was made to organise mills in India or to improve the village hand-loom production, with a view to participation in the new demand of foreign countries for jute sacking. In that year, however, the Ishera Yarn Mills Company was established in Serampore. Three years later the company known as the Barnagore Jute Mills was formed, and in 1863–4 the Gouripore Jute Factory was built. Soon thereafter factories sprang up rapidly in and around Calcutta, until the banks of the Hugli literally teemed with their smoking chimneys. In 1891–2 there were 26 jute mills with a capital of Rs. 1,37,50,000 plus £1,757,000. These had 8,295 looms, 172,696 spindles, and gave employment to 65,423 persons. Ten years later (1901–2) there were 36 mills with a capital of Rs. 4,35,08,040 plus £1,741,358. These possessed 16,119 looms, 331,382 spindles, and gave employment to 114,795 persons. In 1903–4 there were 38 mills with a capital of Rs. 4,03,55,000, plus a sterling capital of £2,263,358. These possessed 18,406 looms, 376,718 spindles, and gave employment to 123,869 persons. In 1904–5 there were 38 mills, capital Rs. 4,66,80,000 plus £2,283,358, possessing 19,991 looms, 409,170 spindles, and employing 133,162 persons. It will thus be observed that while the English capital of the Bengal jute industry has not progressed very greatly, the Indian has advanced from a valuation of 1¼ crores to over 4 crores of rupees. I am unable to discover returns
of a later date than 1904–5, but the following statement from the Moral and Material Progress and Condition of India (1905-6, 177) may be given:

"The number of jute mills in 1905-6 was 39, containing about 22,000 looms and 453,000 spindles, and employing a daily average of nearly 145,000 persons." "The paid-up capital employed by these mills, excluding one which had not reported its capital, was £7,142,000, including debentures issued; of which nearly 2½ millions are  sterling capital. About £600,000 was added to the paid-up capital and debentures during the year under report."

In the Dictionary a calculation will be found as to the comparative value of the Indian and the European operative. Briefly this may be expressed as 3 to 7. That is to say it requires 7 Indian operatives to work one loom as against 3 in a Scotch factory. It is believed that estimate will be found fairly correct. The late Sir John Leng, M.P., for Dundee, paid a visit to India in 1896 and contributed to the Dundee Advertiser a series of articles, one of the chief purports of which was to exhibit the relative advantages of Dundee and Calcutta. The reader will find these highly instructive, and as the articles in question appeared subsequently in pamphlet form, they should not be difficult to procure. It has been claimed that the Indian Factory Act is more favourable to our manufactures than is the English Act to Dundee. This contention has, however, been replied to by the Indian Jute Manufacturers' Association, which among many disadvantages claimed that in India from 25 to 35 per cent. more hands had to be employed than in Europe with mills turning out the same goods. The difficulty in all such calculations is to express the two sets of mills on the exact same standard, but it seems probable the claim just mentioned errs on the side of under rather than overstating its case.

**Jute Presses.**—In addition to jute mills the presses are important, and are concerned with the foreign trade in raw jute. In 1896-7 there were 88 presses that gave employment to 9,890 persons; in 1900-1 these had expanded to 133 presses and 20,387 persons; in 1903-4 there were 156 presses and 23,736 employees; and in 1904-5, 163 presses and 23,991 employees.

**TRADE IN JUTE.**—**Consumption of Jute and Value of the Industry.**

—It will be recalled that in 1828 the recorded exports were 364 cwt. It has already been stated that the Indian area in 1905-6 under this fibre was 3½ million acres and the produce 8½ million bales of 400 lb. each, or say 29½ million cwt. The estimates of the crop of 1906 are 3,336,400 acres and 8,736,220 bales. The exports of raw jute from India in 1905-6 were 14,480,407 cwt., valued at Rs. 17,12,56,641. This would represent about 48 per cent. of the total crop of that year, so that there would have remained in round figures 52 per cent. of the production as available for the Indian mills. In previous years, however, the quantity remaining in the country was ordinarily a little less than the production. Thus, as with cotton, so with jute, the Indian mills and handlooms, etc., have hitherto used up a little less than half the quantity produced; but as a mark of industrial prosperity, let it be added that India's share is steadily increasing. Speaking of jute, therefore, if we accept a ratio based on the declared value shown at the Custom House for the jute exported, as applicable to the share that remains in the country, a conception of the total value of the crop may be obtained that would not be seriously inaccurate. In round figures, and to err on the side of under rather than
overstating the case, a value of Rs. 33,00,00,000, or say £22,00,000, was the contribution of European manufacturing enterprise, paid in 1905–6 to the agriculturists and traders of Bengal for raw jute.

Exports.—Of the exports of Raw Jute in 1905–6, 42 per cent. was conveyed to the United Kingdom; 19 per cent. to Germany; 14 per cent. to the United States; and 10 per cent. to France. In 1906–7 the actual figures in value were Rs. 26,83,86,810. Of the supply drawn to the United Kingdom, a fair amount is reshipped to the Continent—France being the chief recipient, while from the jute secured by the Indian mills, goods are manufactured of which a very large portion is annually exported as jute manufactures and the balance used up in the local markets. In 1906–7 these foreign exports were valued at Rs. 15,68,34,740. The wages and profits of this manufacture, to a large extent, are realised in Calcutta, and the mills gave in 1905–6 an average daily employment to 145,000 persons. The exported manufactures ordinarily represent approximately about two-thirds of the turnover. An estimate, for example, was made of the total value of the manufactures of the Indian mills during 1901–2, and the figure arrived at was 1,150 lakhs of rupees. The exports to foreign countries were that year Rs. 8,71,14,174, which thus left a balance of manufactures to meet the Indian market of Rs. 2,78,85,826. By way of contrast with these stupendous attainments it may be mentioned that some thirty years ago the foreign exports of jute manufactures were returned as valued at Rs. 71,94,776 (or £479,651).

Recently the exports of jute cloth have been progressing in a higher ratio than those of bags, which is possibly to some extent the outcome of the cloth finding new purchasers, such as those of the linoleum manufacturers (see Carthamus, p. 282). The United States of America ordinarily take over 70 per cent. of the jute cloth made in India (479,387,950 yards out of 696,067,945 in 1906–7). Australia is the largest single purchasing country for Bags, though within recent years it has been followed closely by the Argentine Republic. The total exports in 1906–7 were 257,683,115 bags, of which 37,002,300 went to Australia and 22,890,500 to Chili, with 33,882,483 to the United Kingdom.

This brief review of some of the more striking and practical aspects of the jute trade may now be fittingly concluded by the following statistical abstract of the total value of the traffic:

**Statement of Jute Trade.**

To the figures of exports would have to be added the value of the fibre and manufactures consumed locally. It has been already explained that about one-third the produce of the mills is used up in India itself. It may be a surprise, however, to learn that India actually imports raw jute. It comes from Ceylon, and is received by Bengal. Of the manufactured jute the cloth comes from the United Kingdom, Hongkong, the Straits Settlements and Italy. Then again, under the heading of jute canvas Bombay imports a fair amount annually from the United Kingdom.

**Economic Aspects.**—But prosperous though the jute trade is, and although it is perhaps the most valuable single crop—other than food crops—possessed by the people of Bengal, it cannot be upheld that the extreme cheapness of the fibre has been an unmixed blessing. It seems highly likely that its absurdly low price has enabled the manufacturers in their competition for weavers to raise the wages of the operatives until it has come about that they have rendered it all but impossible for other textile industries to exist in the Lower Provinces. And what is more surprising still is that in spite of high wages a sufficiency of desirable labour is not attainable. It has been estimated that jute can be produced at Rs. 2 a maund, and that with freight and agency charges it might be landed at Calcutta at Rs. 3 a maund, or Rs. 32 a ton (or say £5 10s. a ton overhead, or for the first marks say at £7 10s. per ton f.o.b.). The London quotations of Messrs. Ide & Christie, July 15, 1907, are, spot values—Good White to best, £27 to £34; Good, £22 to £24; Medium, £19 to £21; Common, £15 to £17; Rejections, £10 to £13; and Cuttings, £6 to £8. In view of this remarkable state of affairs it has been recently suggested that an export duty might easily enough be placed on jute without doing any harm to the industry, since Bengal enjoys an absolute monopoly and no other fibre can be produced anything like so cheaply.

The Bengal Chamber of Commerce issued on March 12, 1897, a flyleaf on procedure rules for jute arbitrations between mills and sellers. These, it is believed, are still in force and are ordinarily recognised; but, as already intimated, a bill to prevent fraudulent watering seems earnestly desired by all those most interested in the trade.

In the *Dictionary* and other publications will be found details of the classes of goods produced both in India and Europe. In the Consular Reports (more especially of the United States) jute-sacking usually appears under the name "Burlaps," the traffic in which is very considerable. Of Vera Cruz (Dipl. and Cons. Rept., Sept. 1905, No. 3,503, 20), mention is made of two highly successful jute mills that hitherto have depended for their supply of raw jute on supplies drawn from Calcutta. They manufacture the bags used for coffee, sugar, grain and minerals. Recently attempts have been made to grow the fibre locally, and high expectations are held of ultimate success in that direction. It is somewhat significant that in the Indian trade statistics no mention is made of exports to Mexico, though the United States last year received nearly 2 million cwt.

Speaking generally it would seem that the Indian mills run for the inferior, and the European for the superior goods for which jute has been found suitable. It is often affirmed that the Indian mills would perhaps hold a more secure position against the future were they less exclusively concerned in the gunny and sackcloth trades. It has, moreover, been often pointed out that a rise or fall in the price of raw jute

is rarely immediately followed by a corresponding movement in the prices of the manufactures. This is largely a consequence of the stocks that are held and the habit of accepting forward contracts at even lower rates than the ruling prices for the time being.

**Cultivation.**—Coriander would seem to be sown at various seasons in the different provinces of India, frequently as a mixed crop—the cold season in Bengal and the United Provinces, the rainy season in Bombay and the autumn in Madras. Dutthie and Fuller state that it is largely grown in Nepal, whence the fruits are exported to the Basti country. In the Pânjab it is said to be raised in every district, being frequently seen in the fields in a semi-wild state. Owing perhaps to the irregularity of its culture, statistics of the area under the crop or of the annual output are not available, and no sufficient data can be obtained on which to base calculations.

The leaves are eaten by the Natives as a vegetable, also in curries. The fruits (seeds) are universally employed as a condiment; they are one of the ingredients in curry, in confectionery, and in the flavouring of spirits. Many medicinal virtues are also attributed to the plant. From a European point of view by far its most important use is the extraction of a volatile oil. According to Gildemeister and Hoffmann (Volatile Öle, 1900, 541-4) this distillation is said to have been first mentioned by Porta in the 16th century; the oil was included in the price ordinances of Berlin (1574) and of Frankfurt-a-Main (1587). It is referred to as an ingredient in sweetmeats in Camerarius' edition of Matthioli's Kreißtberbuch (1611, 265 c.). Gildemeister and Hoffmann, moreover, state that a true insight into the composition of the oil was brought about by Sémler (1891) and by Barbier (1893). Its sp. gr. is 0.870 to 0.885, and it is soluble in three parts of 70 per cent. alcohol at 20° C. (68° F.). But apparently the constituent to which the specific odour should be attributed has remained undetermined. [Of. Schimmel & Co., Semi-Ann. Rept., 1895, 20-2.] The Indian fruits have the lowest yield of oil, 0.15 to 0.2 per cent., and are accordingly never used for distillation on a large scale. The best fruits for that purpose are those from Moravia, Thuringia and Russia, which manifest a yield of 0.8 to 1.0 per cent. It seems unfortunate that the high prices which have lately been paid for coriander fruits should not have benefited India (Schimmel & Co., i.e., April–May, 1904, 36).

**Trade.**—The total exports of coriander from India stood in 1903-4 at 62,566 cwt., Rs. 3,87,796—an increase on the 52,827 cwt., Rs. 3,47,318, of 1899-1900—and have since risen to 72,670 cwt., Rs. 7,18,340, in 1906-7. Most of the traffic is from Bengal and Madras to Ceylon and the Straits Settlements. It is not possible to obtain any details of the coastwise or inland traffic, but the plant is largely grown in Nepal and exported thence in considerable quantities to the United Provinces. The price in India is about Rs. 3 per 35 lb.

It is perhaps unnecessary to do more than refer the reader to the accounts of Indian corundum contained in the publications cited above. The corundum gems, viz., rubies, sapphires, garnets, spinels, etc., will be found under the heading of gems (pp. 558–60).

Holland (loc. 105) observes that the use of abrasives in manufacturing communities seems to be on the increase, and that whereas emery formerly served most requirements, purer forms of corundum have now been discovered in quantity and natural corundum has to meet many artificial competitors. In the United States corundum is manufactured by electric power to the amount of about 1,700 tons a year; bauxite is used to make artificial corundum at Niagara, and crushed steel is being employed to an increasing extent as a substitute. In India natural corundum is scattered as isolated crystals through the rock, and although for many generations Indian armourers and lapidaries have been supplied from a few comparatively rich deposits, it is doubtful whether these workings will even hold their own against the importation of cheap abrasives, much less prove a paying source for an export traffic. The chief supplies of Indian corundum would appear to be in Mysore and Madras, the total production from the former State having varied from 2,937 cwt., valued at £698, in 1898, to 574 cwt., valued at £108, in 1902. Corundum occurs in Assam, Hyderabad, Panjab, etc. The deposits of Burma are of course famous for rubies, and since 1852 large sapphires have been obtained in Kashmir. The total production and trade for all India is quite indefinite, since much of the corundum sold in Delhi, Agra, and Jaipur, etc., is casually collected and sold by villagers. Since 1898 considerable interest has been roused by the Canadian separation of corundum from nepheline-syenite, such as occurs in the Coimbatore district. The product thus obtained has apparently been found profitable for export.

This, the Indian representative of the European hazel (C. Avellana), is a moderate-sized tree of the North-West Himalaya between 5,500 and 10,000 feet. It flowers in March-April and ripens its fruits in the rains. The nuts are smaller than the European hazel but are very largely eaten and traded in all over India, chiefly by the Kublis. The Afghanistan and Kashmir nuts are superior to those of the British Himalaya. The wood is used for making spinning-wheels, and invariably for the big spoons with which tea is ladled out; it is moderately hard, does not warp, and shows a grain resembling Bird’s-eye Maple.

CORYLUS UMBRACULIFERA, Linn.; Fl. Br. Ind., vi., 428; Forster, Pl. Esc., 1756, 49; Dodge, Useful Fibre Plants of the World, 135, pl. ix.; Semler, Trop. Agrik., 1897, i., 724; Talbot, List Trees, etc., 1902, 343; Gamble, Man. Ind. Timbs., 732–5; Prain, Beng. Plants, ii., 1090–1; Rec. Bot. Surv. Ind., iii., 293; PALMEÆ. The true Talipot Palm or tala, tali, bajar-battler (or bättu), tara, codka-pani, talip-pañi, shridalam, biné, pebin, pélín, etc. A tall fan-leaved palm of Ceylon and the Malabar coast, cultivated in Bengal and Burma.

Common in the moist regions of the Madras Presidency and not uncommon in Bengal, where Roxburgh regarded it as “native.” It is often planted in gardens near the sea-coast and flowers once, usually when about forty years old, after which it ripens its seed and dies. Many of its uses and vernacular names are identical with those of Borassus flabellifer, the Palmyra or Talipot of Bengal (see p. 170), a circumstance which has given rise to much confusion.

The leaves are very large, often ten feet in diameter; are made into
Saffron in Kashmir

fans, mats, umbrellas, etc., very largely worked up as baskets, and strips are utilised as writing materials (ola). (Of: Wiesner, Die Hohen der Pflanzenw., ii., 452-6; Hoernle, Epigraphical Note on Palm-leaf, Paper and Birch-bark, in Journ. As. Soc. Benc., ixix., pt. i., no. 2.) The whole subject of the polished strips of palm leaves is worthy of careful investigation, since (like those of Harassus) they are coming into use in Europe in the construction of ornamental braids. Turning now to the stem fibre, it seems probable that after removal of the pith (to be used as a kind of sago), the long fibre-vascular cords might be employed in the same manner as kitud fibre (see Caryota urens, p. 280). The fruits (seeds) are nearly as hard as ivory and are extensively employed in the manufacture of beads, or are coloured and sold as coral, or even made into small bowls, etc. In Europe they are employed in the manufacture of buttons. They are known in the trade as barabatu, bajurbet or bayurbatum nuts, and a fairly considerable export in these goes from Bombay. The trade is chiefly carried on by Arabs.

Crataeva religiosa, Forst.; Fl. Br. Ind., i., 172; Gamble, Man. Ind. Timbs., 32; Duthie, Fl. Upper Gang. Plain, i., 52; Cooke Fl. Pres. Bomb., i., 42; Brandis, Ind. Trees, 32; Capparid. The brarúa, barúa, barún, barmál, barana, waruna, budst, bila, tikto-shak, künla, maralingam, bitusi, nirveda, ushka, niruñjani, kadet, etc. A moderate-sized deciduous tree occasionally becoming common throughout India, Burma and Ceylon. In some localities undoubtedly wild (Malabar, Kanara, etc.), in others introduced and cultivated by road-sides.

By the earliest writers on Materia Medica (both Native and European) this tree was confused with Eryx Marmelos, the bel fruit (see p. 26), and both trees are often given the same vernacular names. There would seem to be two varieties, C. Nirvata, Ham., and C. Roxburghii, Br., of which the former yields a leaf and the latter a bark employed in Medicine. It would seem probable that the rubescent leaves attributed to this plant may in reality be those of Eryx—the true bel. Like that of the bel the fruit is mixed with mortar to form a strong cement, whilst the rind is used as a mordant in dyeing. The fruit is also sometimes eaten. The wood is employed in the construction of drums, models, writing-boards, combs, etc., but it is not durable and is very liable to the attacks of boring-beetles.

Crocus sativus, Linn.; Fl. Br. Ind., vi., 276; Maw, Genus Crocus, 1886, 56-72, 167-73; also Lacaia, app. i.-xx.; Ir. Med. Saffron, safragh, jadfran, safran, kesar, kekara, kurkum, kunkuma, kāśmirajanmā, saurab, kungumanu, kong, etc. The Crocus would appear to be a native of South Europe, but has long been cultivated at Pampur in Kashmir, and, according to Honigberger, was formerly a State monopoly.

The antiquity and value of the Kashmir trade may be inferred from the circumstance that kunkuma is mentioned in the Sanskrit Medical Glossary—Bhāvaprakāsa—and is referred to by the Emperor Baber (Memoirs, 1519, 313), by Abul Fazl (Ain-i-Akbari, 1500 (many passages)), and by Jahangir (Memoirs (Price, transl.), 125). An interesting account of the modern Kashmir trade is given by Lawrence (Valley of Kashmir, 1895, 342-4), who relates a curious legend with regard to its introduction which would seem to involve a great antiquity. The following passages from his account may be here given: "For seed purposes a particular aspect and sloping ground are required, and it takes three years before the bulbs can be planted out in the small square plots where the saffron is to be grown. These plots must remain fallow for eight years, and no manure can be given to them and no assistance given in the way of water. When once the bulb has been placed in the square it will live on for fourteen years without any help from the cultivator, new bulbs being produced and the old bulb rotting away. The time for planting out the bulbs is in July and August, and all the cultivator has to do is to break up the surface gently a few times and to ensure the proper drainage of the plot by digging a neat trench on all four sides. The flowers appear about the middle of October, and the purple blooms and the delicious, though somewhat overpowering, scent of the saffron turn the dry, uninviting plateau above Pampur into a rare
CROTALARIA JUNCEA
San-hemp

and wonderful garden." "When the flowers are collected the real work of extracting saffron commences. The flowers are dried in the sun, and the three long stigmata are picked out by the hand. The stigma has a red orange tip, and this tip forms the shahi zdfran, the first-quality saffron. The long white base of the stigma also makes saffron, but it is of inferior quality to the tips. The saffron thus collected in a dry condition is known to the trade as mongla, and fetches one rupee per tola. When the mongla saffron has been extracted the sun-dried flowers are beaten lightly with sticks and winnowed. Then the whole mass is thrown into water, when the petals swim and the essential parts of the flower sink. The parts which have sunk (nival) are collected, and the parts which have risen to the top are dried and again beaten with sticks and then plunged into water. The process is repeated three times, and each time the nival becomes poorer. One form of adulteration is to mix nival of the third stage with nival of the first process. The saffron obtained in this way is lighter in colour and of fainter scent than the mongla, and is known to the trade as lacha and sells at twelve annas per tola. The saffron when made is sent to Amritsar and other trade centres by registered post." It has often been suggested that the cultivation might be extended to other parts of India. [Of Journ. Agri-Hort. Soc. Ind., 1899, 1054–10; Plantier, April 21, 1900;...]

Uses.
Dye.

The principal use of saffron is as a Dye and as a colouring material for cheese puddings, etc. It is too expensive to be extensively employed in India, but is in request at princely marriages, and for the caste markings of the wealthy. Its supposed medicinal properties are discredited, its position being an element in "black magic." [Of. Hertodt, Crocologia, 1670, 274–8.] As an auspicious colour its use survives in the "Saffron Cakes" of many parts of Europe. For full particulars of the economic and domestic uses consult the Pharmacographia of Fluckiger and Hanbury and the Pharmacographia Indica (iii., 453–61). Indian cheap substitutes are Crotalaria and Xyletonia.

Trade.

Trade.—The foreign imports of saffron into India amounted in 1899–1900 to 29,974 lb., valued at Rs. 5,43,038; in 1903–4 to 38,141 lb. at Rs. 6,05,208; and in 1906–7 to 43,727 lb. at Rs. 6,27,333. Almost the whole traffic is from France to Bombay. A small quantity is re-exported to Hongkong and Arabian ports. The total amount in 1906–7 was 6,234 lb., valued at Rs. 61,702. No particulars of the Trans-frontier supply are given in the official publication of the trade of British India by land routes.

History.—The later Sanskrit authors allude to the saha fibre in such terms as to leave no doubt that a fibre of that name has very possibly been known in India from the most ancient times. Jones (Select. Ind. Pl. in As. Res., 1795, iv., 296–7) says that the "threads, called panipraca, from their supposed purity, have been made of saha from time immemorial; they are mentioned in the laws of Manu." But the confusion that to-day is associated with the English word "hemp," it is feared similarly prevailed for many ages with the name saha. The account already given of the true hemp (Cannabis sativa, pp. 249–50) should, therefore, be consulted, as also that on jute (Corchorus capsularis, pp. 409–11), and the observations recorded contrasted with the present description of the san or sunn fibre. A very extensive series of vernacular names might be given as denoting this plant, such as san, sanai, sanii, sanbii, shanul, shanambo, sanou, sonala, tag, ausa, svita, funab, janappa or janapa (shanapam), chanam, swucku and hana or sana. It was customary in India, in ancient times, and in fact is so to-day, to distinguish the various forms of san or pat by qualifying appellations. Thus, for example, the present plant (to distinguish it from the true hemp) is called phul-sunn, bhag-pan, badal-sunn, arjha-san, san-tag, or churnpat, the last name separating it from jute. The names ambadii or ambari usually denote Hibiscus cannabinus, but patasan, mestapat are intended to separate that fibrous plant and its fibre from Crotalaria and Corchorus. Sunn- or san-hemp is the commercial name of the present fibre, but it is also known as
Indian Hemp, False Hemp, Brown Hemp, Bombay or Salsette Hemp, Travancore Flax, Jabalpur Hemp, etc. The names Indian Hemp or Ambars are sometimes, though incorrectly, given to this fibre; they usually denote Hibiscus cannabinus Linn.

Though found throughout the plains of India and Ceylon under cultivation (either as a source of fibre or as a special crop to renovate the soil or to be used as a food for milch-cows), it has not very authoritatively been recorded as met with in a wild condition. C. tenuifolia, Roxb., however, by modern botanists, has been reduced to C. juncea, Linn. His plant, Roxburgh says, was indigenous to Coromandel. It has since been identified as the special form of C. juncea grown in Jabalpur (and thus apparently affords a recognisable trade quality of fibre), but it nowhere has, as yet, been recorded as wild or even as cultivated anywhere between these widely remote localities. It is thus more probable that either the determination of C. tenuifolia as the special Jabalpur hemp is incorrect, or that Roxburgh was in error in regarding it as wild in Coromandel. If it be the Jabalpur hemp plant, it would seem, from the economic standpoint, desirable that it should be kept distinct from the ordinary C. juncea. Kurz says of C. juncea that in Burma it grows "like wild, along the banks of the larger rivers." There are numerous purely indigenous species of Crotalaria met with all over India and Burma, many of which are weeds of cultivation, tolerated because of their value as green manure. In this connection it may, however, be added that recent experiments conducted at the Royal Botanic Gardens, Calcutta, support belief that all the trade qualities represent seasons of growth or methods of separation of fibre, and not botanical forms. Thus botanical and historical evidence concur in the acceptance of this plant as indigenous to India, even although it has not strictly speaking been found truly wild.

But it is very remarkable that hardly any of the early European travellers and botanists in India describe this fibre. Rheedee gives an admirable picture of the plant but says nothing of its fibre. Rumphius challenges the accuracy of the statement that a fibre is prepared from the bark, and supposes that the persons who say so had confused this with his Ganja Sativa—the "Capsular Corchorus," as Sir William Jones calls that plant. On the other hand, the Ain-i-Akbari (1590, Gladwin, transl.) distinguishes two fibre plants—one with flowers like the cotton and the other with yellow flowers. The former was doubtless Hibiscus, and the latter can hardly have been anything else but Crotalaria. In the Taleef Shereef (Playfair, transl., 1833, 98) we learn that the bark of sana is used as hemp. Ironside (Phil. Trans., 1774 (ed. 1809), xiii., 500) gives a full description of the cultivation and then adds, "From the bark are made all kinds of rope, packing cloths, nets, etc., and from these when old most of the paper in this country is prepared." Trew mentions that it was introduced into the Physic Gardens of Chelsea in 1744. Hove (Tours in Gujrat, etc., 1787, 93) says that he saw, near Surat, Crotalaria growing to a height of ten feet. Roxburgh (Trans. Soc. Arts, etc.) gives full particulars of his experiments with both Coromandel and Bengal san-hemp. Wissert (Treatise on Hemp, 1808) collected together the available information from all parts of the world regarding the better known forms of hemp. Naturally san takes a prominent position in his work. In fact nothing new of importance has been discovered and next to no progress made in the utilisation of this fibre, during the century that has come and gone since Wissert extolled its merits. But it is significant that in his great work only an incidental allusion is made to the jute plant. Jute was at that time viewed as a fibre of little or no importance. Buchanan-Hamilton gives interesting particulars of san-hemp cultivation in Dinajpur (Stat. Acc. Dinajp., 200-1), and by Symes (Acc. Emb. to Asa, ii., 233) mention is made of Hamilton's having observed it to be "growing spontaneously." Macpherson (Hist. Europ. Comm., 1812, 241, 391) gives the history of the efforts made by the East India Company to have san-hemp introduced into England as a substitute for Russian hemp. The Company procured their supplies from Salsette, near Bombay, and sold these for less than they cost and even gave consignments away for nothing, until they had expended £45,000 in the effort to introduce the fibre into European commerce. Yates (Text. Antiq., 1843, 318 et seq.), while discussing the Spanish broom or Spartum (Spartium junceum of the ancients), contrasts it with the san-hemp of India. Linnaeus explains (Mant. Pl., 1771, 439) that he gave the name juncea (or rushy Crotalaria) to this plant because of its resemblance to the Spartium junceum. Clusius was of opinion that there were two Spartums known to the ancients—the one the modern Spanish broom, the other Crotalaria.
CROTALERIA
JUNCEA
Cultivation

and the other the modern esparto grass (Stipa tenacissima), the juncus of
dry soils alluded to by Pliny. Etymologically the word sparton denotes some-
thing twisted, and since both the Spanish broom and the esparto have from very
ancient times been twisted into string and rope, both might easily enough have
been called sparton. It is curious that the sparton of the Greeks should have
denoted (in one of its meanings) a plant so closely akin to the sana of classic India.
[Cf. Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 84-5.]

CULTIVATION.—Seasons.—It is not possible to obtain returns of the
area under this crop, nor of the extent of the traffic in the fibre, since it is placed
under the heading “other fibres” or under “hemp.” It is usually
grown by itself in small plots or in long strips through fields, but is never
apparently produced as a mixed crop proper. Throughout India as a
whole it is a kharif crop—that is to say, it is sown about the commencement
of the rains and cut at the end of September or beginning of October. It
is thus off the ground in time to allow of its being followed by a rabi crop
in the same year. But in some parts of India it would seem there is another
crop of san. Thus in the Thana and Kolaba districts of Bombay it is
sown in November on moist fields near the sea-coast, following early rice.
The stalks are pulled up by the roots in March. Hove speaks of the
crotalaria of Surat as sown in November. In Khandesh it is sown in
June and reaped in October; in Kolhapur the seasons are August and
December; in Poona, July and October.

In the Central Provinces and the United Provinces it is a kharif crop,
being sown with the advent of the rains, and in Bengal a little earlier,
namely from April 15. Roxburgh speaks of it as sown in May and June
and as flowering in August. He tells us that Coromandel and Bengal
seed were sown in the Botanic Gardens, Calcutta, at the same time in June,
but that the former did not commence to flower till October, the latter
having been in ripe fruit in September. He accordingly called the Coro-
mandel “Winter Sunn.” In the Ain-i-Akbari, sanna is mentioned as
bearing its yellow flowers in spring. Royle (Fibrous Pl., 274), speaking
of Commercio, says there are two kinds—one sown in June and cut in
August, the other sown in April; but this latter kind, he adds, is in Dacca
sown in October. In Madras the sowings would appear to be even still
earlier, namely February 15.

Thus while the mean period of sowing is about the beginning of the
rains (or in June), san-hemp may be sown in almost any month, and
occupies the ground from four to five months. This is an important
feature, and doubtless accounts for the varying colour and quality of the
fibre in market. It seems, in fact, of vital importance to bear this in mind,
in view of future efforts at extended production. It is difficult to believe
that, as with rice, so with san, a wide range of sowings could be possible
unless the plants are accepted as representing different races and hence very
possibly different qualities of fibre produced after centuries of adaptation
to various environments. In fact it would seem fairly certain that these
climatic conditions, though they cannot be identified by the botanist as
separable varieties or even races, are nevertheless industrially quite
distinct. To grow a rabi crop during the kharif season or vice versa may
be to destroy entirely its distinctive merit. This subject has not as yet
received the degree of attention that it deserves. We have been content
to read of special qualities of fibre without any attempt having been made
to ascertain whether these are due to superiority in stock, to climate, to
seasons of cultivation or to method of preparing the fibre. It would

432
VALUE AS GREEN MANURE

CROTALARIA
JUNCEA
San-hemp

seem from the Calcutta experiments that all the forms hitherto grown from seed procured from such remote localities as Vizagapatam, Jabalpur, Philibit, etc., have resulted in plants of varying stature, size of flower, etc., but in no structural departures that could justify even varietal positions being assigned to them.

Soil.—When grown as a fibre crop it requires a light and not necessarily a very rich soil. It cannot be grown on clay nor on inundated lands. It flourishes on moderately deep and fairly retentive soils, such as those used for irrigated crops. But when raised with a view to soil-improvement it might be grown on almost any soil. The practical experiments that have been performed would seem to show that when cultivated on too rich soils the merit of the fibre deteriorates. Wissett, for example, remarks that it will not grow at all on clay soils, that on rich soils the fibre becomes coarse and on high and dry soils it is best of all. On the other hand Roxburgh, speaking of C. tenuifolia and of the North Circars, affirms that strong clay soils suit it best.

Green-manuring.—The cultivators of India have all along recognised this plant as a useful aid in soil-improvement. It may for that purpose (more especially when employed exclusively as a green manure) be grown on all sorts of garden soils and rice-fields, especially if infested with weeds (see Vitis, p. 1116). For this purpose it is usually uprooted when two to two and a half months old and then ploughed in, especially when followed by potatoes. The cultivators regard renovation in this manner as preferable to a manure of one to two maunds of oilcake per acre. It is therefore surprising that the practice is not more general. Early ploughing is of course involved and more labour than is customary has to be given. Mukerji (Notes on a Tour in the Jute Districts) says:—

“The cultivators were asked why they did not grow san-hemp more largely as a rabi crop and a preparatory crop for the jute when they themselves asserted that by doing so they got two maunds of jute more per bigha. They replied that they must grow kalai and other food-crops, and that one special objection to the san-hemp was the retting of it produced a most filthy stink which was unbearable to them, and as there is water only in tanks and khala at the dry season when san is retted in this district, fish die off if retting of san is done in the tanks and other places where there is fish. Owing to these objections, they cannot grow san-hemp extensively, but the cultivation of this useful crop is evidently extending. Kalai and mustard are the standard rabi crops here, but a good deal of san is grown chiefly with the object of benefiting the succeeding jute crop.

“Why a short variety of san (called ghati) should be chosen for feeding cattle and afterwards ploughing in as green manure does not appear clear. The taller variety, though better suited for extraction of fibre, also seems to be more valuable for manurial purposes, as it has far more organic matter in it and the root residue must be also larger. The raiyats recognise that the growing of the larger variety for fibre also has a beneficial effect on the soil.”

Tillage.—San-hemp is most in favour as a catch crop. The seed is sown thickly, hence the value of the crop as a weed-exterminator. In some reports as much as 80 to 120 lb. of seed to the acre are spoken of, in others 40 lb., and in still others half that amount. The plants should be from 3 to 4 inches apart each way. Mollison (Textbook Ind. Agri., iii., 226) observes that a luxuriant crop cannot be grown without careful tillage. Quick growth is necessary whether raised for fibre or as a green manure. “A smooth friable bed is, therefore, required, and this can only be obtained by ploughing and repeated harrowings. The seed is generally drilled in July; in the Deccan with a four-coultured drill, first lengthwise then
across the field. The drill coulters are 12 to 14 inches apart, and the double drilling secures even distribution of the necessary heavy seed rate (about 70 lb. per acre). If the seed germinates properly, no further culture is required until the crop is ploughed in as green manure or reaped for fibre.”

**Diseases and Pests.**—Very little is known regarding the enemies of this plant. Maxwell-Lefroy (Agri. Journ. Ind., i., pt. iii., 187–91; also Memoirs, Dept. Agri. Ind., 1907, i., 158, etc.) gives particulars of three moths, the caterpillars of which often do much harm to the crop.

**Harvest.**—It is customary to read that the crop is harvested after the flowers have appeared, but in certain localities the plants are left on the field until the fruits have begun to form, and in some instances even until they are ripe. “The finest, strongest and best fibre may possibly be got from plants which are not dead ripe, but very good fibre as well as seed are got from a ripe crop” (Mollison). In most cases the plants are pulled up by the roots, in others the stems are cut with a sickle close to the ground. They are left on the field for a few days to allow of withering, and are then stripped of their leaves; these are regarded as a necessary return to the soil. The stems are tied into neat bundles that may be easily handled, each containing not more than 100 stalks. The bundles are then preserved for two or three weeks until they are thoroughly dried, and the remaining leaves and seeds are thereafter thrashed out. But as with jute so with san fibre, much difference of opinion prevails regarding the nature and extent of withering necessary before subjection to retting. Mukerji (Handbook Ind. Agri., 307) says that in the damp climate of Bengal stacking before retting injures the fibre. Stacking is therefore very little practised in that province.

**Separation of Fibre.**—The dried bundles are tied into larger bundles, then placed in pools of water and weighted with stones or logs of wood, until they are completely submerged, much after the fashion detailed regarding jute, only that since the steeping takes place usually in the hot months, a period of five days is ordinarily sufficient, but in cold weather eight or nine days may be required. In some instances retting in damp mud on the margins of tanks or lakes seems to be the system followed; in others complete submergence in water is deemed essential. By some writers stagnant water is condemned as destroying the colour and lustre of the fibre, running water being advocated as preferable. But this seems a mistake, as longer retting would certainly be required in running water. It is also sometimes customary to set the lower and thicker ends of the stems into water for twenty-four hours, so as to secure for these a longer retting than is necessary for the upper portions. In deep water longer retting is required than in shallow. In Salsette there is said to be very little retting, and this circumstance is claimed as the reason of the superiority of the fibre there produced. In many localities the complaint is made that sufficient water does not exist at the harvest season to allow of an extended production. This difficulty, it would seem, might be easily and conveniently disposed of by drying the stems and stacking them till a more convenient season. Districts with a limited supply of water are those where stacking would be easy. The stacking of hemp is moreover believed, if anything, to improve the fibre, and should be tested with san-hemp.

The process of stripping and washing the fibre is very similar to that pursued with jute, but more difficult and laborious. The strips of fibre
are repeatedly beaten on a stone with a stick, then lashed on the surface of the water. This beating and lashing may have to be repeated two or three times before a thoroughly clean fibre is produced. The hank of fibre is now wrung out, to remove the water, twisted and folded into a particular fashion, and hung out to dry and bleach. It is then plaited threefold into a tail, and in that form is usually seen in the market, but it has often been urged that it would be advantageous to discontinue the habit of plaiting the fibre. It will thus be noted that regarding each and every stage in the separation and cleaning there is as great a divergence of opinion as with most other aspects of the industry.

If required for textile purposes, however, or even for the string employed in the construction of fishing-nets, it is opened out and combed or crudely scutched. In most of the reports furnished in Europe regarding this fibre its shortcomings are attributed to incomplete or excessive retting or to imperfect cleaning, breaking and scutching, never to inherent defects in the fibre itself. The loss between washed and scutched fibre is about one-third the weight. Hence the difference in price offered does not, as a rule, tempt the growers to go in for much cleaning.

**Yield and Price.**—It is generally said that the finest qualities fetch in India about one rupee for five pounds. As met with in the bazars san fibre occurs in tangled masses of a dull grevish or greenish-white colour. An official of the Calcutta Custom House, to whom an application was made for information regarding the trade in Indian hemp, furnished in 1901 many useful particulars. The best country hemp comes from Bombay and is called Rajpore or Dugaguddi; it is about four feet long and fetches Rs. 16 to 18 per cwt. The next best is the Jabalpur, the value of which is Rs. 11 to 13 per cwt. The third grade is Phillibit and the last the Bengal. The exports are chiefly in the most inferior stuff. In Messrs. I. Christie's *Monthly Circular* quotations are made of Allahabad, Jabalpur and Bengal hamps, and these would seem to average from 14 to 18 shillings. But a particular shade of colour is desired, and parcels with that colour fetch higher prices, irrespective of strength, the object being to allow of admixture with Russian hemp. Mollison records the yield of an experimental cultivation in Poona. The dried stalks scaled 6,280 lb. and the cleaned fibre 520 lb. per acre. Mukerji gives the yield as 200 to 1,200 lb., or an average of 640 lb. (8 maunds) per acre, worth Rs. 50. A sample examined at the Imperial Institute in 1896 was valued at £15 to £16 a ton in London.

**Properties and Uses of San Fibre.**—For results obtained by the early experimenters consult the *Dictionary*. Although the Indian factories use a fair amount of san in the production of the rope and string generally spoken of as country-hemp, little or no progress has been made to place the production on a sound basis. Madras and Bombay might each have an industry, which if it did not rival the Bengal jute trade might meet some of the markets for that fibre and supply a want for an article of a slightly higher quality. It is indeed surprising that this fibre has not by now become an established and valued feature of the commerce and industry of India. Some few years ago, as co-author of a small book on the *Indian Fibres and Fibrous Substances* (Cross, Bevan, King and Watt, 1887, 28–30), I wrote, "It is impossible to urge too strongly the claims of this much-neglected fibre—a fibre which seems to have suffered severely through the immense success of jute obscuring for a time the properties of all other

bast fibres.” “During the Colonial and Indian Exhibition numerous inquiries were made as to why it was that so little of the better qualities of san-hemp were procurable. Mr. Collyer and several other brokers and merchants stated that their only difficulty in pushing the trade in san-hemp was their inability to procure a uniform and a large enough supply.” Dunstan (Imp. Inst. Tech. Repts., 1903, 70) similarly observes, “The literature on this fibre is extensive, betokening much interest in its qualities, but up to the present the material has been exported only to a small extent.” Two sets of samples were sent to him for examination, viz. from Burma and Calcutta. The results of the chemical analyses of these are given, and it may be said that the ash in the Calcutta sample was considerably higher than in that from Burma, but all the features brought out were regarded as indicative of high quality. Microscopically the ultimate fibres were found to be rather long—5 to 8 mm.—and seen to end abruptly instead of tapering, while the walls were rough and irregular in outline.

As to the utilisation of the fibre, these may be briefly stated as identical with those of true hemp—namely the production of cordage and canvas, the waste or tow going to the paper mills. But in India by far the most important use is the employment of san-hemp for the cordage of fishing-nets. In this connection it may be mentioned that Mr. V. P. Ribeiro, Sub-divisional Forest Officer, Bassein, West Thāna, contributed to the Reporter on Economic Products a most interesting account of the deep-sea nets used by the Koli fishermen (since published in the Agri. Ledg., 1905, No. 7). These are huge traps 160 feet long and 70 feet in diameter. They are constructed entirely of san-hemp, and may cost as much as Rs. 250 each. The mesh decreases from 6½ to 4 inches progressively, from the mouth to the apex of the net. The fibre is carefully tanned. The repairing and tanning of the net cost about Rs. 8 a month. The inference from this is that the fibre is only durable under sea-water when fully tanned. The woodwork of these deep-sea nets, it may be added, is preferably that of Adina cordifolia. Throughout India fishing-nets are largely made of san-hemp, though not exclusively so. Those of Karachi are chiefly madar or akandha fibre (Calotropis gigantea, p. 207) and those of Assam and Eastern Bengal rhea fibre (Behermania nivea, pp. 146, 157).

TRADE IN SAN HEMP.—As already observed, nothing of any value can be said authoritatively regarding the extent of production or utilisation of this fibre, since it is not separately recorded in the Trade and Agricultural Statistics. It is grown in every province, and nearly universally used by the people of India. It seems probable, however, that of the exports to foreign countries shown as “Raw Hemp” of Indian produce, a large proportion is san. The only other fibre of importance (and that one of comparatively recent origin) is indicated by the exports of Indian Agave fibre (Sisal hemp). Of the imports of raw hemp the major portion is doubtless Manila (Musa textilis), and lastly of the imports of hemp manufactures the major portion is doubtless canvas and rope of Russian hemp. The traffic under these headings may be here exhibited:—

It will thus be observed that while both the exports and the imports have increased very considerably within the past twenty-seven years, a scrutiny of the details reveals the fact that the most important import has taken place within the last six or seven years and is due mainly to the expanding supply of Indian Aloe Fibre (see Agave, 44-5).

CROTON TIGLIUM, Linn.; Fl. Br. Ind., v., 393; Pharmacog. Ind., iii., 281-6; Gamble, Man. Ind. Timbs., 1902, 614; Euphorbiaceæ. The Purging Croton, jaya-pala, Jaypal, kanakaphālā, jama-gota, nepāl, neredlam, kanako, bori, dand, etc. A small tree met with under cultivation throughout the greater part of India; said to be naturalised in Eastern Bengal, Assam, and elsewhere.

Gamble states definitely that it is not indigenous. It was apparently first described by Acosta in 1578; and subsequently by Rheede in 1673, then by Rumphius in 1743. The purging croton grows on the poorest soils, such as waste lands, from the sea-level up to about 3,000 feet. Under cultivation no special care is necessary, and it will fruit in the second year. It has been spoken of as a shade-tree for coffee. A little of the powdered oilcake forked into the soil has been recommended as a protection for tea and other plants from grub and white ants. The nuts yield a large amount of medicinal oil, which may be administered as a violent purgative, or applied externally as a powerful vesicant. An inquiry made by Prof. W. R. Dunstan and Miss L. E. Boole into the nature of the vesicating constituent resulted in their obtaining "a small quantity of a yellow oil which, after a time, became a transparent resinous mass, intensely active and burning without ash. It was found that crotonoleic acid owed its vesicant properties to a small proportion of this resin, to which the name of 'croton resin' has been provisionally given" (Imp. Inst. Journ., 1896, ii., 264). It is said that croton oil is used by fraudulent manufacturers as an adulterant of tincture of iodine. (Cf. Brit. and Col. Drugg., 1901, xi., 176.) The seeds have similar properties to the oil and are fairly largely used by the Natives of India. Kino-like exudation has been discussed by Hooper (Rept. Labor. Ind. Mus., 1905-6, 34). Messrs. Hearson, Squire & Francis say that if the London price be taken as 25s. to 35s. per cwt., the freighting, insurance and brokers' commission would have to be borne by the shipper. It is better to express the oil before transit since much is lost on the voyage. For kino see *Pterocarpus Marsupium* (p. 908).

CUCUMIS, Linn.; Fl. Br. Ind., ii., 619-20; DC, Orig. Cult. Plants, 258-62; Cogniaux, DC, Monog. Planer., iii., 479-507; Cooke, Fl. Pres. Bomb., i., 534-6; Duthie, Fl. Upper. Gang. Plain, i., 371-4; Prain, Beng. Plants, i., 522-3; Cucurbitaceæ. A genus of climbing herbaceous plants which embraces twenty-eight species, of which more than half are recognised as African and only three or four Indian. It is noteworthy, however, that of the Indian forms, two are the Melon and Cucumber (economically very far the most important of all) and the third is *C. trigonus*, Roxb.—a truly wild plant, never cultivated nor its fruits eaten.

C. Melo, Linn.; Duthie and Fuller, Field and Garden Crops, pt. ii., 51, pl. 1; Sweet Melon, kharbija, karbus, kharmuj, tarbuj, dungra, chibūda, gidhar, zaphin, sarda, vellari-verai, mulam-pandu, remō, etc.

Most of the early travellers speak of the best melons of India being grown from imported seed. The Emperor Baber makes, in fact, no mention of Indian melons, but extols those of Samarkand. So also in Akbar's time none of the
The Melon

CUCUMIS MELO

Melon

five sorts spoken of in the Aın-i-Akbari (Blochmann, transl., 65) were Indian; all are stated to have come from Badakshan or Kabul. Linschoten (Voy. E. Ind. (ed. Hakl. Soc.), ii., 35) observes that the Indian melons are not so good as those of Spain, and have to be eaten with sugar. Tavernier speaks of the Indian melons as grown from Persian seed. Firminger (Man. Gard. Ind. (ed. Cameron), 1904, 225-9) mentions several kinds of melons as specially excellent. The best or first class is the sarda, a native of Kabul, which does not succeed in India; the second is also a Kabul melon successfully grown in India. Aitchison (Prod. W. Afghan, and N.E. Persia, 48-9; Kew Bull., 1894, 75) is of opinion that the sarda failed because it was not understood. The early supply consists of ordinary good melons, but the later, when ripened with frost, is the sarda proper. It is covered over and left to mature slowly. Some sarda melons sent to Kew in 1894 arrived in excellent condition, and from the seed thus obtained good fruits were grown at the Royal Gardens at Frognmore and elsewhere. It is believed that sarda melons might be exported to Europe, where they would fetch good prices as winter fruits. The third and perhaps the finest of the Indian melons is the safedah or white melon of Lucknow, which is grown in sandy loam along the banks or in the dry beds of the Gumi. It is the size of a very large orange, flattened at both ends and white inside and out. It would appear, however, that so far back as 1866 the Lucknow melon had been allowed seriously to deteriorate, so that perhaps its present condition might be considerably improved. In The Indian Agriculturist (June 12, 1866) Dr. E. Bonavia gave an interesting account of this deterioration, and urged that efforts should be made to improve the stock of the "chitta" or "speckled" melon of Lucknow.

The Melon from an agricultural point of view is the most important species of the genus Cucumis, and is extensively cultivated for its fruits on the sandy banks of Indian rivers. So soon as the water has fallen from the white sandy banks of the Ganges and Jumna, for example, pits are dug and filled with manure within which the melon-seed is deposited. These pits act as forcing-beds and are protected against sand-drift by grass and thorn hedges constructed around them. Less manure is required when the silt of the river is of fairly rich quality and contains organic matter. Sometimes, as at Ahmedabad, the plants are sown in trenches instead of pits. They continue to fruit as a rule from April until the rising of the water in June overwhelms and destroys them. A popular account of the Indian melons may be found in Indian Planting and Gardening (Oct. 3, 1904), and interesting descriptions of the growth of melons on the floating gardens of Kashmir are given by Moorcroft (Agri.-Hort. Soc. Ind. Trans., i., 70), by Rivett (Assess. Rept. Mir Bahri, 1898, 16), and by Lawrence (Valley of Kashmir, 345-9).

The flattened and elliptic seeds yield a sweet edible OIL. Semler says the quantity they contain is about 30 per cent. and that a considerable trade in it exists from the Chinese port of Chefoo. It is a light thin oil, which dries slowly and in addition to being eaten is employed in the soap industry. According to Semler a considerable quantity was formerly exported from Sierra Leone and Lagos, but the low prices offered have killed the trade (Trop. Agrik., 1900, ii., 525). The seeds are also used as a cooling MEDICINE, though it is doubtful if those of the various species are distinguished. In fact the seeds of C. Melo are commonly sold all over India as a cooling medicine in admixture with those of C. Mello, var. utilisima, Benincasa cerifera and Citrullus ovatus. Melon-seeds are also commonly used as a flavouring ingredient—bhag-massala. [Cf. Cannabis sativa, p. 258.]

Pests.—Particulars of the cultivation of Afghan and Baluch melons in the Lower Provinces, together with a description of the life history of the troublesome melon-fly, may be found in Jus. Cleghorn’s most useful paper (Journ. Agric.-Hort. Soc. Ind. Trans., n.s., 1901, ix., 63-82). The fly is also attacked, like other cucurbitaceous fruits, by a small red beetle. [Cf. Ind. Mus. Notes, i., 1896, 92-3; iii., pt. v., 57-8; iv., pt. i., 32-4, pt. ii., 92-3.] The wood-ash preventative, usually adopted by the Natives, must be detrimental, and probably a muslin frame would be found more effective, since only the young seedlings suffer as a rule.

Phut and Kachra.

(a) var. Momordica, Roxb., sp.; Duthie and Fuller, Lc. 50, pl. xlix.; Banerjei, Agri. Cuttack, 1893, 116. The phut or phünk, phúthi, kachra (unripe), mutá, kákri-kai, peda-kai, thákhwá hmvwey, etc. Mentioned as phookh in the Taleef Shereef, and according to Dutt has a Sanskrit name, eravá. Although now reduced by
THE CUCUMBER

botanists to a variety of C. Melo the fruit is cylindrical, smooth (not fluted), mottled yellow and green and more like the cucumber, except that it is less scabrous and larger. There are several distinct forms met with in the hot and rainy seasons. It is cultivated in cotton or maize fields, etc., here and there throughout India, and when the fruit has burst, which it does spontaneously, the flesh is mealy but not sweet, though palatable when eaten with sugar. When young the fruit is a good substitute for the cucumber, and kachra is in fact a valuable vegetable.

(5) var. utilissimus, Roxb. sp.; Duthie and Fuller, l.c. ii., 55, tt. lii., liv. The kukri, kakur, or kankur, kukri, dosray, velluri, kakkurik, kakkadi, kakdi, tarkakdi, takheka, tavashi, etc. This melon approaches the cucumber. According to Buchanan-Hamilton (Stat. Acc. Dina), 1833, 196) it is the fifth most important fruit. It varies from short oval to elongate (sometimes three feet in length). When young it is covered with soft down and is pale green in colour, but with age changes to dark green or white and bright orange when fully ripe. It is cultivated in Bengal, the United Provinces, the Panjab and Western India, etc., during the hot weather and the rains. It prefers a dry, loose, open soil. After manuring the ground should be laid out in beds and three or four seeds sown three feet apart. Being in season long before the cucumber, the young fruit is much eaten by Europeans as a substitute for that vegetable, though it is somewhat insipid. Kakri is moreover an important article of Food with the poorer classes during the hot months. When half-grown it is pickled; when ripe eaten raw or in curries. The seeds are pressed, dried, ground to meal; the oil expressed from them is used with food, in medicine, or in lamps. It seems probable that some at least of the forms spoken of by authors as cucumbers should in reality be placed under the present plant.

There seems to be no doubt that one at least of the original homes of the cucumber was in North India, and its cultivation can be traced to the most ancient classic times of Asia. Royle's C. Harwickii (a plant wild from Kumaon to Sikkim) is in no important respect different botanically from C. sativus, though it has distinctive vernacular names (air-du, páhari-in-drayan, etc.), and is collected and used as a substitute for Cucumis sativus. Hahn (Kulturpl. und Haust., 6th ed., 1894, 308-14) gives a useful account of the historic and etymological considerations. Briefly, it may be said that C. sativus and C. chinensis refer most of the early names for the cucumber, the melon and the gourd to the uses of certain forms of these fruits as water and oil bottles. (Cf. Cucurbita, p. 441, and Lagenaria, p. 700.)

There are two primary forms of cucumbers:—a creeping field plant of the hot weather, and a garden climber of the rainy season. The former has small egg-shaped fruits (mandi kakuri of Orissa) and is sown in drills in February or March, preferably in rich soil. The latter or rainy-season varieties have much larger fruits (kantali kakuri), dark-green or creamy-white, changing to rusty-brown when fully grown. The rainy-season varieties are the most common, being eaten by both Natives and Europeans. The hot-season forms are also, however, eaten either raw or cooked in curries. Gathered in a young state they are generally known under the name gherkin or gherkin, and constitute a much-prized vegetable; they are also very extensively pickled and eaten in that form. It would thus seem fairly certain that the gherkin of India is the hot-season form of C. sativus and not the somewhat doubtful C. Anguria of the West Indies. Sir J. D. Hooker (Bot. Mag., t. 6206) has described a special form of cucumber that seems peculiar to Sikkim.

In the hot-weather cultivate three sowings are usually made, namely at the end of February, in the middle and at the end of March. The seeds are sown along both sides of drills, the drills being one foot apart. In dry soil, water is given immediately after sowing and subsequently every ten days, but not too liberally. The rainy-season forms thrive with little care, and are always sure of

439
CUCURBITA
Squash and
Pumpkin

yielding a good crop. The creamy-white kind ("White Turkey") is regarded as one of the best forms. European cultivation has recently completely changed the character of the plant met with in Indian towns. [Of Ind. Gard., Dec. 21, 1899.] Still it is a curious fact that although the cucumber is now fully acknowledged to be a native of India, most of the fine English forms cannot be grown in that country.

The name Indrayan sometimes given to it more correctly denotes Citrullus colocynthis, but I strongly suspect those two plants, and also the so-called wild states of C. sativus (C. Hurdwickii, Royle) have been much confused by economic and even by some botanic writers. The character of simple bifurcated tendrils would, if rigorously applied, almost of necessity involve the transference of one-half the sheets in most herbaria from Citrullus colocynthis to Cucumis trigonus. Indeed, all the examples of Citrullus with small deeply dissected leaves have simple tendrils, and can with difficulty be separated from Cucumis pseudo-colocynthis, Royle. It is necessary to draw attention to this circumstance since the properties of the kárit do not differ materially from those of the true colocynthis. But the plant of the sandy deserts is very different from that of the Himalayas, and there may be two or more species; but if so, then they have been very indifferently described and identified. Roxburgh pointed out that his C. trigonus resembles very much C. Melo, Linn. var. utilisima, and Prain says C. trigonus is sometimes considered the original source of the melon, and may equally be a form of that plant which had become feral.

The seeds yield a fixed oil by boiling, which is used in lamps by the poorer classes. The pulp of the fruit is bitter and similar in quality to colocynthis. It is not, however, possible to ascertain definitely the exact industrial and medicinal value of this species until the ambiguities above indicated have been removed.

History.—Considerable confusion appears always to have existed as to the history and nomenclature of most cucurbitaceous plants. It seems probable that European pre-Linnaean names are suggestive of the first uses to which the fruits were put, but can hardly be accepted as separately denoting the modern genera and species. Thus, for example, Pliny (Hist. Nat., bk. xix., ch. 5) observes that cucurbitaceous fruits had long been used as wine-bottles, but in his day were just coming into fashion as water-pitchers at the baths. Heurn (Kulturpf. und Haukt., 6th ed., 304-14) derives conjecturally Cucumis and Cucurbita from cumaera and corbica, low Latin words, the one meaning a covered vessel, the other a basket (Germ. korb). Hence perhaps the remark by Columella (De re Rust. (ed. Gesnero, 1773), xi., 3, 49), these fruits "are well suited for employment as vessels." Incidentally it is worth noting that many of the early glass bottles recovered from the Thames, Tiber and Seine are obviously modelled on the bottle-gourd (Lagenaria vulgaris), and some of the bottles used for Italian wines are to-day of that shape. It is thus not surprising that statements sometimes applied to Cucurbita should have to be transferred to Lagenaria or Benincasa or vice versa. Still more frequently are the various species of Cucurbita confounded one with the other and their vernacular names in all countries interchanged. Brief botanic diagnoses for the purpose of facilitating distinction become accordingly almost imperative.
RED, YELLOW, AND WHITE GOURDS

Duthie says that the evidence obtained from historic research favours an Asiatic origin for this plant, C. Sprenger (Bull. Tosc. Ortic., 1893, 333) says a wild form, C. maxima (sylvestris), has been found in the Himalaya which is supposed to be the parent of all the large-fruited gourds in cultivation. [Cf. Kew Bull. (add. ser.), 1900, iv., 120.] Asa Gray is disposed to accept it as American, and in support of that opinion mentions that its name "Squash" is American. It produces the largest known cucurbitaceous fruit; examples weighing as much as 240 lb. have been recorded. The principal varieties have already been denoted by the citation above of European names. It is cultivated in most warm and temperate parts of the globe. In Upper India the seed is sown in the rains and the vegetable eaten in the cold season; but in Bengal it is often sown in October, and Banerjej says that in Cuttack it is sown in February-March. Both the seeds and the oil expressed from them are used in medicine. The fruit when young is used as a VEGETABLE, and when mature will keep for months if hung up in an airy place. It is, like most other forms of Cucurbita, extremely valuable as a vegetable during camping expeditions, since it will keep for months and withstand severe handling. It is largely used by the Natives in curry. In German East Africa the young leaves are eaten like spinach. [Cf. Berichte über Land-und Forst., 1903, i., 419.] In Assam the young leaves of C. Pepo are similarly eaten as a pot-herb.

C. moschata, Duchesne; Duthie and Fuller, Field and Garden Crops, pt. ii., 58-9, pl. lviili-lixii. The Musk-melon, Melon Pumpkin, sitaphal, sapafari khumra, mithá-kaddú, kali-dudhi, etc. Leaves as in the preceding, but very often marbled with whitish blotches; petiole hairy but not prickly; fruiting peduncles angular and furrowed; calyx leaves of the female flower large foliaceous. The Musk-melon is described in the Ain-i-Akbari (Blohmann, transl., 64-5) as distinct from the melon, so that it appears to have been known in India from fairly ancient times. Baber (Memoirs, 1510, 328), for example, in his description of the citron, compares it with the Musk-melon. There are two primary forms of this plant, one bearing smooth and the other fluted fruits; the former is oblong in shape (C. moschata proper), and the latter a flattened spheroid (C. metapepo, Retb.).

The plant is now widely cultivated in both hemispheres and requires a warmer climate than either C. maxima or C. Pepo. It is grown as a field crop in Northern India, and the yellow flesh is extensively cooked and eaten as a vegetable throughout India. There appears to be a small form, about the size of a turnip, which is grown under the names tendi (Bignor), tendú (Duab), tinú (Panjab), and which makes a delicious vegetable when young or half ripe. This is mentioned in the Ain-i-Akbari (1890, l.c. 66) as a sweet fruit.

C. Pepo, Linn.; Fl. Br. Ind., ii., 622; Taylor, Topog. Stat. Dacca, 1840, 139-40; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 170; Sen, Rept. Agri. Stat. Dacca, 1889, 40; Duthie and Fuller, l.c. i., 377. The Pumpkin, White-gourd, Vegetable Marrow (var. ovifera), khumra or kimara, sawed kaddú, lanka, kaula, kohala, pheta, bhungá, etc. Leaves 5-palmate, sinus broad and segment pointed; petiole as long as the blade, the hairs of the lower surface hardened into prickles; corolla narrow towards the base and lobes erect; calyx-segments linear lanceolate; fruiting peduncle woody, strongly grooved, and marked with ridges.

The the kumra is mentioned in many of the ancient Sanskrit works, but \textit{C. pepo} and \textit{B. raphanum} are possibly confused or not distinguished. The Pumpkin is often mentioned as a native of America, though this opinion rests on Lindheimer's observation "apparently indigenous." Asa Gray ({\textit{loc. cit.} 333}), commenting on that, says "no wild specimen has since been received from all that region (nor from any other)." It is grown in vegetable gardens throughout the greater part of India, and is often seen scrambling over the cultivators' huts. It is nowhere, however, extensively grown, and rarely as a field crop. The following notes on Indian cultivation are taken mainly from Firmerger ({\textit{loc. cit. 171}}):—In \textit{South India} the improved custard and patty-pan marrows are delicious vegetables, but they only succeed when sown in the early rains. They should be sown in boxes or pans at the end of May. When the first pair of rough leaves appear the seedlings may be transplanted into richly manured pits, at 5 feet apart, in the kitchen garden. The hardier long-fruited varieties will succeed all through the rainy season. In \textit{Lower Bengal} the seeds should be sown in the open ground about the end of October to middle of December, and the plants must have plenty of space to trail over. The best plan is to sow two or three seeds in pits 16 inches deep and as many wide, filled with richly manured soil. If many seeds germinate, eliminate all except one. When the plants have formed about four of their rough leaves they will almost certainly be attacked by a red beetle, but if they can be preserved at this stage they do not seem to be liable to attack later. When they have set as many fruits as the vines will bear the flowers should be removed. The plants require constant and copious watering, and occasionally with liquid manure. The gourds must be gathered when tender, say in May–June, as they rapidly become hard and woody. Both Taylor and Sen speak of the pumpkin as a garden and field crop characteristic of certain parts of Bengal. In the \textit{United Provinces} the sowing of the seed must not be made before the end of February as the plants will not live in the first season in that part of India. On the hills, sow in April and the vegetable will be in season in July. Duthie says that in these provinces it is a garden, not a field crop. From Mussourie a scarlet pumpkin has recently been reported as brought originally from Kashmir. [{\textit{Cf. Journ. Agri.-Hort. Soc. Ind.}}, 1902, xii., 116–7.]

As a field crop in Europe and America the pumpkin and vegetable marrow are grown 15 feet apart with 12 feet between the rows. Three seeds are deposited in each spot, and 2 lb. per acre will therefore suffice. The yield on rich, well-manured vegetable soil is from 15 to 20 tons an acre. In India the seeds are preserved; they yield a clear edible oil, supposed to be of medicinal value. The use of the fruit as a vegetable is of course well known, and the raw fruit is said to be an excellent food for cows. The fruits of several species of melon, gourd, etc., are candied and sold all over India both as a luxury and in medicine. Similarly the seeds of these fruits are largely used for flavouring certain preparations of Indian hemp, and the root for a nefarious purpose, viz. to make the preparation more potent (\textit{Rept. Ind. Hemp. Drugs Comm.}, iv., 425, 491). [{\textit{Cf. Produce World, Feb. 1896; Planting Opinion, Feb. 5, 1898; Journ. Soc. Chem. Indus.}}, 1901, xx., 1003; \textit{Pharm. Journ.}, 1901, 67, 253; Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 369–70.]

\textbf{CUMINUM CYMINUM, Linn. ; Fl. Br. Ind., ii., 718; Pharmacog. Ind., ii., 113–6; Duthie and Fuller, Field and Garden Crops, pt. iii., 40; Duthie, \textit{Fl. Upper Gang. Plain}, i., 397–8; Cooke, \textit{Fl. Pres. Bomb.}, i., 578; Umbelliferæ. Cumin, zira, jiraka, ajaqi, kamin, zīrā, zīya, etc. This plant is more or less cultivated in most provinces of India, except Bengal and Assam. There is, however, fairly conclusive evidence that it is nowhere indigenous, though in several districts it would appear to be so far naturalised as to have been regarded as "wild" even by competent observers.}

\textbf{History.—Considerable confusion exists in Indian publications through the vernacular name zīrā or jīrā being given to both cumin and caraway (see Carum Carvi, pp. 283–4). A similar mistake is made with regard to \textit{Nigella sativa}, Black Cumin (p. 811). (The authors of the \textit{Pharmacographia Indica} point out that jīrā or jirana, the Sanskrit names for cumin, as well as the Persian zhirch or zirch and all the Indian vernacular names, appear to be derived from the root}
THE YELLOW AND BLACK ZEDOARIES

ji and to allude to the digestive properties of the seeds). The true cumin is generally regarded as a native of Egypt or of the Mediterranean regions, and according to Somller (Trop. Agrik., 1900, ii., 584) the best sort comes from Malta.

The historical records of the use of cumin go back to early times. It was a common flavouring spice during the 17th century in England, as it still is in Germany; it was extensively employed all over medieval Europe and was known even in the dark ages. With the Greeks its small size originated a proverbial reproach—kuminopristes (cumin-skinning). It is referred to in very much the same sense in St. Matthew, xxiii., 23. In Europe, however, it has been displaced to a very great extent by caraway, but is largely used throughout India. The seeds (fruits) afford from 3 to 4 per cent. of an oil which has the sp. gr. of 0.91 to 0.93. The oil is chiefly employed in Europe in the manufacture of liqueurs.

Of. Gildemeister and Hoffmann, Volatile Oils, 1900, 544–5.] In India considerable importance is still attached to the medicinal properties of cumin, which is held to be astringent and cooling.

Trade.—The available information regarding the Indian acreage of this crop and the average yield is unfortunately not sufficient to justify an attempt at estimating the total production and consumption. The United Provinces and the Panjab are the chief producing provinces. There is a large internal trade. Madras, for example, gets its supplies from Bengal. One of the earliest references to foreign trade in Indian cumin is that given by Milburn (Or. Comm., 1813, i., 136). "The plant," he observes, "which produces these seeds somewhat resembles fennel, and grows in various parts of India, Persia and Egypt; it is an article of trade with Surat. The seed is a kind of caraway... they are to be chosen fresh and of a greenish colour. There are several sorts of cumin seeds to be met with, but they are seldom imported from India." At the present day the exports of cumin from India show a steady increase. Thus they were 11,304 cwt., Rs. 2,22,161, in 1899–1900; 17,385 cwt., Rs. 4,03,875, in 1903–4; and 22,308 cwt., Rs. 5,00,535, in 1903–6. The modern traffic is almost exclusively from Bombay and Bengal, and the best customers are Ceylon, the Straits Settlements and British East Africa. The United Kingdom takes only from 20 to 50 cwt. yearly. But there is a considerable import of cumin across the N.W. land frontier and from Red Sea and Persian Gulf ports. The chief trade centres are Jabalpur, Gujarat, Ruttam and Muscat. [Of. Paulus ᾨγινητα (Adams, transl.), iii., 203; Tavernier, Travels (ed. Ball), ii., 20; Birdwood and Foster, E.I.C. First Letter Book, 199, 317, 480.]

J. G. Baker has described (in Fl. Br. Ind.) twenty-nine species under this genus. Some ten of these are more or less of economic value and two of considerable importance. It may suffice, therefore, to give a few jottings regarding the unimportant economic species, under the present introductory note, and to thus concentrate attention on the two chief plants:

C. Amada, Roxb., in As. Res., 1810, xi., 341; the Mango-Ginger, am-haldī, amddā, etc., which is found wild in Bengal and on the hills, the tubers being used medicinally and as a condiment and vegetable.

C. aromatic, Salisb.; Cooke, Fl. Pres. Bomb., ii., 730; Pharmacog. Ind., iii., 396–8; the wild or Cochin Turmeric, Yellow Zedoary, jangli-haldī, ban-haldī, amīr or rān-haldā, etc. This plant, which is a native of Bengal, is practically a substitute for the true turmeric, and was not distinguished from it by Arabian physicians. Used medicinally by the Hindus in combination with astringents or with bitters and aromatics and exported to Europe for use as a substitute for turmeric in dyeing. It is chiefly grown at Alwaye, north-east of Cochin, and is also collected in Mysore, Wynnaed, etc. The unpeeled root fetches Rs. 24 to 25 per cent of 4½ cwt.

C. casia, Roxb.; the Black Zedoary, kātā haldī, is wild and cultivated in Bengal and chiefly used as a cosmetic. It is one of the two seerumbdēs of modern Persian writers. [Of. Aitchison, Notes on Prod. W. Afgan. and N.E. Persia, 15; Pharmacog. Ind., i.e. 403–5.]

C. caulina, Graham; the chawara, chowar of Mahabaleshwar; C. leucorrhiza, Roxb., of Bihar, often specially designated tikor or tikkur; C. pseudo-montana, Graham; the sindervani or sindarbar of the Konkan; and C. rubescens, Roxb., of Bengal, are all said to yield arrowroot that is regularly eaten and which

becomes important in times of scarcity or is used to adulterate that of C. angustifolia. [Cf. Cooke, l.c. 730.]

C. Zedoaria, Roxb.; Cooke, l.c. 732. The long and round Zedoary, bachoora, satt, srote, suraunbod, hukh-ke-gadde, kitchchitk-kishanu, thanu-uen, etc. This plant is wild in the Eastern Himalaya and cultivated here and there throughout India. Roxburgh observed that it was a native of Chittagong, whence the Bengal supply was derived. The round zedoary of the shops is greyish-white and compact. It has a bitter and strong camphoraceous taste. The long zedoary has the same odour and flavour. The red powder, abir, used by Hindus at the Holi festival was formerly largely made from the rhizome of this plant. The powder is purified, dried, and mixed with a decoction of sappan-wood. The rhizomes constitute one of the most important articles of Native perfumery, and a considerable supply is sent from Ceylon to Bombay, the price being about Rs. 20 to 30 per candie of 7 cwt. [Cf. Ain-i-Ahbari (Gladwin, transl.), i., 104; Milburn, Or. Comm., 1813, i., 293; Montgomery Martin, Hist. E. Ind., 1838, iii., 241-2; Paulus Eginetc (Adams, Comment.), iii., 434-6; Pharmacog., l.c. 399-403; Firminger, Man. Gard. Ind. (od Cameron), 1004, 378-9.]

Indian Arrowroot.

C. angustifolia, Roxb.; Pharmacog., l.c. 405-7; Wiesner, Die Rohst. des Pflanzenr., i., 612-3. East Indian Arrowroot, Narrow-leaved Turmeric, the tikkur, tikar, tankir, tavakhira (tavakshiri), ararut-ke-gadde, ararut-kishanu, kuva, etc. A native of the central tracts of India from the mountains of Bengal to Bombay and Madras and, according to some writers, of the N.W. Himalaya as well. It is particularly abundant in the Central Provinces, especially the Upper Godavari district; a considerable trade in the tubers exists at Raipur and Malabar. The arrowroot of the wild tuber is said to be largely prepared and traded in from Cochin and Travancore to Kanara (Malabar arrowroot). [Cf. Hanausck, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 46.]

According to Madras experience the sets are planted late in autumn in properly prepared soil, are watered occasionally during the dry season, and cropped in January. Owing to the dryness of the soil the tubers have, as a rule, to be dug up, not ploughed up, and this process is somewhat tedious. The yield on the prepared soil of the Sylapet Experimental Farm, Madras, was found to be 3,944 lb. of tubers, or 403 lb. of prepared flour per acre. A plot cultivated in the college Experimental Garden yielded at the rate of 7,500 lb. of tubers or 937½ lb. of flour per acre. In preparing the flour, the tubers, after being well washed, are pulped on a grater and the starch and fibre separated by the use of water. It is then strained through a cloth and the fibre thereby separated; the starch is again washed, then sun-dried, and finally broken into fine flour. If sold at 4 annas per lb. the profit per acre would be about Rs. 400. The resulting starch is fine, and the best specimens of it have been even compared to the true arrowroot (Maranta arundinacea, p. 773), but the granules are flat and always stratified. Mr. Nibaran Chandra Chodhury in 1901 wrote an instructive note describing the cultivation of this tuber in Bakarganj, which does not, however, differ materially from the Madras experience and results briefly indicated.

A fairly large trade exists in tikkur or tankir arrowroot all over India. It is used as a substitute for ordinary arrowroot, but regarded as less desirable medially. It is, however, a favourite article of food among the Natives, especially for children. The Travancore arrowroot is reported to be not infrequently mixed with the starch of cassava or tapioca (Manhot utilisima, p. 766). In Upper India it is said the starch of the sweet potato is sometimes employed as an adulterant, and in Bombay the colourless young tubers of the ordinary turmeric are mixed with those of this plant. Of the trade, though known to be extensive, no details are available. In Bombay, Malabar arrowroot is said to fetch from Rs. 3 to Rs. 4 per maund of 28 lb.

The late Dr. Lisboa (Notes on Mahableshwar and Other Indian Arrowroot-yielding Pl. in Journ. Bomb. Nat. Hist. Soc., 1887, ii., 140-7) gives much useful information regarding this arrowroot. He would appear to think that much of the East Indian Arrowroot of Western India (especially that of Mahableshwar) is derived from the tubers of Mithenius cantina, Baker. [Cf. Cooke, Pl. Pres. Bomb., ii., 792.] He then mentions as substitutes and adulterants to the true

THE TURMERIC

arrowroot, in addition to Curcuma angustifolia and C. pseudo-montana, the following:—Arisinga turtoosum, Schott, and Taccu pinnulliflora, Forst.

C. longa, Linn.; Fl. Br. Ind., vi., 214; Duthie and Fuller, Field and Garden Crops, pt. iii., 41, t. lxxvii.; Nicholls, Textbook Trop. Agri., 248-9; Mollison, Textbook Ind. Agri., iii., 186; Mukerji, Handbook Ind. Agri., 1901, 555; Cooke, Fl. Pres. Bomb., ii., 732. Turmeric, haldi, haledge, halada, halud, halja, manjal, pasupu, mannal, arishina or arshana, kahâ, sana, hsa-muen, hardâ (Sanskrit—yellow-wood), and karkom (the Hebrew from which kurkum and Curcuma have been derived), (Lacaita, Appendix in Maw, The Genus Crocus, 1886, v.—xiii.), etc. Turmeric is regarded by some botanists as a native of India, but the finest qualities were introduced from China or Cochin-China.

History and Races.—Ibn Baithar (1200, ii., 370), quoting a writer of the tenth century, says that the Persians call this root al-hard, and the inhabitants of Basra name it al-kurkum or saffron. Garcia de Orta (Coll., 1583, xviii.) gives its chief Indian names, and says that while abundant in Cananor and Colicut, it is only known in Persia and Arabia as obtained from India. He speaks of it as a form of saffron known to the Arabs as habet. The Ain-i-Akbari gives the prices of the qualities of turmeric, so that it was possibly as well known in India in 1599 as it is to-day. The plant is nowadays extensively cultivated all over India for the sake of its rhizomes. There are two main conditions: one in which a fairly soft rhizome is used as a condiment, being one of the indispensable ingredients in curries; the other in which the rhizome is harder and much richer in colour, hence employed for dyeing purposes. Certain qualities of the rhizome are also fairly largely prescribed in medicine. So very different are some of the so-called forms of turmeric that it has often been urged they must be produced from botanically distinct varieties, if not species, quite independently of C. longa. In European trade, for example, there are known the following:—China, Madras, Cochin, Bengal and Java. The first mentioned is the best. Cochin turmeric is a globular tuber, and usually appears in market cut into slices. It is an edible tuber, and is possibly to some extent often C. angustifolia or C. pseudo-montana rather than C. longa. But according to some writers the special qualities of the dye rhizome are more a question of age than of specific distinctions. If left in the soil for a longer period, or if dried and stored for some time before being used, the tubers assume the dye condition. There are, however, special dye stocks known as lok-handi-haladi, moela-haldi, jowala-haldi and ambu-haladi. These, very possibly, have been produced by the careful selection of centuries of cultivation. The vernacular names of indigenous turmeric could easily have been transferred to an imported plant, just as the foreign arrowroot is displacing the indigenous.

Cultivation.—1. Bengal.—The description of cultivation in Bengal given by Roxburgh is held by most writers to be in the main applicable to the greater part of India. It may, therefore, be quoted here in full. "The ground," he says, "must be rich, friable and so high as not to overflow during the rainy season such as the Bengalese about Calcutta call danga. It is often planted on land where sugar-cane grew the preceding year, and is deemed a meliorating crop. The soil must be well ploughed and cleared of weeds, etc. It is then raised in April and May, according as the rains begin to fall, into ridges, 9 or 10 inches high and 18 or 20 broad, with intervening trenches 9 or 10 inches broad. The cuttings or sets, viz. small portions of the fresh root, are planted on the tops of the ridges, at about 18 inches or 2 feet asunder. One acre requires about 900 such sets, and yields in December and January about 2,000 lb. weight of the fresh root." From more recent publications it may be learned that in Bengal two varieties are grown, the deshi or country and the Patna; the latter is of a richer colour and gives a better outturn. The crop is often lifted the first year, but the produce is inferior both in quality and quantity to that obtained when left in the soil for a year.

---

Two Forms: Grown.

Twelve to Twenty-one Months' Crop.
and nine months. The cost of cultivation, which is in the main the same as that of ginger (Zingiber officinale), is estimated at from Rs. 7 to Rs. 15 per bigha (one-third of an acre), and the yield is variously stated at from 8 to 18 maunds. The former estimate (8 maunds) appears to refer to dried roots. Another estimate for Bengal (Ind. Planter, Feb. 14, 1903) gives the cost of planting one bigha as Rs. 22–8–0, and the net profit—allowing 16 maunds of fresh turmeric to the acre) as Rs. 25–8–0. Banerjee (Agri. Cuttack, 1893, 102–3) speaks of Cuttack having three locally grown roots, collectively designated country turmeric, and one imported from the Tributary States known as kuarpuria. Of the local forms dhanna is most highly prized for its flavour, and like the gangakuria is long in shape, while the hadua is round. The last mentioned is strongly flavoured and discarded for cooking purposes. The kuarpuria is said to be often left in the fields for five years before being dug up, and is sometimes manured with buffalo-blood. Mukerji says the outturn of turmeric boiled and dried comes to about 16 maunds per acre and of fresh ginger about 50 maunds, but as much as 150 maunds have been sometimes obtained.

2. United Provinces.—In these provinces the crop is very extensively cultivated in Kumaon and Garhwal and constitutes an important article of export from the lower hills. It is grown in jungles where nothing else can be raised, as well as in the open Duns and Bhabar. It is planted in April–May and gathered in November. The cost of cultivation is calculated in Kumaon at Rs. 36 per acre, the crop being worth Rs. 75. In the Cawnpore district it is grown with ghuián (Colocasia antiquorum) and requires abundant irrigation. It is planted in June and gathered in January, the yield being 2,000 lb. fresh roots to the acre.

3. Panjab.—Turmeric is not often cultivated in this province, though in the Kangra district it is considered quite as remunerative as sugar-cane, and in addition only occupies the soil six months (May–June to October–November). It requires much care and a liberal supply of manure.

4. Bombay.—Mollison (I.C. 186) observes that there are two forms, the hard, highly coloured rhizome, used as a dye, and the large, soft, pale-coloured edible root. Turmeric, he says, does best in the medium black soil of the Deccan, especially where naturally well drained. In Gujarat, on garden lands, it is rotated with sugar-cane, ginger, onions, garlic, etc., or (as a subordinate crop) with ginger. Where mixed with yams it is the chief crop, and about 1,800 to 2,000 lb. of turmeric with 600 to 700 lb. of yams are required to plant an acre. If planted in May the crop may be collected in December–February, but neither the turmeric nor the yams are damaged by being left in the field after maturity till convenient, since in the Bombay Presidency turmeric enjoys a practical immunity from disease. Two crop-tests (1896) in Surat, of mixed turmeric and yam, gave an average to the acre of 14,200 lb. (127 cwt.) of green turmeric, worth about Rs. 1 per 60 lb., and the cost of cultivation per acre Rs. 159–8–0, thus leaving a net profit of about Rs. 77 an acre, with the yams over and above.

5. Madras.—In Coimbatore it is said that turmeric is grown with yams, maize, castor, brinjal, etc., the rhizomes being planted on ridges in June–July and dug up in March–April. As a rule turmeric is not grown more than once in three years and is followed by râjâ and paddi. The cost of cultivation seems to be about Rs. 116 per acre and the produce from 3,000 to 5,000 lb. of prepared turmeric (value Rs. 120 to Rs. 200) and of yams 6,250 lb. (value about Rs. 200), but the actual yield of each crop

446
PREPARATION OF THE RHIZOME

When grown together is probably much less. Of North Arcot, A. F. Cox (Man. N. Arcot, 1895, i., 276-7) says that the plant occupies the ground for nearly a year. Ten maunds are sown to an acre and the yield is about 200 maunds. When prepared as a condiment the root is called kari manjal (Tamil) and sara pasupu (Telegu), and when prepared as a dye it is saya manjal and saya pasupu. Buchanan-Hamilton (Journ. Mysore, etc., 1807, i., 328-9; ii., 450, 469; iii., 85-6) gives a full account of the cultivation witnessed by him.

The above review has been deemed desirable since no single person has studied province by province the production and yield of turmeric. It may have been observed that the yield per acre and the duration of the crop are matters of the greatest obscurity. This seems due to various sources of error: it is often a mixed crop; the returns are given in maunds, a measure that may vary from 82 to 25 lb.; it is often not possible to discover whether the figures mentioned refer to dry or green tubers; and lastly, ignorance regarding the races of plant grown. It is difficult to believe that soil or difference in methods of cultivation could account for a range of from 15 to 262 cwt. per acre.

Preparation of the Rhizome.—Various systems of preparing the rhizomes for market appear to be in vogue. In Bengal they are cleaned, stripped of the fibrous roots and heated gradually in earthen pots, the mouths of which are carefully closed by lids fastened with cowdung. The rhizomes are thus stewed in their own juice and freed thereby of the raw smell. Afterwards they are dried in the sun, for nearly a week, being protected at night from dew. In some localities (especially Madras) the rhizomes are boiled in water, to which a little cowdung has been directly added, this practice being believed to protect the tubers against insects. In the United Provinces the bazár-turmeric is prepared by boiling and drying in the sun. In the Kumaon district the prepared roots are soaked in lime-juice and water instead of being boiled anew. In the Panjáb the drying is done by artificial heat.

Uses of the Turmeric.—When intended to be used as a dye the rhizomes are boiled a second time, powdered while still wet, and a decoction made of this paste with water. The history and properties of turmeric Dye have been very fully dealt with in the Dictionary and it is unnecessary to repeat the details here, though desirable perhaps to invite attention to recent publications. Formerly turmeric dye was very largely used in India at marriage ceremonies, etc., but this practice has considerably declined of late. On ceremonial occasions it was also largely employed to rub on the skin, and is so used to this day. [Cf. N. N. Banerjei, Monog. Dyes Beng., 1896, 15-6.] The dye is cheap, easily prepared and easily removed, but these conditions are also even more characteristic of aniline dyes, which consequently largely replace the old vegetable dyes. The principal use of the dye in India at the present day is as an auxiliary to such other dyes as al-dye (Morinda tinctoria), safflower (Carthamus), lac dye (Tachardia), etc., etc., and in the production of shades of green along with indigo. It is still fairly largely employed in calico-printing and in the coloring of Native-made paper. In Bengal it is extensively employed in dyeing cotton clothes, toys and other articles of sola pith (Eschynomene aspera, pp. 29-30). In the United Provinces it is said to be more commonly used as a condiment than as a dye, and is as a rule grown along with Colocasia antiquorum (Hadi, Monog. Dyes, U. Prov., 1896, 77).
Mordants are rarely required with turmeric since the dye attaches itself readily to wool, silk or cotton. Calcutta dyers, however, obtain a brilliant yellow by mixing turmeric with \textit{sajji matti} (carbonate of soda, p. 51). The use of borax (see p. 172) in Kumaon is dependent on an important chemical feature of the dye. The dye is fleeting, but Fawcett (\textit{Monog. Dyes, Bomb.}, 1896, 16) says that the colour can be made more or less fast by adding to the alum solution a preparation of pomegranate rind. The use of vegetable acids to clear dyes is common all over India, and these are often spoken of as making them permanent, though that is not so. Thus, for example, Duncan (\textit{Monog. Dyes Assam}, 1896, 22–3) observes that in Cachar a light yellow dye is produced by boiling turmeric with a \textit{“sour lemon-like fruit called \textit{thaikar}.”} Alkalis deepen the colour, making it almost red, while alum purifies it. For this reason a common test in India for alkalis is paper saturated with an alcoholic solution of turmeric. The action of the alkalis turns the paper brown. In Europe turmeric is still employed in dyeing compound shades of wool, usually in conjunction with \textit{orchil} (a purple lichen-dye from \textit{Roccella tinctoria}) and indigo extract. It is rarely used on silk (Rawson, Gardner and Laycock, \textit{Dict. Dyes, etc.}, 1901, 339). Lastly, turmeric is said to be employed in the adulteration of mustard and to colour varnishes. For the uses of turmeric in \textit{Medicine} the reader is referred to the \textit{Dictionary or to the Pharmacographia Indica}, (iii., 407–14), where also will be found a long discussion of the Indian ceremonial utilizations of the dye. As a \textit{Food} adjunct turmeric is chiefly employed in curries, of which it is an indispensable ingredient, and in colouring food-stuffs, etc. The leaves are used as a condiment, especially with fish, which are wrapped up in them and then fried.

The reader will find much useful information regarding commercial turmeric in Hanausek's \textit{Microscopy of Technical Products} (Winton and Barber, transl., 1907, 262–6), the appearance under the microscope of the various grades, their adulterants, and methods of examination of the same being fully exemplified.

\textbf{Production and Trade.}—Recent returns do not show the total area under this crop. Mollison speaks of 5,300 acres as the Bombay portion in 1898, and the official statistics for 1905–6 show the area to have been 5,581 acres, of which 4,414 acres were in Satara district alone. Some years ago the total for all India was estimated at 56,500 acres, but the extensive use of the tuber and the remunerative character of the crop would suggest that the total Indian acreage may be considerably larger than that mentioned, though, as stated, it is impossible to furnish the exact acreage.

The exports of turmeric to foreign countries show considerable fluctuations. Milburn (\textit{Or. Comm.}, ii., 542–3) gives the imports into England by the East India Company in 1805 as having been 422 cwt., valued at £1,052, and the duty £2 16s. per cwt. The \textbf{Exports} from India amounted in 1899–1900 to 48,000 cwt., valued at Rs. 5,78,199. In 1901–2 the figures were 82,436 cwt. and Rs. 9,40,215; in the following year they rose again to 126,076 cwt. and Rs. 9,87,577; but sank in 1903–4 to 68,234 cwt. and Rs. 4,52,653; in 1906–7 to 62,246 cwt. and Rs. 7,08,967. The bulk of the trade goes to the United Kingdom, the Straits Settlements, Aden, the Ceylon, Germany, Arabia, Persia and Turkey-in-Asia. Of the foreign traffic Bombay contributed 33,477 cwt. in 1906–7; Madras 16,231; and Bengal 11,988, but ordinarily Madras supplies more than Bombay. The total amount of turmeric exported coastwise in 1903–4 was 21,448 cwt.
was 121,540 cwt., valued at Rs. 9,15,556, of which Bengal took 53,308 cwt. and Bombay 43,661 cwt.; the coastwise exports, however, have since fallen to 63,122 cwt. in 1905-6. The Bengal supply came from Madras and the Bombay from ports within its own presidency. Madras is thus the presidency most concerned in the external supply, and Bengal the most dependent of all Indian provinces on external production. The total traffic by rail and river was in 1906-7, 641,662 cwt., against 526,009 cwt. in 1904-5. The chief distributing provinces are usually Madras, Bombay and Bengal, and of the ports, Calcutta followed by Bombay are those most concerned. But the rail-borne traffic from Calcutta is a direct consequence of the large receipts by sea from Madras.

With regard to commercial qualities, Semler (Trop. Agrik., 1900, ii, 639) says that the best turmeric is considered to be the Chinese, especially Formosan; the next the Indian, produced in Bengal, Pegu, and Madras; whilst Bombay and Sind afford the worst qualities. As a rule turmeric is sold in Europe in powder-form, but if the solid be desired, the rhizome-fingers should be chosen big, hard, heavy and difficult to break, deep-coloured, with warm aromatic taste and a distinct aromatic effluvia. In these directions for selection, Semler practically repeats the advice given by Milburn in 1813 (l.c. 542), but it is possible they are quite applicable to the modern trade. The price on the European markets varies from 12s. to 26s. per cwt.

CYAMOPSIS PSORALIIOIDES, DC.; Fl. Br. Ind., ii., 92; Duthie and Fuller, Field and Garden Crops, pt. ii., 24-5, pl. xxxv; Church, Food-Grains of Ind., 124; Mollison, Textbook Ind. Agri., iii., 84-5; Duthie, Fl. Upper Gang. Plain, i., 247-8; Cooke, Fl. Pres. Bomb., i., 308; Leguminosae. The Cluster-bean, guár, gauri, guvar, kowára, kauri, kachkur, húrti, daráhí, mutki, buru ráher, pai-páoon. A robust annual pulse cultivated in many parts of India from the Himalaya to the Western Peninsula, and never found truly wild in any part of India.

Mollison mentions three forms met with in Kaira and Baroda Territory, viz. (1) párdeshi, sown sparsely amongst khairí cereals; (2) sotía guvár, growing eight to ten feet high and sown extensively in Gujarat. It is raised as a shade plant to ginger and the leaves are left on the ground as green manure; in the garden lands of Surat it is grown with cucumbers, being planted in May and irrigated till the rains. The pods are used as a vegetable and served like French beans; (3) deshi, the common form, with violet seeds, sown as an ordinary dry crop and extensively used as cattle-fodder. Duthie and Fuller mention a form known as deoband kowára, which is often cultivated in the United Provinces as a hedge or shade plant: They observe also that when the plant is cultivated as a vegetable it is grown on highly manured land near villages, but when raised for cattle-fodder it is cultivated on light sandy soils. It is sown at the commencement of the rains and cut in October. The average yield of dry pulse is about 10 maunds to the acre. Guvár is specially suitable as a green manure or green fodder crop owing to the amount of nitrogen it contains and its comparative freedom (when young) from fibre. Church gives the nutrient ratio

of the dry beans as 1:1.7, and the nutrient value 79. In certain districts, such as Meerut, where this plant is regularly and largely grown as cattle food, the breed of animals met with is remarkably fine—a high testimony to the care taken of them.

D.E.P.,

1., 244-52.

I have decided to retain *Cymbopogon* as a separate genus instead of placing it under *Andropogon*, but I confess to being influenced more by industrial than botanical considerations. While engaged writing the brief account that follows, of the Indian economic species, certain specimens were received at Kew, which necessitated a re-examination of the genus or rather the sub-genus *Cymbopogon*. Dr. O. Stapf entered on this study energetically, and his report which has since appeared deals with the botanical aspects more thoroughly than can be attempted in this work. He has, however, most obligingly permitted me to consult him freely, and has done me the favour to read through the brief abstract of the subject here given, and to offer useful suggestions. It may be said that the practical result of his studies is the definite establishment botanically of the plant that yields the Lemon-grass Oil of India as distinct from the Citronella Oil of Ceylon.

The present may be described as a genus of grasses that contains some forty species, widely dispersed in the tropics, principally of the Old World, rare in the temperate regions, as also in America. The species that are of chief economic value are aromatic, but it would almost seem as if that property had been acquired, or rather was dependent on environment for its existence or its intensity. There are four essential oils recognised by the chemist and in trade. These are Palmarosa (Rusa), Citronella, Lemon-grass, and Ginger-grass Oils. While that is so, a few writers have affirmed that these are not necessarily the produce of separate plants, but may be a consequence of climate and soil or of methods of cultivation and seasons of collection, or systems of preparation if not even degrees of adulteration. It is certainly the case that a species or variety that will yield the oil for which it is noted in one region, may not do so (or only to a very small extent) in another. But while environment doubtless exercises a powerful influence, it seems certain that the properties recognised by the chemist can alone be secured by the cultivation of particular forms that are known to yield these. It accordingly follows that the selection of stock with this (as with all other cultivated plants) becomes a question of supreme importance. In India one or more species of *Cymbopogon* occur from the extreme north in Afghanistan, Baltistan, Tibet and Sikkim, to the extreme south at Cape Comorin. And what is more surprising, some of the forms are dispersed from the tropical plains to the temperate alps. One exists in the vegetable gardens of the well-to-do from one end of India to the other (a few roots, at most, in each garden), the leaves being plucked and used in cookery (Firminger, *Man. Gard. Ind.*, 322). That particular plant appears, however, to flower very rarely, and it has accordingly not as yet been satisfactorily described. In the *Dictionary* I assumed, as others had done, that *Andropogon citratus*, DC, might be the Indian garden plant. The name *citratus* suited its properties and popular reputation. De Candolle has nowhere, however, described the plant to which he gave that name, but Nees (*Allg. Gartenzeit.*, 1835, 265) accepted *A. citratus*, DC. Recently a fairly extended cultivation of what is spoken of as Lemon Grass has taken place in Travancore and Cochin. The oil obtained from that plant has been pronounced different from and very much superior to either the citronella of Ceylon or the rusa of the Decan. The rapidly expanding trade in this Cochin oil has caused an inquiry to be instituted with a view to extending its cultivation in the West Indies. The oft-repeated statement that it exists in India both "wild and cultivated" is, however, distinctly misleading. In Ceylon *C. nutans* might be spoken of as systematically cultivated, but there is no production of it in India for commercial purposes.
C. Martini, Stapf, l.c. 335-41, 359-60; Andropogon Martini, Roxb., and the A. Schenianthus of most recent authors, but not of Linnaeus; Fl. Br. Ind., vii., 204-5.

This is the Rusa Oil plant of Northern, Western and Central India, which in European commerce has received various names, such as "Palmarosa," "East Indian Geranium," or simply "Indian-grass Oil," "Nimai Oil," etc., etc., the inferior qualities being sometimes returned as "Ginger-grass Oil." The vernacular names are numerous, but since it seems probable that no form of C. Nardus exists as an abundant wild plant on the plains and lower hills of the region where the rusa oil is mainly produced, the names given in that country must be viewed as denoting the present species, except where they may embrace one or other of the forms of C. Schenianthus as well. In South India wild forms of both C. Nardus and C. Schenianthus are met with abundantly, and the vernacular names for the grass oils of that portion of India hopelessly confuse the species. It has been suggested that the most general name "rusa" or "rusa-katel" (abbreviated into "rosel") and rose oil is in reality a corruption from "rose," seeing that the most important use of the oil is the adulteration or fabrication of rose oil. But as opposed to that view it may be mentioned that until very recently (if not even to-day) the people of India were not aware that the oil they sell goes mainly to Turkey to be used in admixture with rose oil. The most general names are—rusa, rosa, rauns, rhausa, rhauns, roima, rosha-yavat, rohish, also gundhabena, mirchiagand, mircha, makara, gandi, panni, chipara bhor, tikhari, tikadi-moti, etc. According to Dutt (Mat. Med. Hind., 271) and the authors of the Pharmacographia Indica (l.c. 557), it is bhustrina, bhutrina or Earth-grass of the Raja Nirghanta and is the rohisha of the Sanskrit authors and the surosa—the "well flavoured," and the su-gandha—the "agreeable odour," of recent classical writers.

Varieties and Races. It is a perennial grass plentiful throughout the warmer tracts of India. There is no very direct evidence, however, of its being anywhere cultivated, though certain tracts of country are more or less protected and regularly leased out for the supply of the grass employed in the manufacture of the oil. There are six varieties of the species, described in the Flora of British India, two of which are Burmese plants not apparently utilised industrially, and a third would appear to be unimportant. Stapf has raised to specific rank the following of these varieties; but while the first mentioned affords the true rusa oil, the others may be and in some instances have been used apparently for the same purpose:

This is the plant collected by General Martin in Ballaghut, Mysore, in 1791-2 and cultivated by him afterwards at Lucknow. There are specimens of it in the Kew Herbarium from Kashmir, Panjáb hills, Simla, Almorah, Garhwal, Nepal, also the Black Mountains, etc.; of Bengal from Rajmahal and Singhbum; of the Central Provinces, from Chanda district; from Bombay; from Rajputana; and lastly from South India.

(b) C. cespitum, Stapf; A. cespitum, Nees (in part). The majority of the specimens of this form seen by me in the Kew Herbarium came from South India. It is evidently the plant of which Herbert de Jager wrote, in 1683, that he found whole fields fragrant with it when travelling in Coromandel, and of which he found the people of Golconda preparing a perfume.

(c) C. polynuro, Stapf; A. versicolor, Nees, in Wight, Cat. n. 1705; Lisboa, l.c. iv., 120; 1891, vi., 65; A. polynuro, Steud. A South Indian plant,
but mention is made of its having been procured from the Central Provinces, and of its existing in Ceylon. A specimen was sent from the Botanic Gardens, Nilgiri hills, with a label bearing the following remark:—"Wild on the grassy hills about Ootacamund and from which species the oil, shown as specimen No. 98, was obtained in Feb. 1902."

According to Forsyth (1827) the best rusa oil is obtained from the first few cuttings, and an inferior oil from the second crop of the plant. The authors of the Pharmacographia Indica (1893, 558) say the grass is called motiya when young and of a bluish colour, and soufiya when old and red-coloured. This view was also advanced by Lisboa, who speaks of the change from the bluish-green to the red inflorescence as a characteristic feature of the autumn in the country where the grass is at all abundant. It would thus seem that certain authors often uphold the opinion that the variety cassinus is but the autumn condition of the variety Martini, or perhaps rather that cassinus is the less robust condition found on dry soils as well as the autumn growth of Martini. In part support of that view I would point out that while many writers, including the original discoverer of the plant, speak of it as found on the dry hillsides, others repudiate that statement and say it is met with only in low-lying dumpy or marshy soils (Ind. For., 1901, xxvii., 602). On the other hand, the strict botanical view of the above varieties is supported by the author of the Khandesh Gazetteer (1880, 23), who says there are two forms which grow freely at Akrami, the one with bluish flowers, called sophia, the other with white flowers, called motia; the oil from the last fetches the higher price. Duthe had two specimens sent to him by a correspondent in the Central Provinces, who strongly maintained that they were two distinct plants.

Reasoning back from the chemical results, it would seem as if the varied qualities of rusa oil might all be obtained from one or from more than one variety of C. Martini, but that C. Nardus, while it yields the varying qualities of citronella oil, is not capable of yielding rusa oil as well. The assumption that the South Indian cultivators are producing lemon-grass oil from the same plant as that from which they have recently begun to produce palmarosa (rusa) oil is, therefore, not correct. And what is even more to the point, the reputation of their lemon-grass oil, as rich in citral, will be destroyed should they take to mixing it with rusa. These both afford geraniol, the perfume for which they are valued by the soap manufacturers. [Cf. Gildemeister and Hoffmann, Volatile Oils, 132.]

To the promising new industry in lemon-grass oil, definite knowledge regarding the individual properties of the plants grown may be said to prepare the way for more rational efforts in production. As already stated, it is essential to enforce recognition of four distinct oils—Citronella, Lemon, Rusa and Ginger-grass, with varying qualities of each, and in consequence to recognise four distinct plants as affording these oils. The present species is that which yields:—

**RUSA OIL.—Central Provinces.** The industry of preparing this oil, so far as can be discovered, is a comparatively modern one. No mention is made, in the list of court perfumes used by the Emperor Akbar in 1590, of any form of grass-oil. [Cf. A'in-i-Akbari (Blochmann, transl.), 57.] The oldest detailed account of Indian rusa would seem to be that written by Forsyth (Trans. Med. and Phys. Soc. Calc., 1827, iii., 213–8) regarding the district of Nimar (Nemaur) of the Central Provinces—hence the trade name of Nimar oil. The grass, he says, is met with in frequent distinct patches in the greatest abundance along the foot of the Vindhya hills in the vicinity of Gauin Ghat, and thirty miles farther west on the tableland of the same range near Nalcha, at which places only he believed it to be prepared to any appreciable extent. By about the latter end of August it begins to bud, and continues to flower in tolerable vigour till the end of October, during which period alone it gives out the oil in sufficient quantity to cover expense and trouble of preparation.

The oil is obtained by distillation. A wrought-iron boiler is fitted over an earthen fireplace and surrounded with a head from which two straight tubes, from five to six feet in length and two inches in diameter, conduct the vapour into a couple of large copper receivers immersed in

Bombay. Khandesh Oil.

Bombay.—The production of this oil was fostered by the Muhammadan rulers of the Deccan, hence Khandesh oil came to be more spoken of than that of Nimar. Some writers in Europe would appear to have thought Nimar and Khandesh were one and the same place. [Cf. Sawer, Odorography, 46.] Speaking of the Khandesh industry, the Gazetteer affords useful particulars. It would seem that the original seat of the industry in that province was Pimplarner, but the manufacture has spread to Nandurbar, Shahada and Taloda. The makers are Muhammadans, who, at the close of the rains (about September), as the grass is maturing, buy it from the Bhils, stack it, and set furnaces on the banks of the brooks where wood and water are plentiful. The distillation pursued is in all essential points the same as that of Nimar, except that when the cauldron which serves as a condenser begins to vibrate, it is removed from the stream, emptied and refixed. The fluid from the condenser is stirred until the oil begins to form. To make very strong oil, the contents of the condenser are redistilled; the oil which forms on the surface is then skimmed off and the distillate used as the water for a fresh charge of the still. The oil is packed in skins and sent over the Kundabari Pass to Surat or via Dhulia and Mammad to Bombay.

Berar.—While touring in Berar (Ellichpur district in 1894) I devoted some attention to the ru8a oil manufacture at Muktagiri. Four stills were found by me fitted into a furnace with their condensers submerged in a stream. The plant used was C. Martini, Stapf, found on the dry hilly slopes around the distillery. The crop had been cut and stacked, pending the termination of the rains. During the time of my visit in December it was being distilled. The flowering tops had been cut and tied into pulis or bundles, each containing from 60 to 80 stalks; five of these were tied into a larger bundle; 20 of these larger bundles were counted as 100. Into the boiler from 230 to 350 pulis were placed, and packed transversely. Over this was poured four kerosene tins of water. Each charge was said to yield 32 chatal, or one-fifth seer of oil. The dis-
PERFUME-YIELDING GRASSES

**CYMBOPOGN MARTINI**

**Rusa**

tillate (or fluid obtained from the condenser) was decanted on cooling, the water being allowed to strain off slowly, and thrown away, and thus not used a second time as in Khandesh. But before decanting, the owner skimmed off with a feather certain globules of oil that had formed on the surface. This was said to be the finest and most highly valued oil, and though troublesome it was profitable to remove it by itself even although only a few drops were obtained from each distillate. After the greater proportion of the water had been strained off, the mixed oil and water was placed in a clear glass bottle, and, the hand being held against the mouth, it was inverted. The water was then allowed to gradually escape, and the oil thus purified. It is at first dirty brown in colour, but clearer as it is kept. According to the estimate made by me on the spot, from the data furnished by the owner of the distillery, the cost of working each still, including labour, rent of land, hire of apparatus, etc., would be Rs. 1-12 and the net profit Rs. 1-10, even were the oil sold pure; but it is largely adulterated with kerosene oil. It is sold at about Rs. 9 a seer (2 lb.) I was told that Jamod, in Akola, had the best name of all the localities in Berar for its *rusa* oil.

**Madras.**—Mention has been made in the concluding remarks under *C. polyneuros* (above) of a new supply of what would appear palmarosa oil having been organised in South India. But let it be here repeated that Staßl regards that as a distinct species, and, therefore, very possibly the oil may have distinctive properties of its own, though classed in trade as a quality of *rusa* or in some cases of lemon-grass. The subject will be found dealt with more fully below under the trade of lemon-grass—*C. flexuosus*. Instead of being exported from Cochin along with the lemon-grass oil, this is conveyed to Bombay and shipped from there to Europe and America, in direct competition with the Khandesh and Nimar oils. This has so materially increased the supply that a serious decline in the price paid has taken place. Schimmel & Co. (*Semi-Ann. Rept.*, May 1904, 54) say, “The producing districts have been extended so largely, that it is difficult to arrive at a proper estimate of the market, and it is an extremely difficult matter whether to advise buying at present low prices or not.” “An excellent selection of qualities of so-called East Indian geranium and palmarosa oil of the last harvest is available, and is quoted lower than at almost any previous time.” It seems fairly certain that the increased production and high-class degree of oils offered is the direct result of the South Indian supply, and of the endeavours of the Forest Department in the Central Provinces.

**Properties and Uses of Rusa.**—According to Gildemeister and Hoffmann (*Volatile Oils*, 281-5, 433-4), the chemical examination of Rusa oil led to the discovery of *geranial*, which is present in good qualities to the extent of 76 to 93 per cent., the greater proportion in a free state. Of *citronella*, if present at all, there are traces only. It is thus an oil widely different from that obtained from *C. Narvia*, the citronella. It is a light-coloured oil, soluble in three or more parts of 70 per cent. alcohol. Its saponification number lies between 20° and 40°, but after acetylation between 230° and 270°. It is frequently adulterated with various fatty oils, as also with turpentine and kerosene, which latter lowers the specific gravity while the fatty oils raise it.

It is chiefly used for admixture with rose oil, and, since it does not solidify by cold, it prevents the crystallisation of the rose oil. Sawer
and others tell us that it is redistilled in Paris, and in Turkey is subjected to a special treatment which appears to render it more fit to mix with *attā* of roses without betraying its odour; this consists in shaking it with water acidulated with lemon-juice, and then exposing it to the sun and air. By this process it loses its penetrating after-smell and acquires a pale straw colour. This was originally explained by Mr. Baur of Constantinople. It may, in fact, be said that the traffic in *palmarosa* oil is very nearly entirely for the production of cheap *attā* of roses, and hence purchasers of that article require to deal with firms that will give a guarantee of its purity, should they desire to possess the expensive *attā* of roses. [Cf. Gildemeister and Hoffmann, l.c. 433–5.]

**Indian Trade in Rusa.**—It has already been stated that the traffic in this oil is mainly to Europe and from Bombay. Formerly it was shipped to Red Sea ports and conveyed by land-routes, mostly via Cairo to Constantinople and thence to Europe. Hence it came to bear the absurd name (now happily discontinued) of “Turkish Geranium Oil.” It is nowadays shipped direct from Bombay to Europe, but in Bombay it is assorted and deposited within large tins or copper vessels of 100 to 200 lb. capacity. These are surrounded by a network of ropes, but are not placed within boxes. It has been estimated by Mr. Bhote and others that the annual exports from Bombay come to something like 50,000 lb. In the modern trade Ellichi pur in Berar has become one of the chief towns of Northern India, from which Bombay draws its supplies. But that estimate must very possibly refer to the produce of Bombay and the Central Provinces alone, since the actual exports in 1902–3 were returned at 125,595 lb. The difference is possibly a direct evidence of the immense supplies being nowadays derived from South India. Of these exports, France, Germany, the United Kingdom and the United States are the receiving countries, mentioned in order of importance.

The value of the essential oils exported from Bombay (chiefly *rusa* oil) was returned as follows:—1899–1900, Rs. 2,78,005; 1900–1, Rs. 3,41,670; 1901–2, Rs. 6,10,783; 1903–4, Rs. 5,38,774; 1906–7, Rs. 3,19,949. At the prices presently ruling, *palmarosa* oil is sold wholesale at 3s. 9½d. a pound, and ginger-grass oil at 2s. 3d.

As recognised by modern botanists this is a protean species, since it has been made to embrace some ten varieites. Stapf has, however, come to the conclusion that it is perhaps more expedient to treat the following as distinct forms: **C. Nardus**, Rendle, *C. confertiflorus*, Stapf, *C. flexuosus*, Stapf, and *C. citratus*, Stapf. For the purpose of this work it would seem sufficient to group them together, treating the first as more especially the commercial plant. Thus constituted it occurs throughout the hotter parts of India, Burma, the Malay Peninsula and Ceylon, and is distributed to tropical Asia, Africa and Australia. But it would almost seem as if some at least of the better-known oil-yielding forms had (as cultivated plants) originated in the Malaya, since even in Ceylon citronella is admitted to be different from the undoubted indigenous stock. In India no form of *C. Nardus* (other than the allied *C. citratus*) existed until quite recently in a state of systematic cultivation. In any
effort at extended production it would, therefore, seem essential that separate attention be given to the forms of this and the allied species as established by Stapf, namely:

(a) C. Nardus proper. The Citronella Grass. The first definite account of this grass would appear to be that given by Grimmius (Laborat. Zeylon.), an author who died in 1711 but who mentions the oil made from citronella. Stapf remarks that he is unable to distinguish the different kinds of Ceylon citronella, but in his opinion all the cultivated races have been derived from C. confertiflorum. Stapf.

This is the pangiri maana grass of Ceylon, and is there only known in cultivation. It now seems possible that many of the vernacular names given in the Dictionary under this species belong in reality either to the plant given below as C. flexuosus or to one or other of the forms of C. Martini. The present plant does not appear to have been known to the Sanskrit, Arabic or Persian 'medical' writers. It owes the botanical name Nardus very possibly to a confusion. Linnaeus assumed (Mat. Med., n. 32) that it was the nard of India; it was early known in Europe as spica indica or spigo nardo. But it is surprising that there is no very distinct early record of the wild plant having been systematically distilled in South India as C. Martini is in the North, although it is probable that Ainslie may be alluding to it, since botanically the cultivated stock would appear to have been derived from a plant that is wild in South India.

**CITRONELLA Cultivation in Ceylon.**—It is cultivated chiefly in Ceylon and Malacca. Winter (Chem. and Drugg., lii., 646)—one of the largest distillers of citronella oil—says there are two varieties. These are (1) a form known as lana batu, which appeared naturally in 1885; and (2) another, known as maha pangiri, which represents the older stock—a more delicate plant than (1). There is no specimen in the Kew Herbarium specially labelled as maha pangiri, but there is one of lana batu. This is C. Nardus proper, but it is attacked by a form of Ustilago or Smut—a parasitic fungus—that lives within the tissues of the plant throughout its life, and may thus possibly influence materially the yield of the essential oil. This might (if so desired) be completely eradicated by the seed being previously washed in water at a temperature of 120°F. In the Administration Report of the Royal Botanic Gardens, Ceylon, for 1903, mention is made of the appearance of Ergot (Claviceps) as a disease on the maana grass.

It is said that the lana batu is the most widely distributed form of this species and can be produced on soils of a much poorer quality than those required for the maha pangiri. The plantation once established needs little attention further than to cut the shoots systematically so as to prevent flowering. There are two seasons, the first and principal in July and August; the second from December to February. The yield averages from 16 to 20 bottles (according to some writers 22 to 28 lb.) per acre for the first crop, and 5 to 10 bottles (7 to 14 lb.) for the second. But with age the plant yields less and less, so that by fifteen years the plantation has to be renewed. The yield also varies greatly with seasonal conditions. In the Ceylon report above mentioned particulars will be found of test experiments on the yield of different forms of the plant, as also different seasons of collection. The variability will be seen to be remarkable, especially the lower yield of the indigenous as compared with the introduced and cultivated forms.

In Ceylon the distillation is accomplished by direct steam without the addition of water to the grass. A charge of dry grass is distilled in about six hours, and the exhausted grass, after being dried in the sun, is used as the fuel for the works. Citronella is the principal bearer of the citronella
odour. The *lana batu* variety yields an oil that contains *citronellal* (28.2 per cent.), is relatively poor in *geraniol* (32.9 per cent.), affords methyl eugenol (8 per cent.), and has a high specific gravity. It constitutes the bulk of the citronella oil of commerce. The oil of *maha pangiri* contains 50.45 to 55.34 per cent. citronellal, 38.15 to 31.87 per cent. geraniol, and only 0.78 to 0.84 of methyl eugenol. The low percentage of the last-mentioned substance accounts for its low sp. gr. The *maha pangiri* is the first quality, and is often in trade called "Singapore Citronella," while the *lana batu* is the second quality. Citronella is mainly in demand by the soap manufacturers on account of its geraniol, one of the chief constituents of rose oil.

*Trade in Citronella.*—The traffic in this oil first attracted attention about 1887, when the exports from Ceylon were returned at 551,706 lb.; in 1890 they became 909,942 lb.; in 1895, 1,182,255 lb.; in 1900, 1,409,056 lb.; in 1901 they stood at 1,430,168 lb.; and recently (1902) suffered a serious decline to 1,294,750 lb.; and in 1903 still further to 1,062,594 lb. But the decline in the production has caused a satisfactory rise in the price from 9d. to 1s. 2d. per lb. Schimmel & Co. say the demand at present exceeds the supply, and that a decline in the price is inconceivable. The oil goes mainly to England, America, Germany and Australia. The industry centres chiefly in the southern parts of Ceylon, where there are said to be 50,000 acres under the crop, and over 600 stills at work. As compared with this the production in Singapore is reported hardly to exceed 30,000 lb., obtained from about 2,000 acres.

The Ceylon traffic has suffered, however, very greatly through adulteration with kerosene, fixed oils, and more recently alcohol, as also in consequence of overproduction. Of late the vigorous development of the cultivation in Java and the rise of the Travancore industry in lemon-grass oil are circumstances that have operated unfavourably on Ceylon production. Mr. Bamber (the Ceylon Government Chemist) has interested himself in this subject and has invented a process by which the adulteration of the oil that is being exported may be readily and effectively detected. Satisfactory endeavours are being made by the Ceylon Government to improve the methods of production and manufacture presently pursued by the Natives and to discountenance if not to check adulteration.

(b) *C. flexuosus*, Stapf. The Malabar or Cochin Grass. This is the Lemon-grass plant of Travancore. Stapf draws my attention to the fact that an excellent figure of this plant was given by Rheede (Hort. Mal., 1703, xii., 107, t. 57), who calls it *kodi-pullu*. It is the ginger-grass oil (*sukkanaru pullu*) of some writers, such as Ainslie (Mat. Med., ii., 401), spoken of as procured from the Courtallam hills and from Tinnevelly district. It has been distributed by Wight to herbarians under the name *A. flexuosus*, Nees (Staudel. Syn. Pl. Gram., 1855, 388).

**LEMON-GRASS OIL CULTIVATION.**—Very little of a definite and trustworthy nature has been published of the production of this grass as distinct from several others that are known to be grown. Every writer on the subject of the grass oils of India speaks of *Lemon-grass OIl* as being used by the Natives of India in the treatment of rheumatism and cholera. It seems fairly certain that these passages have little to justify their retention under the present plant except where they make exclusive reference to the extreme South of India, and especially to the Travancore and Malabar oil. [Cf. Gildemeister and Hoffmann, *Volatile Oils*, 1900, 285; Wiesner, *Die
PERFUME-YIELDING GRASSES

Cymbopogon Nardus

Lemon-grass Oil

Rohst. des Pflanzenr., 1903, ii., 577, etc.] But while the greatest possible obscurity has prevailed as to the botany of the Indian lemon-grass oil plant, the chemical identity of the oil has been fully established. It was first made known in 1888 that the most interesting feature of lemon-grass oil was the large percentage of Citral that it contained. This has been variously stated at from 70 to 80 per cent., and inferior or adulterated samples 40 to 50 per cent. It is employed in the manufacture of artificial perfumes such as the violet known as ionone, and like all the other grass oils is utilised mainly in perfuming soaps. The demand for lemon-grass oil has increased with surprising rapidity, and given to South India a new industry of considerable promise. The Travancore area may be described as the slopes of the mountains to the north of Anjengo, close to Quilon. It would now appear the plant is both wild and cultivated. The hill-sides are said to be fired in January to burn down the old and useless grass. Six months later the fresh crop is ready to be cut: by that time the countryside becomes dotted all over with furnaces and stills. During July, August, September and October operations are continuously maintained, but there would appear to be no second crop. Speaking of the more recent Cochin industry, various public newspapers have afforded a few particulars. Mention is made, for example, of Mr. Barton Wright having leased large tracts of lemon-grass land in Waluvanad and Ernad of Malabar and built a distillery on the most improved plan. The Moplahs are said to recognise twenty-seven forms of the wild plant, of which five only are of commercial value and one is cultivated and never flowers. The wild plants are of necessity forms allied to C. Nardus. Whether they all yield the same oil is doubtful, the more so since the allied form of C. Nardus all yield perfectly distinct oils.

Indian Trade in Lemon-grass Oil.—In recent returns we read of a new trade in rusa oil from South India to Bombay. As already explained, that is distilled from a wild plant, possibly C. Martini, var. polyneuros, and unless it be used as an adulterant is perfectly distinct from the lemon-grass. Schimmel & Co. (Semi-Ann. Rept., May 1903, 42), speaking of the lemon-grass oil, say, "It may be taken for granted that this new source of supply will in future form a strong competitor, and that the prices will permanently remain low, which would promote the consumption. At the present values the article will have all the more interest for the soap manufacturers, as the parcels which have appeared on the market were chiefly of such a fine quality as had not been met with last year." It would thus seem certain that the aromatic grasses of South India (like those of Ceylon) yield at least two perfectly distinct oils—rusa and lemon, and that the traffic in lemon-grass has become an important one. This may be indicated by the fact that the wholesale price has increased from about 2s. a pound in 1891 to 9s. 6d. (7½d. per ounce) in 1904. The chief commercial centre is said to be Trivandrum, and the exports are made from Cochin and Quilon. In 1891–2 these came to 1,450 cases, in 1896–7 to 3,000 cases; the subsequent years were as follows:—1899–1900, 2,792 cases; 1900–1, 1,933; 1901–2, 2,322 cases; and in 1902–3, 2,807 cases. But according to local reports the outturn of the last-mentioned year came to something like 5,000 cases, each containing twelve bottles of 24-oz. capacity. The statement is frequently made that the price paid for this oil has been forced up to an extent that greatly interferes with increasing demands.
LEMON-GRASS OIL

**CYMBOPOGON NARDUS**

Culinary Lemon-grass

(3) *C. citratus*, Stapf, Kew Bull., 1906, 322-30; Andropogon Schenauianthus, Linna. Syst. (10th ed.), 1759, 1904; Sp. Pl. note; Roxb., Fl. Ind., i., 274-5; Dailz. and Gibs., Fl. Bomb., 1861 (suppl.), 99; *A. citratus*, Trim. & Hook., Handb. Fl. Ceyl., v., 246; Ridley, Journ. Roy. As. Soc. (Straits Branch), 1891, 3. Lemon-grass of Indian vegetable gardens. This is the obi-cha, niti or liki-cha, hirva-cha (=green tea), vishanop-pulla or vishana-pilla, nimma-gaddi, áyya-gáh or agin gáh. The name cha (tea) is doubtless Chinese in origin but has been used in India for centuries, and indicates doubtless the use of the leaves as a flavouring ingredient with tea. The employment of such terms denotes, however, recent knowledge—or rather European knowledge of the grass. It is thus the edible lemon-grass or Indian verbena of Europeans.

Stapf informs me that he makes the *serch* of the kitchen gardens of the Malays, which is identical with the Lemon-grass of Singapore, correspond with the vegetable garden plant of India. It was probably first mentioned by Franc. Martinellus (1604), and the earliest unmistakable description of it was given by Eusebius Niemenberg (*Hist. Nat.*, 1635, lib. xv., ch. 19, 343), who called it *tanglaff*, a name still in use in the Philippines. It is next mentioned by Bontius (*Hist. Nat. et. Med. Ind. Or. in Piso, Ind. Uttri. re Nat. et Med.,* vi.), but Herbert de Jager in a letter to Rumphius, published by Valentini (*Hist. Simpl.*, 1732, 392), points out that Bontius was wrong, and that *Schenauianthus* does not grow in Java; Jager calls the plant *sirc*, and this is apparently the first occurrence of that name. Rumphius, in a letter to D. W. ten Rhyno, also employed the name *sirc* but added that it might be called the sterile Indian *Schenauianthus* in order to distinguish it from the Arabian (*Herb. Amb.*, v., 181, t. 72, f. 2). Sam Browne (*F. Ind. Pl. in. Phil. Trans.*, 1702, xxiii., 1251-2) remarked that this grass was in his day used by the Portuguese women at Fort St. George, but was little esteemed by the Natives. It was met with in gardens near the sea coast, and had been introduced from Batavia about 1660 A.D. Lemon-grass was conveyed to England by Sir Joseph Banks in 1786. Roxburgh gave *A. Schenauianthus* the Bengali name of *gandha-beni*, but the description and the drawing made by him leave little doubt that the plant in question was the present variety of *Nardus*.

**Culinary Lemon-grass.**—From the observations already made (see p. 450) it may be inferred that hitherto the very greatest possible obscurity has prevailed regarding the botanical sources of the lemon-grass oils of modern commerce. Before having seen Stapf’s interesting report I had written that if not a perfectly distinct species (for which the name *citratus* had been accepted in the *Dictionary* and might with advantage be continued), the present plant would prove one of the many races of *C. nardus*. Apart from the fact that there is a plant widely cultivated in Indian gardens which is generally designated lemon-grass (Lisboa, *Bomb. Grass.*, 1896, 87), and that a grass oil (named lemon-grass) is in South India obtained from a wild and apparently distinct plant (see *C. flexuosus* above), there is the still further surprising circumstance that the trade recognises “lemon-grass oil” as produced in Ceylon in addition to citronella. [Cf. Gildemeister and Hoffmann, *Volatile Oils*, 288-9; *Ann. Rept. Roy. Bot. Gard. Ceylon*, 1903, 15.] It would thus appear that the Ceylon planters have for some time been regularly growing the lemon-grass oil plant.

To obviate possible confusion between the edible lemon-grass of India (*C. citratus*) and the lemon-grass oil of Malabar (*C. flexuosus*), Stapf uses for the latter the name Malabar or Cochin grass. Unfortunately, however, lemon-grass oil is by no means exclusively obtained from Malabar, and “lemon-grass” is likely, therefore, to be continued to designate the oil in commerce, irrespective of the local Indian usage mentioned. But has it been proved that the lemon-grass (*C. citratus*) might not itself afford, or that it is not actually affording, an odorous oil? It is understood that the lemon-grass oil of Ceylon is less valuable than the lemon-grass oil of Travancore. But has it been definitely
CYMBOPOGN
NARDUS
Culinary Lemon-grass

proved that both these are obtained from one and the same species, the differences being climatic, not racial? In other words, has it been established beyond dispute that the peculiarities in the grades of lemon-grass oil denote the species of plants used? With such uncertainty it is perhaps permissible to think that at least some of the grades of lemon-grass oil are obtained from the culinary lemon-grass—the *oleum sinee* of Lochner (*Ephem. Acad. Nat. Cur. Cent.*, 1717, v–vi., app., 157); and if this be so the name must be retained.

The extraordinary anomaly is thus presented of an important plant, such as *C. citratus*, known possibly to a large number of the inhabitants of India and Ceylon, not having been systematically studied. This subject should, therefore, commend itself as worthy of attention to those who may have the opportunity of contributing either new material or fresh information.

Rumphius says the leaves were used in cooking fish and in flavouring wine, but he throws doubt on the roots being medicinal. In India as a whole (excluding the modern Travancore and Cochin industry) the CULINARY LEMON-GRASS does not appear to be distilled. Wallich (*Pl. As. Rar.*, 1832, iii., 48, t. 280) under the name *Andropogon Schemnuthus* gives an illustration of what is possibly a distinct species but which has by Hackel, followed by Hooker, been treated as *A. Nardus, Linn., var. grandis*, and with that East Himalayan plant Wallich has associated the economic information of the garden lemon-grass. He quotes, for example, from Fleming (*As. Res.*, 1810, xi., 156), who says, “Many Europeans with whom tea does not agree, use, instead of it, the infusion of this plant, to which they have given the name of lemon grass.” Dr. Wallich then adds, “Dr. Maton, one of the Vice-Presidents of the Linnean Society and Physician Extraordinary to the late Queen Charlotte, tells me that he has repeatedly been treated with a dish of lemon grass tea by Her Majesty, who used to be very fond of it, and was supplied with the plant from the Royal Gardens, Kew.” “There are few people,” Wallich concludes, “who have experienced the influence of an Indian climate, who have not found benefit from the wholesome and refreshing beverage prepared from this grass.” It might almost, however, be said of India, as it can certainly be said of England, that Queen Charlotte’s lemon tea has become completely forgotten. The lemon-grass is occasionally added to certain soups or used while cooking fish and curry, but as affording a refreshing beverage it is unknown to the people of India to-day.

Lastly, in this place mention may be made of Mrs. Lisboa (*Journ. Bomb. Nat. Hist. Soc.*, 1889, iv., 123) having figured and described a new species, viz. *Cymbopogon odoratus*, found wild at Lanowli, Poona, which is said to yield an oil “soft, sweet and more agreeable than that of *C. Martini*.” It is thus evident that even if *C. citratus* be excluded from consideration as an odoriferous oil-yielding species, there are very possibly several distinct plants that afford oils, many of which are treated as lemon-grass oils.

GINGER-GRASS

C. Schœnanthus, Spreng. According to Stapf (l.c. 303-13, 352) there are at least two fairly distinct plants commonly assigned by authors to Andropogon Schœnanthus, Linn. These are as follows:

Ginger-grass.—This is the Schoenus, Schœnanthus, or Squinanthus, and to some extent also the Juncus odoratus, etc., etc., of Greek and Roman writers, as also of most of the early writers on Materia Medica. An oil prepared from it would appear to be known as Ginger-grass. The Oriental names for the plant have been so much confused with the next species (if not with several other species) that it would be a bold step indeed to separate them and to affirm that izkhir (Arab.), gürgiyah (Persian) and bhustrina (Sansk.) denote this particular species and no other. It follows accordingly that the modern vernaculars of India cannot be arbitrarily separated. In fact it would perhaps be the safest course to call in the aid of geographical distribution and to assign the names in common use for perfume-yielding grasses in the respective areas where the spices abound, as being the names proper to these species. The present form, according to Stapf, is met with "from Morocco to the Panjab and Ladakh." "In the Panjab it is common in some of the desert tracts from Karachi to Peshawar and Ludhiana, growing on rocks, in sand or in hard loamy soil." The Indian vernacular names best known for it within that area are khavi and ghatyari.

It would appear that an oil is actually produced in the Panjab from this plant, though only very occasionally. In fact the reports that have appeared on the diversified properties of such oils are very possibly due to incorrect determinations of the plants concerned. In a few instances records of oil exist, however, that leave little room for doubt of having been actually obtained from the present species. Edgeworth (Journ. Linn. Soc., 1862, vi., 208) describes under the name Cymbopogon Ariana the plant met with in Multan—the country where the Malli resided in the time of Alexander the Great. Stapf has pointed out that on the label of one of his specimens Edgeworth wrote, "An essential oil expressed from the roots, manufactured only at Kasur in the Panjab." This, adds Stapf, "is probably the same kind of oil which Vigne records from Hassan Abdul (between Attok and Rawalpindi) with these words: "A stimulating oil is extracted and used in medicine." Mr. J. R. Drummond confirms Edgeworth's report by the information communicated to Stapf that a family of priests at Kasur produced this oil quite recently (see Rosa, p. 925).

It perhaps need hardly be reiterated that the oil in the above passages is spoken of as expressed from the roots, not from the leaves and shoots. The fact of there being a medicinal root, or rather two species of roots—the nard of the early explorers of India—known to all modern Indian medical writers is of great historic interest, and the botanical evidence would support belief that when dealing with the Western Panjab, Sind, Baluchistan and Persia, the plant in question may be accepted as C. Schœnanthus, Linn., but when dealing with the Eastern Panjab and the United Provinces, it is in all probability the species presently to be discussed, viz. C. Ivarancusa, Schult. (b) C. Ivarancusa, Schult., Mant., 1824, ii., 458; Nardus indicus, Blane, Phil. Trans., 1790, lxx., 234, t. 16, f. 1; Andropogon Ivarancusa, Jones, As. Res., 1795, iv., 109; A. Ivarancusa, Dierbach, Fl. Apiciana, 73; A. Ivarancusa, Roxb., 461
MEDICINAL GRASS

CYMBOPOGN
SCHENANTHUS
Medicinal Grass

Sweet-scented Medicinal Grass.—Of this plant—the Nardus indicus of early writers—Stapf observes that it occurs on the outer hill-zone of the United Provinces, Kumaon, Garhwal, and westward as far as Peshawar—mainly in the neighbourhood of watercourses. This is, therefore, a much more abundant Indian form than the preceding. It frequents, as a rule, colder and moister regions. But the name jwarankusa, which Stapf treats as Sanskrit, is so in derivation very probably, but was apparently never used by even the most recent of Sanskrit authors as the specific name for this or any other grass. Dutt (Mat. Med. Hind., 1900, 271) gives the Sanskrit name lamajjaka as denoting A. iwarancusa, Roxb.—the lamjak of Hindi and the karankusa of Bengali. But according to him, the A. Schenanthus (the bhustrina, Sanskrit, and ganda bena, Bengali) was the plant we now call C. citratus, so that the Sanskrit and vernacular names above very possibly denoted both C. Jwarancusa, Schult., and C. Schenanthus, Linn. [See Cyperus rotundus, p. 466.]

Duthie gives it the following vernacular names (some of which may, however, denote C. Schenanthus):—sirghurai, solada, bur, khair, gandhi, khawi, gander, runa, dalbulo, babhori, jaranunkush, azkhur, khavi, gandel—none can be said to be derived from its supposed Sanskrit name. Roxburgh, who rendered the name iwarancusa as unwarancusa, gives as its synonyms ibharankusha, ivarankusha, karankusha, and says these are Bengali, but makes no mention of Sanskrit names. So also Dutt accepts karankusa as Bengali, but does not give jwarankusa as a Sanskrit name. Moreover, Roxburgh very properly observes that as stated by Blane, the virtue of the plant resides entirely in the root. Duthie, speaking doubtless of this grass under Andropogon laniger, Desf., says it is one of the sweet-scented grasses, “the roots of which are sometimes used like khas-khas in the manufacture of tatties.” “As a fodder grass it does not rank high in regard to its nutritive qualities. It is, however, largely made use of by cattle when it is young and tender. Its scent is said to affect the flavour of their milk. It is often stacked and forms a useful supply in times of scarcity. Mr. Coldstream says that it will keep good in stock for upwards of ten or twelve years.” “The khair grass grows in hollows where water collects, and seems to prefer kallar, that cows graze upon it if hard pressed, but not otherwise; also that bár housewives use wisps of this grass to clean out vessels used for churning and holding milk.”

The perfume being chiefly resident in the root, not in the stems and leaves, justifies the association of the Nard (perhaps more C. Schenanthus than C. Jwarancusa) with the story of the Phoenician followers of the army of Alexander the Great in Lus and of the confusion that long existed regarding the spikenard of the ancients. This, doubtless, is the plant spoken of by Pliny and in more recent times by Garcia de Orta as found on the banks of the Ganges.

The preceding observations may be accepted as setting forth the separation of the two forms of Nard, both of which industrially have been treated as one plant. It has also been affirmed that the chief property of the plant is its sweetly scented roots. But apparently the leaves and shoots of one or other (or of a third species not separately recognised from them) yields by distillation an oil with slightly different properties from rusa. In some

Spikenard versus Nard.

Dub

Perfumed Oil.

Mixed with Rasa.

Ginger-grass Oil.

CREEPING PANIC GRASS

parts of the country the present plant is more sweetly perfumed than in others, as, for example, in the vicinity of Rawalpindi. Dutthie tells us that a "perfume is manufactured from it, and the aromatic oil is sometimes used as a cooling medicine." The authors of the Pharmacographia Indica (iii., 558) mention that in the time of the Tuhfat-ul-muminin (about 1669 A.D.) a distilled water was made from izkhir and apparently the oil of C. Martini was then unknown, if the name izkhir was not used indiscriminately for C. Martini and C. Schwananthus. Indeed it is believed that the variability of rasa oil may to some extent be due to this grass being mixed with C. Martini and both distilled together, or to the oil of the present plant having been mixed with that of rasa (palmarosa). In fact, according to most authors on essential oils, this is very possibly the chief source of some of the "ginger-grass oils" of commerce (Gildemeister and Hoffmann, Volatile Oils, 285). If pure it is valued at 2s. 3d. per lb. Schimmell & Co. say, "Our examinations have proved that it is a pure distillate deserving absolute confidence. Never has this oil been on the market in such fine quality as at present" (Semi-Ann. Rept., 1904, 44-8). Gildemeister and Hoffmann (l.c. 300) say it has the sp. gr. of 0.915 at 15° and its odour recalls that of elemi. It distils between 170° and 250°. The statement that an oil is not prepared from C. Juvaneseus would, therefore, appear incorrect. But the roots and lower stems which constituted the Schwananthus of the ancients would seem not to be collected in India to any material extent at the present time. Garcia de Orta (1563) was the first European writer to refer to that product in connection with India. He tells us that it came from Muscat, was known as "Herba de Mascat," and was used by the Portuguese in India, but not by the Natives. He makes no mention of any of the essential oils derived from this or the allied grasses.

But in spite of the fact that so great an authority as Sir William Jones repudiated hotly Blano's opinion that the Nardus of many authors was in reality C. Juvaneseus, I am strongly inclined to agree that a too literal acceptance of Jones' view may be misleading and has possibly in the past induced error. Pliny (Hist. Nat., bk. 12, ch. 12 (Holland, transl.), 364) says the "Nardus spreadeth in certain spikes and ears whereby it hath a twofold use both as a spike and as a leaf." Apicinus speaks of the spica indica being used in sauces and costly dishes, but this may have been C. citratus—the plant that I have spoken of as the edible lemon-grass. Paulus Aegineta (Adams, transl., iii., 265) derived his information mainly from Galen, who draws again on Dioscorides and speaks of it purely as a drug and ointment. It seems highly probable, therefore, that the Nardus of the ancients was different from the Jutamansi of the Sanskrit authors, though the plant known to botanists as Jutamansi doubtless is the spikenard. Garcia de Orta (Col., 1; also in Ball, Proc. Roy. Ir. Acad., 674), followed by most of the older Indian travellers, speaks of the Nardus as obtained from the plains of India, and can only be referring to one or two species of Cymbopogon, certainly not to the alpine Jutamansi.

CYNODON DACTYLON,

Lisboa says this grass is now generally spread in the settled parts of Australia, where it may have been introduced with cultivation. According to Vasey (Rept. Grasses U.S., 1883, 54-6, t. 59) it takes the place in the Southern States of the famous blue grass of the more northerly States of America. In India it is particularly abundant on roadsides and delights in an admixture of sand, gravel and ordinary soil, and is one of the first grasses to appear on the partial recovery of râh soils. It ascends from the plains to 8,000 feet in altitude, but varies in habit and nutritious qualities according to soil and climate. It readily propagated by cutting up the shoots and roots and spreading these over the surface of the

D.E.P., ii., 678-81.

Dúb-grass.

Propagation.
CYPERUS
BULBOSUS
Edible Tubers

Fodder.

prepared soil, or depositing them in furrows, each row of cuttings being covered over by the preparation of the next furrow or by hand dibbling the cuttings all over the field.

It is the commonest and most useful grass in India, since its stems and roots form a large proportion of the food of horses and cows; it has great fattening and milk-producing qualities. Makes good hay, which if carefully stacked will keep for years. Voelcker (Improv. Ind. Agrt., 175) says of dūb grass in India that "in many parts it comes up naturally or may be easily propagated from cuttings simply stuck in the ground. As a crop for irrigation it gives a great yield, and is about the only grass that keeps green in the hot weather. To one coming newly to the country it is surprising to notice how from an apparently burnt-up and dead surface a crop of fresh grass will spring up on the first fall of rain." According to the Madras Experimental Farm Manual, dūb, like most other meadow grasses, should be cut for hay directly the flowers appear, since under these circumstances the juices are more nutritious and the plant will produce another crop much sooner. The great object should be to retain the green colour of the grass by drying it as quickly as possible; two or at the most three days should suffice for making the hay, and if the hay are heavy it should be put into haycocks at night. The richness of the saccharine juices renders the hay more liable to heat and ferment, but excess in this direction may easily be checked by the ordinary methods of putting pipes from the centre to the outside of the stack, or building in two or three layers of dry paddy or cholam straw.

Cultivation.

It is necessary, however, to notice that C. bactryum, while very easy to grow, is very difficult to eradicate. In the Farm Rept. Bombay (1898–9, 6) it is said to be a persistent weed in black soil and to require deep hand-digging in the hot weather to destroy it. The plant is used medicinally and a cooling drink is said to be prepared from the roots. Dūb is also used fairly extensively in Hindu religious ceremonies, but it is necessary to distinguish carefully dūb, dāb, dab and dīb, which denote separate grasses.

Crop.

This genus of sedges contains some 60 Indian species. Most of these are fairly valuable fodder plants, especially when young, others are dangerous weeds of cultivated lands. A few yield culms and leaves that are employed in thatching and in grass-matting, and others afford tuberous rhizomes that are either eaten (especially in times of scarcity) or are collected and sold as perfumes or medicines. The greatest possible obscurity still prevails, however, as to the determination of the Indian economic species, so that it may for the purposes of the present work suffice to discuss them under two groups, those of value because of their tuberous roots and those with culms and leaves utilised in mat-making.

Medicine.

(A) Tuberous Rooted Forms:

This small sedge is often very plentiful in sandy situations, as for example in Sind and Baluchistan, the Upper Gangetic basin, the Deccan, Malabar, the Coromandel Coast and Ceylon. It is distributed to Arabia, Abyssinia, Central and North Africa. The characteristic (economic) feature of the plant is the tuberous rhizomes (often called bulbils) that it produces. These are not much larger than grains of rice, and since they are borne on long, thin, non-persistent shoots they are found in great abundance in the soil, free from each other and free from the parent plant. They are accordingly collected by sifting the sandy soil. They are encased in several easily separated scaly coats and, after the removal of these, are roasted and eaten or are soaked in water, washed, pounded into a flour, and baked into bread or cooked into puddings, etc. They have no aromatic property, and are strictly speaking edible not medicinal tubers.

464
AROMATIC TUBER

If the determination here suggested should prove correct, the Chinese would have to be accepted as having known the edible sedge from as early a date as can be shown for any other country. But it so closely resembles *C. rotundus* that it is highly probable the reputed discoveries of it in India and elsewhere are in some instances at least due to mistaken determinations. It has, however, been recorded as found in one or two localities in the Panjab and in the Nilgiri hills, but nowhere common. It thus no doubt exists in India, but until fresh investigations have been made it is perhaps desirable to leave the matter in this position. Repeated efforts have, however, been put forth (so it has been affirmed) to introduce the cultivation of this plant, but with absolute failure everywhere. The present species, therefore, contributes no known portion of the supply of edible *Cyperus* tubers in India. Of other countries it is reported the tubers are often roasted, then ground to a powder, and used in the preparation of **chufas** coffee or **chufas** chocolate. [Cf. R. Mus. Guide, 1895, No. 2, 59.]

Govt., Apr. 21, 1892; Pharmacog. Ind., iii., 552-3; Dewey, U.S. Dept. Agri., 1894, 1-4; Bretschneider, Bot. Sin., 1895, pt. iii., 126; Woodrow, Gard. in Ind., 1899, 547; also Fl. W. Ind., i.c. 431; Bull. Haarlem Mus. Pl., 1903, ii., 1145; Gage, Rec. Bot. Surv. Ind., iii., 112; also Prain, i.c. 303; Hosie, Rept. Ssu-ch'uan, China, 1904, 45. This is the *motha*, *mutha*, *batha-bijir*, *tandi sura*, *musta*, *sila*, *gundra*, *korai*, *koreki-jhar*, *bimbai*, etc. Bretschneider points out that the Chinese name for the odoriferous tubers of this species (which occurs in Buddhist books), namely *mu ts'ui ta*, comes from the Sanskrit *mustuka*.

This is a very troublesome weed of fields, gardens and waste lands, plentiful throughout India from the sea-level up to 6,000 feet in altitude. Its occurrence as an enemy of cultivation has been recorded in nearly every tropical country. The underground shoots that bear the economic rhizomes or tubers are persistent and become woody, the plant being in consequence difficult to eradicate. The best results at extermination have been attained by low shade and repeated moving down of the herbage. But *C. tuberosus*, Roth., is a plant so closely allied to it that the late Mr. C. B. Clarke informed me it might quite safely be viewed botanically as a variety of *C. rotundus*. Economically the two plants are identical, and are therefore treated here conjointly. One of them is possibly *C. pertennis* (or *nagar-moth*) of economic writers (Dutt, Dey, Dymock, Liotard, Buck, etc.), which yields an odoriferous medicinal root but is not *C. pertennis*, Roth., which by modern botanists is called *C. scariosus*. Dymock speaks of two kinds of *nagar-moth* met with in the Bombay markets, viz. Surat and Kathiawar. Gammie informs me of two kinds—a small tuber common in the Deccan, and a large one that does not extend beyond the heavy-rainfall zone of the Konkan and the Ghats. Clarke, who most kindly perused this article and made useful suggestions, asked the question—Could the medicinal root alluded to by Dymock and others be *Mariscus bulbosus*, C.B.C. ? *C. scariosus* has not at all events been recorded as found in Western India. Woodrow writes me that it does not occur in Western India as far as he knows. It is thus hardly likely to be the economic plant *C. pertennis*, Dymock.

The rhizomes of *C. rotundus*—*C. tuberosus*—are very much larger than those of *C. bulbosus*, are highly aromatic, and when mature are so woody that they could hardly be eaten. Ground into a powder, however, they are used medicinally, especially for external applications as a dep. They have been regarded as diaphoretic, stimulant and astringent. The Scythians are said to have em-

EDIBLE TUBERS

EDIBLE Fl. Prain, G. ^ Eleocharii. Parsi ii., Vegetable. Kaseru. Eaten, ROTUNDUS CYPERUS 685-6. Roxburgh’s to carried three vi., in are material obtained tunga, Nowgong of thon-tnyaung. to the Central Ki/noor Ceylon, HvirintH a the writer’s appear no writers, however, affirm that the tubers of C. rotundus and C. tuberosus are eaten, especially in times of scarcity and famine. They are, certainly, greedily eaten by pigs, and in famine times may therefore be eaten by men. But it would almost seem as if either of two conditions were necessary: — (a) that the tubers of certain localities or particular stages of growth are more palatable than the tubers described as medicinal, etc.; or (b) that some altogether different plant affords the edible tubers attributed to this sedge.

Throughout India an edible tuber bears very frequently the vernacular name kaseru; in fact it is mentioned in the Ait-i-Akbari. Roxburgh described Scirpus Kysoor as the keur, common in Bengal and growing on the borders of lakes, ponds, etc. It possesses, he says, tuberous roots, but curiously enough he makes no mention of these tubers being edible. Most Indian writers who mention C. rotundus as yielding edible roots, speak of the plant, to which they refer, as frequenting the margins of tanks (Beng. Offic. Corresp., i.e.). It would thus appear highly probable that the so-called edible tubers of C. rotundus of many writers may have to be transferred to Scirpus Kysoor, Roxb., which Clarke makes a variety of S. grossus, Linn. Gammie’s Note on Plants used for Food during Famine, etc., in Bombay, while it gives C. bulbosus, makes no mention of C. rotundus nor of C. tuberosus as having been eaten, but enumerates the following species of Scirpus as affording edible products: — (a) the bulbs of S. grossus, the kysoor or kachara, and (b) the seeds of S. maritimus, the chid (the miraj of Woodrow). In passing it may be added that so far as can be discovered Gammie’s allusion to the “ seeds” is the only record of the grain of a Scirpus being eaten. But thinking that Woodrow (formerly Professor of Botany at the Poona College of Science) was likely to be able to throw some light on this question, I asked for his views. His reply was briefly as follows:— “I found tubers in the markets, carried these off to Poona, and produced from them S. Kysoor. The tubers are globular in shape, like a marble, have a brown fibrous covering and inward are white, farinaceous with an agreeable flavour.” In a similar communication Gammie, the present Professor of Botany at Poona, informs me that the tubers of S. grossus are the favourite vegetable of the Parsis during the cold weather. The plant grows abundantly in the fresh-water tanks of the Konkan but not in the Deccan. Lastly, Mr. I. H. Burkhill writes me that the Calcutta supply of these edible tubers comes from Patna, Allahabad, Aligarh, etc. In Nowgong the plant is called ghogal; in Ganjam, santra; and in Pramo, myethon-myavung. Burkhill then adds that another cyperaceous root is edible. This is believed to be Eleocharis. It is known in the Santal country as chichoor, and in Central India (Tonk) it is kasuria. There can thus no longer be any doubt that S. Kysoor is at least one of the edible tubers of India. Hooper (Rept. Labor. Ind. Mus., 1906–7, 11) speaks of keshar tubers from Singapore, which it would appear are regularly imported and sold in the Calcutta market.

(B) Fibrous or Mat-making Forms:

4. C. corystosus, Roxb.; C. seminodus, Roxb., Fl. Ind., i., 187; Fl. Br. Ind., vi., 612. A glabrous rush-like sedge which often grows to the height of two or three feet. It is met. with from Kumaon to Assam and Burma, and is distributed to Ceylon, Africa and America. It is known in India as gol-methi, matha, godin tunga, kodu, kurrai, herhia, nwa-myat-yn. var. B. P. Pangori, C.B.C., is founded on a specimen furnished by Dr. Bidie from Timneckly, which had been originally obtained from Madagascar. This removes, therefore, any doubt regarding the material of the finer mats of that locality.

5. C. malaccensis, Lam.; C. gangeticus (MS.), incurvatus, Pangori and procerus, Roxburgh’s Fl. Ind., i., 203; Prain, Beng. Planta, ii., 1144; Fl. Br. Ind., vi., 608. A native of brackish mudbanks from Bengal to Sind and distributed to Singa-
GRASS-MATS

Prain and the Persian Gulf. It is in Bengal known as chumati pati, and apparently by popular writers has been much confused with *C. corymbosus*. Hance (*Journ. Nat. Hist.*, 1879, viii., 99-105) gives a most interesting account of the matting sails and floor-mats of China. The former are not exported, but the latter constitute an important item of traffic from Canton to the United States of America. Hance identified the plant as *C. tegeticiformis*, Roxb., but C. B. Clarke informed me that he regarded it as being more correctly *C. mutaceaetis*.

5. *C. tegeticiformis*, Roxb.; *C. nudus*, Roxb., *Fl. Ind.*, i., 209; *Fl. Br. Ind.*, vi., 612; Prain, *l.c.* 1144. This form is closely allied to *C. mutaceaetis*, and the two plants seem to have often been confused by economic writers. It is a native of Bengal (Central and Eastern—the Sundribans), Chittagong, Assam, Belundhur, and Madras, and is distributed to China and Japan. A tall glabrous rush-like sedge known as *gola-methi* or *sura*. D.E.P., *ii.*, 688.

6. *C. tegetum*, Roxb.; *Fl. Br. Ind.*, vi., 613; Prain, *l.c.* 1144; the Sedge or Grass-matting Plant of Calcutta, the mudar-kati, weeta, korai, mandri, yerkuti, etc. An extremely abundant and widespread sedge. It occurs throughout the plains and ascends the hills to 6,000 feet in altitude from Kashmir to Burma.

GRASS-MATS: Calcutta-mats: Madras-mats.—Here and there throughout the greater part of India mats are made of the culms of certain species of sedge. Some are coarse, being woven of the entire culms, and others exceedingly fine, the triangular culms being split into two, four, eight, twelve, etc., pieces. These strips of culms are carefully dried, when it is found they have rolled round on themselves lengthwise, thus carrying the polished epidermis uniformly on the outside of the rush-like strands. The process of splitting the culms is perhaps the most difficult and laborious part of the grass-matting art, especially when exceptionally fine mats are to be woven. The collection of the culms and the splitting and drying of the same are duties entrusted to the women, whose patience and delicate fingers are in consequence important factors in success. The men do the weaving. The species of sedge most largely used is *C. tegetum* (No. 7 above), but Nos. 4, 5, and 6 are (according to some writers) each and all employed in the localities where procurable abundantly. In fact, as already stated, the finest mats are those produced in Tinnevelly from *C. corymbosus*, var. *Panigorei*. But the question whether the production of the finer mats necessarily depends on the special properties of the sedge used or on the patience and skill of the operators has never been definitely investigated. In certain regions species of sedge are used in the mat trade that in other countries are never so employed, though plentiful. The greatest uncertainty still pervades the literature of the grass-mat trade, more especially as to the particular forms of sedge used in the centres of special repute. But the exceedingly fine mats of Tinnevelly, Cochin, Pallampett, Palghat, Vellore, Indrawatty, Sevry, Talpier, Middnapur, etc., Mats, though often marvellously fine, very beautiful and highly artistic, are commercially much less valuable than the ordinary grass-mats, the so-called Calcutta-mats or mudar-mats, which are made mainly, if not exclusively, of *C. tegetum*.

Manufacture.—The method pursued in the fabrication of grass-mats, however coarse or fine, is the same with all the Indian grass-mats, and may be here briefly detailed. Threads of ordinary country twine (more rarely cotton) are stretched along the surface of the floor of the factory or workshop, one inch or an inch and a half apart, and extending for the length of the desired mat. If intended for a large-sized room they may cover, or nearly so, the entire floor of the workshop, or may be placed in one corner, being only a few feet in length and breadth, or many yards in length and only a few feet in breadth (the last being a
Dairy Farming

Stock

sort of piece-goods form which has recently been sent to Europe and America very largely). The lengthwise strings constitute the warp of the mat. Previously they have been threaded through a crudely formed weaver's comb or beam of the desired breadth, and they have also been attached to bamboos at both ends, which are so adjusted that they may be tightened as desired and the warp raised an inch or so above the floor of the room over which they are stretched. The operators commence at the far end. They sit in a row across the breadth of the fabric and on the top of it. Each possesses a crudely formed wooden needle (which takes the place of the shuttle), and through the eye of this is inserted the end of the split and carefully prepared culm. This is passed alternately over and under the threads of the warp and thus placed in position by each operator along his allotted portion of the weft. Simultaneously the comb is beaten home and the next street of the weft commenced by being threaded above the warp, where the previous street went below. If colours or patterns are desired they are inserted by the hand at the proper positions. Thus slowly the work progresses. It is hand labour from beginning to end, for so far machinery has not invaded this peculiarly tropical craft, the prototype very possibly of the weaver's art.

As already indicated, the finer artistic and coloured mats are mainly derived from Madras; the plain white mats, or mats with coloured borders only, come from Calcutta. In Western India grass-mats are never made, though several of the plants required appear to be fairly plentiful. The mats of Bombay are made from the leaves of Phoenix robusta, Hook. f.

Statistics of the trade in grass-mats cannot unfortunately be given. It is known that large quantities are regularly exported, and within recent years the trade has greatly expanded. But the grass-mats are returned conjointly with all other Mats and Matting Materials (see p. 776).

Dairy Farming and Dairy Produce.—In its modern comprehensive signification Dairy Farming embraces not only milk but many other substances, the production of which can be economically combined with the supervision of milch-cows. These may be classified as follows:—Live Stock—such as oxen, buffaloes, sheep, goats, pigs, poultry and bees. Produce—meat, milk, dahi, butter, ghee, cheese, fowls, ducks, eggs, honey, bees'-wax, hides, skins, wool, horns, hair, feathers, bristles and farmyard manure. Requirements—capital and stock, technical knowledge, suitable buildings, grass lands, a supply of cattle food and fodder, appliances and machinery, and easy, quick and cheap transport to large markets.

So far as known, no one in India has as yet attempted Dairy Farming in anything approaching the degree of thoroughness necessary to ensure complete success. While that is so, the larger towns have recently begun to receive some portion of their supplies from establishments usually designated Dairy Farms, and for many years past the necessity for a large and pure supply of milk and butter for the British troops resident in India has induced the military authorities to organise special dairy farms of their own. In Thacker's Directory (1905, 28–30) mention is made of the
following Dairies:—Bengal, 4; United Provinces, 11; Central India and Rajputana, 2; Panjáb, 6; Assam, 1; Burma, 1; Bombay, 18; and Madras, 5. Still, the problem of the protection of the public against disease through the supply of impure and adulterated milk has hardly been even contemplated. For kindred subjects consult:—Bees and Honey (see pp. 123-9); Poultry and Ducks, etc. (pp. 131-6); Feathers (pp. 138-42); Eggs (p. 137); Hides and Skins (pp. 632-40); Horns (pp. 644-6); Manure, Farmyard (p. 768); Pigs and Bristles (p. 752); and Wool, Hair and Pashm (pp. 1121-31). In the present article Dairy Produce, such as Milk, Butter, Ghee, Cheese, etc., will be dealt with in such detail as space will admit.

History.—Voolcker (Improv. Ind. Agrt., 1896, 206-11) has very properly observed that "the two most striking features of Indian dairying are, the small yield of milk given by the cows, and the richness of the milk of the buffalo. In Bengal the ordinary country cow will not give more than 2 lb. of milk a day. In Madras it may yield from 2 to 4 lb. a day. As a rule, the cows will only yield for milk, six months, and often have but one calf in the course of two years. The milk of the buffalo, on the other hand, is very much richer than the average cow's milk in England, for, whereas the latter may be said to contain 3 to 4 per cent. of butter-fat, and 12 to 13 per cent. of total solids, buffalo's milk has no less than 7½ per cent. of butter-fat and 18 per cent. of total solids." These are exceedingly important facts which cannot be overlooked. No conception of the value and extent of dairy farming in India could be formed were the part played by the buffalo and the goat to be omitted.

Another highly significant feature is the extent to which milk and the preparations derived from it are boiled before being eaten. Milk, butter and cheese have been boiled preparations from the most ancient classic times of India—(confer with the references below to the Institutes of Manu)—a direct and practical adaptation doubtless to the greater danger in the East than in the West of consuming articles of food so liable to contamination as milk and its derivatives. Buchanan-Hamilton (Journ. Mysore, etc., i, 6, 116; ii, 14-5, 382) wrote in 1807 an account of the milk and butter of Mysore that is fully corroborative of the extent to which in India boiling is and has always been an essential feature. His description is not only true to-day (and not of Mysore only, but of the greater part of India), but it is one of the most concise and accurate that has been penned. It may, therefore, be interesting to give here an extract from that historic work:—"The cattle in this country are milked by men who carry the produce home to the women; for they prepare the butter. The milk on its arrival, is immediately boiled for at least one hour; but two or three hours are reckoned better. The earthen pots, in which this is done, are in general so nasty, that after this operation no part of the milk of the dairy is tolerable to an European; and whatever they use, their own servants must prepare. The Natives never use raw milk, alleging that it has no flavour. The boiled milk, that the family has not used, is allowed to cool in the same vessel; and a little of the former day's Tyre, or curdled milk, is added to promote its coagulation, and the acid fermentation. Next morning it has become Tyre or coagulated acid milk. From the top of each potful, five or six inches of Tyre are taken, and put into an earthen jar, where it is churned by turning round in it a split bamboo." "After half an hour's churning some hot water is added and the operation is repeated for about half an hour more; when the butter forms. The Natives never use butter but prefer what is called Ghé not only as that keeps better but also as it has more taste and smell. In order to collect a quantity sufficient for making Ghee the butter is often kept for two or three days and in that time a warm climate renders it highly rancid. When a sufficient quantity has been collected it is melted in an earthen pot and boiled until all the water mixed with the butter has been evaporated. It is then taken from the fire and is eaten when even a year old." Buchanan-Hamilton (Stat. Acc. Dihaj, 277) gives the following:—"Chhana or curd is prepared by boiling the milk, and by adding to it while hot, some acid milk, which coagulates the whole into one mass. This is put into a cloth and the whey expressed so that it is a kind of cheese." In his Gazetteer of Bihar and Patna (published by Montgomery Martin) Buchanan-Hamilton speaks of two distinct classes of milkmen: the one, he says, churns the milk as it comes from the cow,
and the other boils and curdles it before attempting to separate the butter. The former thus produces fresh butter and mahuya-dahi, the other boiled milk-butter and milha dahi. To the present day Monghyr and Bhagalpur enjoy the reputation of producing high-class butter from fresh (not curdled) milk. But in India as a whole the manufacture of butter from fresh (not boiled) milk is only occasionally practised, and mostly in response to European demand. The high death-rate of Europeans from typhoid fever may to some extent be a result of their objection to Native boiled milk and boiled butter. The Natives, when they do make fresh butter, never attempt, however, to set the fresh milk aside to allow the cream to rise to the surface, since it would most certainly, under the tropical conditions, sour and be thus ruined. In fact it may be said the Natives of India do not know cream, the substance they skim from dahi being rather crudely formed butter than cream. But sometimes the boiling of milk is continued until it is reduced to a kind of extract called khyir—a substance largely employed by the sweetmeat makers. The milk of goats, cows and buffaloes, when available, is invariably mixed before being treated in the manner above indicated.

I have given these passages from one of the most observant of Europeans who ever resided in India, not only because they are fully expressive of modern Indian practice but because they were penned long before the discoveries that in Europe have revolutionised dairy practice and knowledge and recently begun to modify Indian methods. Thus then it may very nearly be said that the milk, butter, cheese, etc., of India are all cooked, if they might not be called sterilised, articles of food.

1. MILK AND CREAM.—Composition and Properties.—It may be explained that in Upper India there are two main castes who are dairymen. These are the ghośi and the guvālas. The former have no other occupation, and sell their milk and dahi (khoya) to the halwais. The latter are cultivators as well as milkmen, but they rarely sell their produce to the halwais but to the actual consumer direct. Dutt (Mat. Med. Hind., 1900, 281–3) gives many interesting particulars regarding the properties attributed by the Hindus to the various kinds of milk and the preparations from it. He discusses cow's milk, buffalo's milk, goat's milk, ewe's milk, mare's milk, ass's milk, camel's milk and human milk. He then mentions the following preparations, of which he gives the Sanskrit and sometimes the vernacular names:—butter-milk (takra), clarified-milk (dadhī or dahi), whey (mastu), curd (kilataka, vern. chhêna), cream (santanikā), butter (navanita), and clarified butter (ghrita, vern. ghī).
After the buffalo and the cow, the goat is the most important milk-giving animal, but its milk is poor in butter-fat and thus not of much value in the manufacture of ghī. The sheep, while not much employed in the supply of milk, is so used in some districts of the Panjáb, as for example Montgomery and in many parts of Rajputana, and the butter is made into ghī which fetches the same price as cow’s butter. It is said that in Rajputana a flock of 100 sheep can be maintained at the same cost as ten buffaloes and yet the yield of milk and butter is nearly treble.

A fair amount of information has been published in recent years on the composition of Indian as compared with European milk. Leather (Agri. Ledg., 1900, No. 19, 195) says “the composition of cow’s milk has been found in England to be very regular for different breeds, and to possess a relationship between the several component parts of all breeds. It is of importance to know whether these relationships hold good for Indian breeds of cows and to what extent they vary in the case of the buffalo.”

“It has been found in England that (a) there exists a relationship between the solids—not fat, the fat and the specific gravity, and (b) between the proportions of proteids, lactose and mineral matter (ash), and that these relationships are constant, within certain limits, for all the several breeds.” The proportions of proteids, lactose and mineral matter were found to be as 9:13:2 in English, and the same with Indian milk. “In the case of the buffalo milk, however, the relationship is different, that of the proteids being distinctly higher and that of lactose lower, than in cow’s milk.” Leather gives numerous tables showing the analyses of cow’s and buffalo’s milk (and these should be consulted); he then concludes by observing that generally it may be said:

(a) The milk of the Indian cow contains a high proportion of butter-fat, varying from 4 up to 6 per cent. Buffalo’s milk contains usually much more, varying from 5 or 6 per cent. up to as much as 10 per cent;

(b) The percentage of proteids (albumen and casein) usually varies in cow’s milk from 3:1 up to 3:5; in buffalo’s milk from 3:5 up to 4:3;

(c) The percentage of milk sugar (lactose) in the cow’s milk varies from 4:4 to 5:0, and in buffalo’s it is present in about the same proportion;

(d) The percentage of mineral matter in cow’s and buffalo’s milk varies from about 0:7 to 0:8, as it does in the English cow’s milk.

Mollison (Agri. Ledg., 1895, No. 5, 53) observes:—The quantity and quality of the milk varies greatly by the nature of the food given. “The morning’s milk is usually not so concentrated as the evening’s milk, but on the other hand the morning yield is greater.” But so constant is the composition and sp. gr. of milk that extreme variation from the standard must be accepted as denoting adulteration. The milk-sugar present in Indian milk to the extent of from 4:6 to 5:05 exists in a state of solution, and hence it very easily undergoes decomposition and is in consequence converted into lactic acid and the milk is then spoken of as sour. This fermentation at once becomes active when milk rises in temperature above 15° C. (59° F.). To ensure the preservation of milk it must therefore either be cooled below that temperature or retained at 50° C. The curdling of milk is the result of lactic fermentation, but this may be accomplished by means of organic or mineral acids or is simulated in cheese-making by the precipitation of casein by means of rennet. But rennet (the digestive agent of the stomach of a calf) has induced other changes than the mere precipitation of the casein, and its action is far greater than
SOUR MILK VERSUS CURDS.

Sterilisation.

Tainted Milk.

Fermentation killed.

Sterilised Milk.—The greatest cleanliness is imperatively necessary, for even proximity to offensive smells will taint the milk. Some of the fermentative germs immediately start growing and commence the souring process, but these are instantly killed if subjected to a temperature of 50° to 75° C.; and should the milk also contain pathogenic germs (i.e. the germs of such diseases as typhoid fever) these will at the same time be destroyed. But other fermentative germs are latent and little affected by such temperatures as mentioned. In fact they are only killed either by continued boiling for some hours or by repeated heating and cooling. While left in the cool stage they are induced to assume the active condition, and are then killed by the succeeding heating. Repeated heating will thus serve the same purpose and more effectively (though more troublesome) than continued boiling, and it avoids the undesirable changes in flavour caused by prolonged boiling. When once completely deprived of the germs of its fermentation by heat, milk is described as sterilised or "pasteurised." Even if not protected it will now remain wholesome for some considerable time, but if kept in airtight vessels or bottles may be stored for months without undergoing any injurious change. The success of the Agra, Aligarh, Allahabad, Cawnpore, Darjeeling, Jabalpur, Lucknow, Ootacamund, Poona, etc., dairy farms in supplying sterilised milk is being followed by many other institutions, so that supplies of good and safe milk may be now had in all the larger towns. The trade is a prosperous one with immense possibilities for the future.

PRESERVED OR CONDENSED (DESICCATED) MILK.—This is made by boiling fresh (whole) milk, to which sugar has been added, until it attains the consistence of syrup. This is called khir (khýir) and in some parts of India, râbûi, but sugar is not always added. Of Bengal districts, Tipperah is spoken of as producing khir of special quality. Sen, discussing Dacca, says, "The flavour of this preparation of milk depends on (a) the quantity of milk boiled at a time, (b) the care with which the milk is stirred at the time of boiling, and (c) the nature of the heat applied. (a) To obtain khir as white as possible, and possessed of the best flavour, not more than half a seer of milk should be boiled at a time. (b) All the time the milk is boiling it should be stirred with a wooden rod. Some prefer to stir with a number of rods. (c) A strong and steady heat should be applied. Tamarind wood is considered the best fuel for this purpose. Khir of an inferior quality is sometimes made from fresh butter-milk." Banerjei remarks, "In order to get the khir or thickened milk of a fine white colour, a little flour is added. In private houses arrowroot is used instead. When thick enough it is removed and allowed to cool, when it is ready for sale."
This is, therefore, a different substance from desiccated or strained dahi, although both are largely used by the sweetmeat makers. It has been recently upheld that the khir or houwa (mawe) made from separated milk is as good and marketable an article as that from whole milk, and hence the double profit in the khir and the butter. It has also often been urged that India might do a large trade in the production of condensed milk and in milk boiled down to a powder. Sweden, with its population of five millions, is believed to produce annually and export £20,000,000 worth of preserved and dried milk, a large share of which comes to India, instead of India itself exporting these preparations of milk. Thorpe and others have pointed out that the action of sugar in desiccated milk is preservative, but for this purpose 12 per cent. of the weight of the milk must be sugar. [Cf. Fleischmann, The Book of the Diary (Aikman and Wright, transl.), 1890, 282-6; Thorpe, Dist. Appl. Chem., ii., 615.]

Reputed Preservative Agents.—In this connection also reference may be made to the passage above where Buchanan-Hamilton remarks that it is very nearly the universal practice to boil the milk immediately it is drawn from the cow, goat, etc. This fact cannot be reiterated too frequently. It will have been observed also that the earthen pots into which the animals are milked are often so nasty, to European taste, as to be regarded as destroying it. It may be explained that in many parts of India it is customary to smoke the milking-pots, but whether this is done to directly impart the smoky flavour or from the belief that it has a protective action, does not appear to have been investigated. When milk is to be carried for a distance it is placed in earthen pots with fairly large open mouths. These are swung over the shoulder by means of a bamboo, and a swift runner carries the milk to its destination. Within the mouths of such earthen or brass pots it is customary to find a few twigs or leaves—such as rice straw, date-palm leaves, twigs of Coic bus villosus or leaves of Pediatium Murex. The milkmon affirm these prevent the milk turning sour, but it is much more likely that their action is mechanical in preventing the milk from lapping over or being churned. Coicbus and Pediatium are known to have the curious property of thickening water, and may be added to the milk with the object of preventing the detection of water adulteration. Any one who will take the trouble to go to a railway station in the early morning and witness the arrival of Calcutta’s daily supply of milk will not be surprised at the danger of direct and accidental adulteration, but rather at the rarity of outbreaks of disease being attributed to the impurities of milk. Speaking of Bombay experience, Lisbon (Journ. Bomb. Nat. Hist. Soc., 1887, ii., 143) mentions the fact that arrowroot is employed to thicken milk which has been watered. [Cf. Agr. Ledg., 1893, No. 17, 114-5; Pharm. Journ., l.c.]

In concluding these observations on the preservation and manipulation of milk it may be added that boracic acid, carbonate of soda, carbonic acid, salicylic acid, oxygen and saltpetre, as also several other substances, are all spoken of as milk-preservatives, because they retard the action of the bacteria.

Separators.—Some few years ago (1889), at the suggestion of the Bombay Government, the Dairy Supply Company sent Mr. Howman to India in order to ascertain by trial whether the cream separator is needed in India, and whether it can be profitably utilised in the manufacture of ghi. After an extended tour in several provinces, and after having made various trials, the following conclusions were published:—

1. Tak, a bye-product of ghi-making, can be prepared perfectly well from separated milk.
2. Mawe or Khouwa, which consists of desiccated milk sweetened with sugar, can be made from separated milk, and the cream saved for butter or ghi.
3. As much Ghi can be made from separated cream as by the Native process.” [Agr. Ledg., i. 111.]

There are many designs or patterns of separators, but the principle is the same in all. They take advantage of the fact that cream or butter-fat is lighter than milk. By centrifugal force the liquid revolving within a

Imports.

Trade in Milk.—Absolutely no information can be given regarding the internal trade in milk. Within the past few years the foreign traffic has been officially recorded. In 1902–3 the imports of condensed milk were 1,490,154 lb., valued at Rs. 4,08,251; the following year, 1903–4, they had suddenly expanded to 4,137,066 lb., valued at Rs. 11,34,187; and in 1906–7 became 6,196,492 lb. and Rs. 17,68,347.

Dahi.

2. DAHI OR CURDLED BOILED MILK.—The names most generally given to thickened or coagulated or specially soured boiled milk are dahi, dadhi, khoyá, mówá, tyre, etc. It is usually prepared by throwing boiled and partially evaporated milk into a vessel that has contained dahi, but has not been subsequently washed. At other times a certain quantity of dahi or some other acid substance is added to the boiled milk, or a vegetable or animal rennet is employed. Sen, speaking of Dacca, observes that, “To understand the method of preparation of dadhi of superior quality, we should remember that its formation depends on a fermentation of milk, and that milk undergoes a number of other fermentations besides that of dadhi, and that the particular fermentation it will undergo depends on the conditions under which this takes place. It is only when the milk is kept at a certain temperature, when a given quantity of dadhi of a particular degree of sourness is mixed with it, and when the extraneous germs of which the atmosphere is full are excluded from it, that the dadhi fermentation takes place properly.” “A preparation of sugar, batasha and spices is sometimes added to the milk which is set to undergo the dadhi fermentation.”

As a rule Muhammadans only will use animal rennet, and the vegetable rennets such as Withania coagulans are not very widely known. Hence dahi differs from curd, as prepared in Europe, in being practically sour.
boiled milk, the fermenting agent being added when it is nearly cold. And the milk, being boiled immediately as obtained from the cow, contains all its fat or butter. In this form it is called sara, and if kept hot may be accumulated for some days till sufficient has been collected to form it into dahi. This, as Banerjei explains, is therefore basa-dahi. If butter be removed from the dahi by churning, the liquid that remains is butter-milk or ghol-dahi (máthá, lassí). But a top layer of the dahi may be simply skimmed off and used in the manufacture of butter. Hence there may be whole-milk dahi (basa-dahi), skimmed-milk dahi, as well as butter-milk (ghol-dahi). Dahi in the liquid state is largely consumed; hence its whey (nastu) contains all the milk-sugar and its curd (chhena) may or may not have embedded in it all the butter-fat. Whole-milk dahi thus contains too much fat to be made into cheese. It is, in fact, cream-cheese, and some localities such as Bandel near Hugli and Dacca in Eastern Bengal are famous for their cream-cheeses. When curds are intended to be prepared the acid or rennet is added to the hot milk. This is called dud-chhena, but dahi is often heated and allowed to cool in order to prepare imitation curds known as dahi-chhena. The whey (as it may be called) of dahi is separated by pressing the curd within a clean cloth, but if it be completely dried the chhena crumbles to a powder. All qualities of dahi and also of chhena are largely used in cookery and with khír constitute the chief ingredients of sweetmeats, which may thus be regarded as possessing all the elements of food and are not merely luxuries like the sweetmeats of Europe.

Trade.—The trade in compressed (or partially compressed) dahi is very extensive, and within a radius around the chief cities immense quantities are daily conveyed by rail and road from the country to the towns, the curd being wrapped in damp cloths and deposited in open baskets. Dahi and ghi are therefore the products of greatest value in Indian dairy farming. Although every resident in India will readily admit that the traffic must be enormous, no sort of computation is possible of the total production of either the one or the other product.

But in conclusion it may be pointed out that the fermentative agents concerned in the coagulation of sour milk (not boiled), of boiled milk (dahi), of soured cream and of the various forms of curds (chhena), are probably all different and that success in the production of the manufactures named, to a far greater extent than as yet appreciated, depends on the use of the correct agent for each fermentation. [Cf. Sen, l.e. Dacca, 1889, 54-7; Banerjei, Agri. Cuttack, 1893, 128-30.]

3. BUTTER.—Of India it may be said that two kinds of butter are known:—nani or the butter of fresh or only scalded milk, and mahán or the butter of soured milk (dahi). The former is held to be inferior and more difficult to prepare than the latter, but valued because the butter-milk obtained may be sold as dahi, and khír may even be made from it. Fresh milk is hardly ever set on one side to allow of the rise of the butter, and in consequence cream (shar) can hardly be said to be known in India. The article sold as cream (except that obtained by the modern cream separators) would more correctly be described as liquid (boiled) butter mixed with dahi. But the so-called Indian cream (as with the cream of Europe) is set aside to mature or ripen (as it is called), and when sufficient has been collected and matured it is churned and made into butter. Terry (chaplain to Sir Thomas Roe) (Voy. E. Ind. (ed. Havers), 1665, 359)
DAIRY FARMING

CHURNS AND CHURNING

Butter

observes that "butter is obtained by beating their cream into a substance like unto a thick eryl, for in that hot climate they can never make it hard, which though soft is very sweet and good." Fresh cream (that is to say whole milk) yields a smaller quantity and an inferior flavoured butter than matured cream. The peculiar flavour of butter is, in fact, very often a question of the method and degree of ripening that has been pursued. Moreover the best butter-makers lay stress on the necessity for the cream being repeatedly stirred during the ripening process. The time required depends on the temperature of the atmosphere. It will be sufficiently ripe in from 12 to 24 hours if the temperature average from 60° to 70°F., according to Fleischmann, but 90°F. according to Meagher and Vaughan; below 60°F. it will take 48 hours, but cream should never be allowed to fall below 55°F.

The study of the exact germs concerned in the production of recognised flavours of butter is by no means complete, but is engaging the attention of experts. In the near future pure cultures for the maturing of cream may be demanded but the subject is at present not understood, and both in Europe and in India empirical rules prevail. Cream is not pure butter-fat, but is a mixture of that substance floating in milk. The milk sours, the lactic acid precipitates the casein, and thus forms butter-milk. Butter, however, always retains some proportion of the sour curd mechanically mixed with it, and upon this depends the souring of the butter and its rancid flavour.

Churning.—Butter consists of the consolidated oil globules present in the milk. These are collected together and compacted into butter by various contrivances that may be called churns. As already fully explained, a small proportion only of butter is made in India from the milk as it comes from the cow. There is very little or no cream-butter made by the ordinary Indian milkmen, for the reason that the climate will not allow of the milk being set on one side until the cream rises to the surface.

Recently, however, cream separators have been introduced at the larger centres and cream-butter has in consequence to a certain extent come into use. The bulk of the Indian butter is of a kind practically unknown to Europe, namely boiled soured-milk butter. It has been estimated that Indian milk yields butter at the rate of one pound to every 14 pints of best cow's milk or 9 pints of buffalo's milk; with separators very much smaller quantities will, however, suffice. The amount of butter nowadays made from separated cream is fairly large, and Bombay and Aligarh might be spoken of as the centres of the trade.

In The Agricultural Ledger (1895, No. 23) I have described the churns most commonly met with in India. The simplest contrivance of all is a wide-mouthed bottle or bamboo joint into which a quantity of milk is placed and shaken in the hand until the butter forms. Methods of preserving milk and of preparing from it special articles of human diet, that would wholly or partially withstand climatic tendencies, must have early become axioms of household economy in India. But in the consequent development of this knowledge it would seem that the introduction within the liquid of a contrivance intended more fully to agitate it, than could be attained by shaking in a bottle, would be a natural and simple one, which might fairly well have suggested itself spontaneously to the most remote and diverse races. The first conception of this would most probably be a beater worked by the hand. The step from that to a rotatory whisk would be a direct and necessary one. But a vertical plunging action might not so readily suggest itself. This is the position in India. The rotatory churn is common, the vertical rare, though both forms exist. Whether or not the Aryans introduced the rotatory churn, the one most generally used throughout India,
DAIRY FARMING

Churning

The Art of Churning.—Great skill is required in judging when the churning is complete. If stopped too soon much may be lost in the butter-milk; if too long protracted the butter may become greasy. The almost universal Indian practice of adding hot water, during the middle of the churning process, prevailed in some parts of Europe also, but it is now much condemned by scientific writers. [Cf. Fleischmann, l.c. 188.] After straining to remove the butter-milk the butter is washed once or twice in order to remove the curd and other impurities, as also as much of the butter-milk as possible. The butter is worked up, squeezed and beaten until it attains the desired consistence, and is then ready for the market. Water is, however, one of the chief adulterants of butter. As much as 25 per cent. may be present, though good-quality butter may sometimes contain as much as 10 to 15 per cent. As already observed, the presence of butter-milk impairs the lasting quality of the butter, and by turning sour makes it rancid. The melting-point of butter is a feature of some importance as it affords a means of readily detecting impurities. Indian butter, curiously enough, has a higher melting-point than European, a fact urged in favour of its great suitability to India. The food given to milch-cows also affects the melting-point of the butter. Cotton-seed, pulse meal, pea straw, ground-nut cake, etc., produce firm butter, whilst most other oilcakes soften it or make greasy butter. The cream from buffalo milk can be churned at a higher temperature than that of the cow and yet produce equally firm butter, and hence one advantage claimed for the churning of mixed cow and buffalo milk. If the mixture be thought to show too strongly the pale (bleached) colour of the buffalo or sheep butter, the colouring ingredient used should be added before churning. The best substance for this purpose is the pigment of the seeds of Arnotto (Bixa Orellana). Three ounces of the seeds soaked in 8 oz. olive oil, then strained, makes a good staining preparation. One teaspoonful to 40 lb. buffalo milk will usually suffice.

Trade in Butter.—Very little of any importance can be furnished regarding India’s trade in butter. The article is in daily use by the well-to-do of all castes and communities, but, India being an agricultural country, the supply is home-made. As an indication of the progress in modern dairy farming, it may be mentioned that in the Administration Report on Dairy Farms in the Bengal Command for 1901–2 it is stated that 101,402 lb. of butter, 1,119,216 of whole milk, and 182,799 lb. of cream were produced and disposed of at the dairy farms of Allahabad, Jabalpur, Lucknow, Cawnpore and Agra for that year.

The returns of foreign transactions give, however, certain particulars of value. The IMPORTS of butter were in 1875–6, 76,658 lb., valued at Rs. 65,633; in 1885–6, 184,183 lb., valued at Rs. 1,65,335; in 1895–6, 477
4. GHI (GHEE) OR CLARIFIED BUTTER.—Manipulation.—It may be said that the three great products of milk in India are khir, dahi and ghi. The first two have already been disposed of. It is perhaps hardly necessary to describe the preparation of ghi (neyi) in great detail, since so much has already been said that has a direct bearing on the subject. Ghi is clarified butter. That is to say the butter is heated for about twelve hours or until the greater part of its moisture is evaporated. An oil is at the same time formed that rises to the surface, and the refuse (mostly casein) forms below as a sediment. Too much heating is said, however, to cause the ghi to assume an acid taste, while imperfect heating renders it liable to putrefaction. Great skill is thus required, but the ghi sold in the market has usually been undercooked owing to the loss in weight which takes place when fully cooked. Butter loses about 25 per cent. in the process of clarification. The yield of ghi from the butter of the buffalo is higher than from that of the cow. The boiling butter is allowed to be partially cooled, when the ghi may be decanted from the top of the sediment. The ordinary ghi of the bazars is principally derived from buffalo milk. One quart of buffalo milk yields about 3 oz. of ghi, while the same quantity of cow milk may only afford about half that quantity, or with extra fine qualities, three-quarters of the ghi mentioned. Ghi from goat milk is very inferior owing to the disagreeable odour it possesses, while that of sheep milk is often spoken of as superior even to buffalo butter.

Old Ghi.

Old and New Ghi.—So much has been written on the subject of clarified butter or ghi that a special volume might have to be written before even the more important historic and trade facts had been exemplified satisfactorily. Ghi is mentioned in some of the most ancient of the classic works of the Hindus. It is the grhita of Sanskrit authors, and according to ancient medical opinion the ghi of cow milk is superior to that of buffalo or goat. As manifesting the antiquity of the knowledge in this article, it may be mentioned that in the Periplus (80 A.D., McCrindle, transl., 12, 113) ghi is spoken of as exported from India. It may thus be said to have been closely associated with the life and social customs of the Aryan races, but curiously enough has never been of much value with the people of Mongolian blood. Here and there all over India, especially along its

211,516 lb., valued at Rs. 2,43,439; in 1903-4, 277,112 lb., valued at Rs. 3,16,536; in 1905-6, 782,738 lb., valued at Rs. 3,12,510; and in 1906-7, 244,577 lb., valued at Rs. 2,66,636. To what extent this may be margarine is not at present known. The exports of Indian butter appear to have only begun to be separately returned in official statistics about the year 1890-1, when 1,118 lb., valued at Rs. 472, were sent to China and the Straits Settlements. In 1895-6 the exports were 152,462 lb., valued at Rs. 94,780; in 1905-6 they were 307,755 lb., valued at Rs. 2,16,614; and in 1906-7, 298,344 lb., valued at Rs. 2,09,292. It would thus appear that the export traffic is steadily improving. It goes almost exclusively from Bombay, and the countries that take the greater proportion of the Indian butter are Ceylon and Aden, and after these British East Africa, followed by the United Kingdom. This improved export trade is apparently the direct result of the recent endeavour to establish dairy farming on modern lines.

Old Ghi.

Old and New Ghi.—So much has been written on the subject of clarified butter or ghi that a special volume might have to be written before even the more important historic and trade facts had been exemplified satisfactorily. Ghi is mentioned in some of the most ancient of the classic works of the Hindus. It is the grhita of Sanskrit authors, and according to ancient medical opinion the ghi of cow milk is superior to that of buffalo or goat. As manifesting the antiquity of the knowledge in this article, it may be mentioned that in the Periplus (80 A.D., McCrindle, transl., 12, 113) ghi is spoken of as exported from India. It may thus be said to have been closely associated with the life and social customs of the Aryan races, but curiously enough has never been of much value with the people of Mongolian blood. Here and there all over India, especially along its

478
mountainous frontier, certain races, such as the Kashmiris, are said not to eat ghi (Lawrence, Valley of Kashmir, 339). In the Ain-i-Akbari (Blochmann, transl.), 130 mention is made of the allowance to the State elephants. [Cf. also Jahangir, Memoirs (Price, transl.), 63, 71, etc.]

If carefully enclosed in skins while still hot it may be preserved for many years without requiring the aid of salt or other preservatives. It is somewhat significant, in fact, that medical writers should speak of purana ghrīta (old ghi) as being superior to fresh. Dutt, for example, observes that ghi ten years old has a strong pungent taste and is of the colour of lac. “The longer this butter is kept the more efficacious it is said to prove as an external application. Clarified butter a hundred years old is often heard of. The richer Natives always have a stock of old ghrīta of this description which they preserve with care for their own use as well as for distribution to their poorer neighbours.” Fryer (New Acc. E. Ind. and Pers., 1672–81, 137), in his description of Surat and a journey into the Deccan, speaks of “the granaries hewed out of stone” and of “several Tunks filled with butter of 400 years standing, prized by the Gentiles as high as Gold, prevalent in Old Aches and Sore Eyes, one of which was opened for my sake, and a present made me of its black stinking and viscous Balsam.” Butter preserved in skins has been known to remain for many years without deteriorating very materially. It usually, however, dries and becomes almost like wax instead of changing colour and assuming the condition of the purana ghrīta or medicinal ghi of the Hindus and the roghan of Persian travellers.

Food.—Ghi has been for many centuries at least an important article of food in India. Linschoten and most of the early travellers allude to its extensive employment in all forms of cookery. It is, in fact, used for all purposes to which butter is put in Europe—such as the cooking of meat, fish, vegetables, curries, rice, etc., or utilised in the preparation of sweetmeats, and is also eaten uncooked with bread and rice. With the poor it is a luxury for feast days, and in everyday life its place is taken by sweet vegetable oils.

Adulteration.—The chief articles used in the adulteration of ghi are vegetable oils such as cocoa-nut, ground-nut, cotton, safflower, poppy, sesameum, niger and kokam. These are all harmless enough, though cheaper than ghi; but injurious oils are also used, especially mahua, Salvudora (kakhan) and castor-oil. Other animal fats, especially mutton, are largely utilised. Starches, such as rice, bajra, plantains, potatoes and yams, are frequently resorted to in order to thicken oily compositions. Impure or adulterated ghi is also often remade with milk or curd, to render detection difficult. The simplest method of ascertaining adulteration, and to purify the ghi at the same time, is to boil a given quantity, and when it is in a state of complete ebullition to dash cold water on it. The oil will rise to the surface and part from its admixtures. One of the most valuable papers on the adulteration of ghi is that written by Mr. Shroff, who states that the Bombay ghi trade is in the hands of a dozen merchants, and that adulteration is effected, not by the dairymen, but by the traders. The fats used are often most offensive and deleterious substances, at times even obtained from the carcases of diseased animals. Numerous complaints have been made and even legal proceedings recently taken regarding the adulteration of ghi. In consequence the necessity for protecting the poor and helpless has been urged as justifying special legislation.
DAIRY FARMING

Ghi

Packing.

Packing.—Formerly all ghi was packed in earthen jars (matkas), or for transport to a distance in leathern cases (kuppas), but in recent years old kerosene-oil tins or specially made tins have been employed.

Production and Consumption.—The chief ghi-producing tracts are the United Provinces, Bengal, Rajputana, Central India, and the Panjáb. It has been estimated that about one-fourth of the total population of India use 8 lb. per head per annum. Assuming these figures to be correct, this would represent a consumption of about 300,000 tons a year, or at a valuation of £45 a ton, say 134 million pounds sterling. There are no data by which to verify these estimates, but as they stand they are suggestive of India’s necessities in this direction.

Trade in Ghi.—Prices.—No doubt by far the greater proportion of the ghi produced in India is consumed locally, and never appears either in the trade returns of internal nor of external traffic. It has been ascertained that the retail price of superior ghi ranges from 5d. to ls. a pound. In the statement of Prices and Wages published annually by the Government of India, particulars are given of the prices of ghi in certain localities of Western India since 1855. These would seem to show ghi selling at a lower price than the figures just mentioned, but the difference between pure first-class and adulterated lower grade ghi is such as to render averages misleading. Still, the official returns as they stand manifest a considerable enhancement of price. Thus the average for all the Bombay centres in the quinquennial period of 1855–60 was 19:19 rupees per maund, and in 1903, Rs. 35:32; in Sind, Rs. 17:12, and in 1903, Rs. 33:28; in Central India and Rajputana, Rs. 24:3, and in 1903, Rs. 28:38. But taking the quinquennial average of 1871–5 as 100, Bombay is now 112; Sind 124; and Rajputana and Central India 110. In a further series of tables, Prices and Wages gives returns of the wholesale rates of ghi. These, for the year 1903 (and reduced for purpose of comparison to rupees and decimals of rupees per maund), would be as follows (in sequence of price):—Bengal, Rs. 34:3; Mysore, Rs. 34:1; Sind, Rs. 32:3; Madras, Rs. 31:4; Panjáb, Rs. 30:6; Berar, Rs. 30:4; United Provinces, Rs. 29:9; Central Provinces, Rs. 28:8; and Rajputana, Rs. 27:8. In a still further series of tables the prices of ghi are shown for selected centres such as Calcutta, Benares, Allahabad, Lucknow, Bareli, Cawnpore, Meerut, Agra, Ambala, Lahore, Rawalpindi, Multan and Peshawar during the years 1875–6 to 1902–3. These are divided into buffalo ghi, cow ghi, and each of these again subdivided into 1st sort and 2nd sort. But the provincial averages just given approximate very closely (as the mean between all four classes in each centre), so that it is not necessary to furnish other estimates.

Internal Trade.—The total internal trade in ghi, as manifested by the railway returns, shows certain interesting peculiarities. The chief exporting provinces are the United Provinces, Rajputana and Central India, the Central Provinces, Madras and Bombay (enumerated in order of importance). But it is significant that the exports of the United Provinces and of the Central Provinces have manifested extreme fluctuations for some years past. Thus from the United Provinces the exports in 1899–1900 were 236,718 cwt.; in 1902–3, 161,670 cwt.; in 1903–4, 140,617 cwt.; and in 1906–7, 164,222 cwt. The exports of the Central Provinces manifest a decline; thus in 1899–1900 they were 86,187 cwt.; in 1903–4, 63,079 cwt.; and in 1906–7, 42,665 cwt. So also the exports of
TRADE IN GHI

Rajputana and Central India have shown corresponding fluctuations. In 1899-1900 they were 63,756 cwt.; in 1902-3, 151,451 cwt.; in 1903-4, 130,296 cwt.; and in 1906-7, 83,035 cwt. An expanding proportion of these Central India and Rajputana exports are consigned to the United Provinces, thus making up apparently the deficiencies of these provinces. A large percentage of the total exports are, however, consigned mainly to the port town of Calcutta, followed by Bombay, and appear again in the foreign exports from these towns.

Turning now to further provincial details, mainly imports: Assam, with its great herds of buffaloes, exports no ghi but draws upon Calcutta and the Province of Bengal for about 9,000 to 31,000 cwt. Bengal Province drains its foreign supply chiefly from the town of Calcutta. The United Provinces, as already said, import largely from Rajputana and Central India. The Panjáb annually exchanges about the same amount, namely from 11,000 to 34,000 cwt. Sind buys largely from Central India and Rajputana and Bombay, a quantity varying from 29,000 to 50,000 cwt. The Central Provinces are self-supporting, since they practically import little ghi but export a large amount. The traffic to and from Bombay Presidency is subject to extreme fluctuations. The imports in 1900-1 were 121,257 cwt.; in 1903-4, 10,376 cwt.; and in 1906-7, 10,348 cwt. The exports, on the other hand, were in 1900-1, 16,134 cwt.; in 1903-4, 54,157 cwt.; and in 1906-7, 97,166 cwt. Bihar takes little or no part in the traffic in ghi, but its imports are double those of its exports. Madras Presidency is self-supporting, since it imports very little, but exports very largely to its own ports and to Mysore and Bengal. It has already been observed that Rajputana and Central India export very largely, chiefly to the United Provinces, Sind, Bombay and the Panjáb, in the order named, but in years of famine or scarcity these States also import. Lastly, it is significant that Mysore with its herds of fine cattle exports no ghi to speak of, but is a fairly large receiving centre, the imports averaging about 14,000 cwt. derived from Coimbatore district in Madras.

The most noticeable feature of the Coasting Trade is the traffic, chiefly from Bengal (followed by Madras), to Burma, which in 1905-6 was valued at Rs. 17,01,609. [See Sesamum, p. 986.]

Trans-frontier Trade.—A fairly large quantity of ghi is brought across the land frontiers of India. The imports and exports by these routes during the years 1902-7 were as follows:—

The import traffic is thus exceedingly valuable, and Kashmir stands unmistakably first. Lawrence observes, “It is by far the most important article of the export trade of Kashmir.” The supply of ghi sent to India from that State was in 1906-7, 74,096 cwt., valued at Rs. 36,23,577. This may fairly be called a prosperous trade, since the figures just mentioned are nearly four times those of twenty years previously. Then come Dir, Swat and Bajaur, which furnished India with 50,544 cwt., valued at...

ANIMAL FATS AND OILS

Trade in Ghi

Nepal. Rs. 23,57,459; and lastly Nepal sent 42,765 cwt., valued at Rs. 22,09,334. The Kashmir ghi goes to the N.W. Frontier Province and the Panjáb; the Dir, Swat and Bajaur also into the N.W. Frontier Province; and the Nepal into the United Provinces and Bengal.

The re-exports of foreign ghi are unimportant, but have ranged from a valuation of Rs. 1,037 up to Rs. 2,07,186.

Foreign. Import.

Foreign Trade.—The imports being the least important may be disposed of first. This traffic is subject to extreme and sudden fluctuations. In 1876 the imports of ghi were valued at Rs. 2,76,395; in 1880-1, Rs. 16,486; in 1886-7, Rs. 7,03,432; in 1890-1, Rs. 4,13,299; in 1896-7, Rs. 4,28,432; in 1900-1, Rs. 10,71,024; in 1901-2, Rs. 4,17,476; in 1902-3 they were 21,370 lb., valued at Rs. 8,515; in 1903-4, 127,868 lb., valued at Rs. 50,722; and in 1906-7, 492,493 lb., valued at Rs. 2,13,861. The supply comes from Mekran and Sonmiani, Turkey-in-Asia, the neighbouring pastoral tracts of Southern Baluchistan, and recently from East Africa.

It is consigned mainly to Sind and Bombay.

Turning now to Exports, these for many years past have manifested a continuous expansion. In 1876-7 they were 1,004,661 lb., valued at Rs. 3,57,250. Twenty years later (1896-7) the figures were 3,672,349 lb., valued at Rs. 15,00,990, and during recent years which returns are available they were in 1902-3, 6,418,045 lb., valued at Rs. 27,26,750; in 1903-4, 5,390,865 lb., valued at Rs. 22,90,825; in 1904-5, 6,097,917 lb., valued at Rs. 26,67,250; and in 1906-7, 4,884,252 lb., valued at Rs. 22,65,443. By far the most important centre is Calcutta, followed by Bombay, and the receiving countries may be said to be the Straits Settlements, Natal, Aden, Ceylon, Hongkong, Mauritius, British East Africa, Aden, etc. An effort was made some few years ago to foster the traffic in Indian produce sent to Australia, and ghi at that time attracted considerable attention. But the trade cannot be said to have materially expanded.

Other Animal Fats.—In conclusion it may be desirable to extend this brief review of the traffic in ghi so as to include all animal oils and fats, since these are often closely associated with ghi. The imports are Animal Oils, Butter, Ghi and Tallow. The traffic in the last mentioned is a large and prosperous one. In 1876-7 the imports of Tallow were 305,088 lb., valued at Rs. 62,671; in 1903-4, 2,352,224 lb., valued at Rs. 5,93,127; and in 1906-7, 4,125,744 lb., valued at Rs. 9,14,834. Next in interest are the Animal Oils, which in 1876-7 were 3,246 gallons, valued at Rs. 10,664; in 1903-4 were 389,256 gallons, valued at Rs. 4,45,217; and in 1906-7, 584,428 gallons, valued at Rs. 5,70,655. The lard and animal oils to some extent doubtless manifest the demands of the soap and candle works of India. The butter trade has been already noticed (p. 477), and need not be further mentioned. It is not known to what extent the imports of butter may in reality be margarine. But by adding the tallow, animal oils and butter to the ghi, the total imports of these substances were in 1903-4 valued at Rs. 14,05,602, and in 1906-7, Rs. 19,65,986. Similarly the exports may be briefly discussed. These are Animal Oils, Ghi, Lard and Tallow. In 1903-4 these were valued collectively at Rs. 25,52,340 (ghi being, as will be seen from the figures above, by far the most important article); in 1905-6 the corresponding total was Rs. 30,75,319; and in 1906-7, Rs. 23,84,765.

[Cf. Institutes of Manu, ii., 29; iii., 274; iv., 39, 233; v., 37, 144; vii., 131; 482]
5. **CHEESE.**—Cheese as known in Europe can hardly be said to be made in India (except at the modern dairy farms under European supervision). Curd or *chhena* is prepared by boiling milk and throwing into it, while still very hot, some acid milk or other acid substance (such as lime or tamarind-juice) or a vegetable rennet; after a time it in consequence coagulates. The curdled milk is put into a cloth and the whey (*mastu*) expressed or drained away, the result being a kind of soft cheese (often called in India cream cheese). Many localities are noted for their cream cheeses, such as Hughli, Dacca, etc. Sen gives the following account of the Panakona, Sylhet, or so-called Dacca cheeses:—"As soon as the milk is taken from the buffalo, it is put in an earthen vessel and rennet is mixed with it at the rate of a seer to a maund of milk. About two hours after the curd is broken with the hand and put in small quantities in shallow bamboo baskets known as *dalis*. Next day it is mixed with a little salt and repeatedly cut across with a knife, and each time the knife is passed through it the curd is pressed with the palm of the hand. This process is repeated for three consecutive days, and altogether 2$\frac{1}{2}$ seers of salt are used to a maund of curd. The cheese is then left to cure. This cheese is sent to Dacca, whence it is exported as Dacca cheese. A maund of milk gives 10 seers of cheese. The price of buffalo milk here is from Rs. 3–8 to Rs. 4 a maund. The whey is kept aside for a day or two, when the oily matter floating over it is removed and made into *ghi*, and the rest of it thrown away."

Lawrence says the Gujars and Pathans of Lolab make a kind of cheese they call milk-bread. He mentions an experiment in the manufacture of European cheese, and affirms that Kashmir might supply the British troops with good cheese and butter. At the Dairy Farms of Poona and Aligarh excellent cheddar cheeses have been produced (*Agri. Ledg.*, 1895, No. 5, 64). For cheese made from peas, consult Pogson (*Man. of Agri. Ind.*, 1883, 186); also see *Glycine* (p. 565). The following are the better known Indian vegetable rennets:—*Withania coagulans*, *Crotalaria Burhia*, *Lencas Cephalotes*, *Razya stricta*, *Streblus asper*, and apparently also *Curthamnus tinctorius*.

**Trade in Cheese.**—The **Imports** of cheese are much larger than might at first sight be realised, and seem on the whole to be increasing. In 1899–1900 they stood at 872,296 lb., valued at Rs. 5,34,278; in 1902–3 1,123,260 lb. and Rs. 6,18,577; in 1903–4 they had slightly decreased to 966,492 lb. and Rs. 5,34,158; but rose again in 1904–5 to 1,228,707 lb. and Rs. 6,29,274, and in 1906–7 to 1,275,111 and Rs. 7,04,487. Bombay and Bengal each receive on an average cheese to the value of 1$\frac{1}{2}$ lakhs.

Sind takes about a lakh and Madras and Burma each half a lakh. About two-thirds of this supply is drawn from the United Kingdom, the balance from Holland, Belgium, Italy and Australia. The **Exports**
of Indian cheese are at the present unimportant. In 1903–4 they were 4,980 lb., valued at Rs. 2,625, and in 1906–7, 4,543 lb., valued at Rs. 2,784.

[Cf. Montgomery Martin, Hist. E. Ind., ii., 942–3; Mad. Exp. Farm. Rept., 1883, 76; Sen, l.c. 57; Mollison, l.c. 63–8; Lawrence, Valley of Kashmir, 1895, 360; Collis Barry, Legal Med. Ind., 1903, 562.]

**BLACKWOOD OR ROSEWOOD**

of Indian cheese are at the present unimportant. In 1903–4 they were 4,980 lb., valued at Rs. 2,625, and in 1906–7, 4,543 lb., valued at Rs. 2,784.

[Cf. Montgomery Martin, Hist. E. Ind., ii., 942–3; Mad. Exp. Farm. Rept., 1883, 76; Sen, l.c. 57; Mollison, l.c. 63–8; Lawrence, Valley of Kashmir, 1895, 360; Collis Barry, Legal Med. Ind., 1903, 562.]

**DALBERGIA LATIFOLIA**

Blackwood

D.P.,

**DALBERGIA, Linn., f.**; Fl. Br. Ind., ii., 230–8; Prain, Species

1. *D. assamica*, Benth., is the medowoo of the tea planters (Watt and Mann, Peas and Blights of the Tea Plant, 1903, 141–4). 2. *D. cultrata*, Grév., yendike or *yinna* is a fair-sized tree common in deciduous forests throughout Burma. It is said to exude a red resin, to furnish a useful oil, and to be utilised by the Karens for propagating the lac-insect. The heart-wood is blackish and ebony-like, often streaked with red. It is exceedingly durable, and is used for making wheels, agricultural implements, spear-handles, etc., and sometimes for carving.

3. *D. lanceolaria, Linn., f.* is the takoli, bithia, chakemdia, angaria, piri, chapot airo, gengri, dandous, tantosi, nal valanga, pedda sópara, etc. A deciduous tree of the Sub-Himalayan forests from the Jumna eastward, ascending the hills to 2,500 foot; also in Central and South India and Bombay. An oil is expressed from the seeds, and the leaves and bark are reported to have medicinal properties. The timber is said to be useful in building. 4. *D. Oliveri*, Gamble, is the lamaijan or tabuvik tree of the *eng-daiing* forests of Upper Burma (Wuntho and Bhamo). It attains a height of about 60 feet and girth of 4 to 6 feet. The wood is handsome, reddish, hard, close-grained, and takes a fine polish; is very like some of the South American rosewoods. It is largely used for axe-handles, dog-cart shafts and other purposes for which great strength is required and is employed in the Royal Indian Marine dockyard at Mandalay for bushings to propeller-shafts, in place of Lignum-vite (Guaiacum officinale).

**D. latifolia, Roxb.;** Prain, l.c. 80–1, pl. 62; Thurston, Ind. For., 1894, xx., app.; Koorders, in Ind. For., 1894, xx., 282; Watt, Ind. Art at Delhi, 1903, 100, 126–34. The Blackwood or Rosewood of Southern India, *sital* (or *swet-sal*, white *sál*), *shisham*, *sisu*, *sissu*, *satsiya*, *rute*, *ruzerap*, *tali*, *kalarukh*, *iti* *jitengi*, *eruvadi*, *yerugudu*, *jitali*, *bitti*, *thodagati*, etc. A deciduous tree fairly plentiful from the submontane forests of Nepal, Sikkim to Chota Nagpur, Oudh, the Central Provinces, Central and Western India to Southern India. It attains its greatest size in the Western Ghats, south to Wynnaad and Travancore, and ascends the hills to altitudes of 3,500 feet. Gamble (l.c. 250) says it is found in dry forests with teak and bamboo, as well as in moist evergreen jungles. It may reach a height of 80 feet and a girth of 12 to 15 feet, but it is of slow growth, especially at first. It is easily propagated by seed and is readily self-sown.

The wood weighs from 50 to 66 lb. per cubic foot, and sinks in water before being seasoned; it has a fine handsome grain, and is exported from the forests of Kanara, Malabar and Travancore to Bombay, Kathiawar, Kach, Karachi, London, Havre, Hamburg and Chinese ports. The planks when not well seasoned have a tendency to split longitudinally.

In India it is extensively used for furniture, cabinet-work, knees of vessels,
agricultural implements, combs, etc., for the vases and other ornamental articles of Trichinopoli, and for the finely carved chairs, tables, etc., which constitute the well-known blackwood furniture of Bombay. The art of making this furniture was introduced many years ago, and to this day it is mainly produced by the Portuguese inhabitants. Of late, popular fancy has discarded blackwood and good specimens of the furniture are said to be scarcely procurable. But most famous perhaps of all black woodwork is the Dravidian and Chalukyan carving of Madras Presidency and Mysore. If it is desired to darken the colour, this may be effected by rubbing the wood with oil until what is often spoken of as imitation ebony is produced.

Outturn, Trade, etc.—The outturn of this wood in Madras, as recorded in the Madras Forest Administration Reports, was 2,374 cubic feet in 1900-1; 6,306 cubic feet in 1901-2; 11,808 cubic feet in 1902-3; and 10,182 cubic feet in 1903-4. These are the only available statistics of outturn, sale or export. In 1895 inquiry was made in London as to prices which might be obtainable for Indian rosewood. A report was subsequently issued by Mr. J. R. Royle, at that time Secretary of the Indian Section of the Imperial Institute. It was pointed out by the English firms consulted that the wood suffered from several disabilities. It is gritty and therefore much harder in the working than other cabinet timbers; it loses its bright colour and goes almost black after being cut and exposed; it is somewhat porous, and therefore absorbs the polish to a large degree.

As rosewood it is inferior to Brazilian, though superior to that of Madagascar or Honduras, but in England it has to compete with the cheap and usually reliable rosewoods sent from Jamaica. It would, however, prove specially useful where great width is required, as for example for table-tops, large carcass ends, and mouldings. Further it has to be remembered that rosewoods of all sorts, both for furniture and decoration, are very largely subject to the caprice of fashion, and at the time of the inquiry the European demand was very small. Gamble says that the usual London rate for good timber is about £10 per ton, and that there would seem still to be scope for greater activity in utilising the English market for the sale of at least the best pieces of Indian rosewood. In the reports mentioned above, one of the firms consulted thought that "the rate should not exceed 10d. to 1s. per superficial foot cut one inch," but that quotation, allowing 58 lb. to the cubic foot, would work out to about £23 per ton for picked, ready-sawn timber, a price thus considerably above the £17 10s. per ton reported to have been paid for a fine piece sent to London in 1878. On the other hand, some of the reports speak of Indian rosewoods as fetching an average of only from £5 to £8 per ton, but these low prices were for large lots not specially selected. Lastly, the quotations published by the trade for May 1905 were "Rosewood £5 to £12 per ton." "But it must be clearly borne in mind that rosewood of all grades is not at present popular." "At the present time East Indian is in fair demand and stocks are not heavy." In the Indian Forster (loc. cit. xx., app. 3) the selling prices, from the Madras forests, were given as from Rs. 20 to Rs. 75 per ton, according to distance from the coast, but in out-of-the-way places it could not be sold even at Rs. 10 per ton; from Travancore about Rs. 1-8-0 per cubic foot good quality (= about Rs. 58 per ton); of Bombay from Rs. 30 to 50 per ton. Logs for export should not be less than 24 inches in diameter, have the sapwood removed, and be exported in the round. The length should not, as a rule, be less than 15 feet, although shorter lengths find a market.

D. Sissoo, Roxb.; Notes on Changha Manga in Ind. For., 1895, xxi., 286-8; Prain, l.c., 57-8, pl. 34; Eardley-Wilmot, Ind. For., 1898, xxv., app. The sissu, shishu, sissu, shisu-kad, tali safea, shin, nelkar, sheva, zagar, tanach, yette, karra, bidri, sinsapá, etc. A deciduous tree of the Sub-Himalayan tracts from the Indus to Assam, ascending to 3,000 feet, but probably nowhere in India strictly speaking indigenous. Gamble remarks that it is often, however, gregarious on the banks of sandy, stony, torrential rivers. On higher lands it may grow, and grow well, though not gregariously unless planted. Cultivated and often self-sown on the plains of India. But even when the trees are growing close together the shade given is light, hence sissu is an important shade-
tree with tea planters of Dehra Dun. The seed on germinating at once makes a great length of root compared to its growth above ground, a circumstance that greatly minimizes the chance of its being swept away when spontaneous germination takes place within the sandy and stony beds of rivers.

Propagation.

Sissu coppices well and reproduces itself freely from suckers. Artificially it is best grown from seed deposited in suitable positions, because transplantation is sometimes difficult and the young trees have to be protected till fairly established. It grows most luxuriantly on low-lying sandy tracts and has been successfully raised on irrigated lands, e.g. at Changa Manga in the Panjab, at Shahdera near Lahore, etc. But it is reputed that the timber of trees raised under irrigation is of poor quality and subject to serious damage by fungi. When young the growth of sissu is very quick; it is said to attain 2½ feet of girth in twelve years, but as it gets older its growth gets slower. The full height of a tree is about 60 feet or so, and in girth it is rarely more than 6 feet. It is very successfully grown in Sind, and is said to be the best hardwood of the Panjab.

Uses.

The wood is very durable, seasons well and does not warp or split. It is highly esteemed for all purposes where strength and elasticity are required, as, for example, for agricultural implements, wheelwrights' work, frames of carriages, boat-building, etc. At one time it was extensively employed for gun-carriages, but owing to the limited supply of the timber it is now very little used for that purpose. It is one of the finest timbers in India for furniture and wood-carving, and is in regular demand all over the North of India. In Upper India the shisham wood (D. Sissoo) replaces very largely the rosewood (D. latifolia) of Western and Southern India. It attains its position of greatest importance in the United Provinces, the Central Provinces and the Panjab, being replaced on the north by deedar and to the south by sal and rosewood. The wood-carving of Saharanpur, Farakhabad, Lucknow and Nagpur and the inlaid work of Chintot, Hoshiarpur, Jallandhar and Mainpuri are largely on shisham. In Rajputana also, this wood is to a considerable extent employed by the wood-carvers, but for particulars of the methods of treatment and styles of carving the reader should consult Indian Art at Delhi, 1903 (103, 108-9).

Owing to the fact that the sissu very rarely grows straight, the timber is not of much use for beams though it is in much demand for knees of boats. It has been successfully tried for railway-sleepers, is an excellent fuel and makes very good charcoal, but it is too expensive to be utilised for these purposes. The wood is said to yield an empyreumatic medicinal oil, and the rasplings of the wood are official, being regarded as alterative. Near towns the tree is largely lopped for fodder and the fallen leaves collected and valued as fuel by the sweetmeat makers.

Nepal Paper.

DAPHNE, Linn.; Fl. Br. Ind., v., 193-4; Collett, Fl. Sim., 1902, 485; Gamble, Man. Ind. Timbs., 577; THYMELACEAE.

There are two or three shrubs of economic value which belong to this genus: - 1. D. cannabina, Wall., is the most important and may be spoken of as one of the best Nepal Paper Plants. It occurs on the temperate Himalaya from Chamba to Bhutan, at altitudes of 3,000 to 8,000 feet. It is the seburoa, seburos, satpura, dunkotah kaghuli, dhak chamboi, chamboi, barua, niggi, jeku, etc. 2. D. involucrata, Wall., is the chota aryli and is met with in Sikkim, the Khasia hills and Tenasserim, and in the countries where at all abundant it is used similarly to D. cannabina. 3. D. Mezereum, Linn., is not indigenous to India, but is often met, irrigated by Indian medical writers and is perhaps introduced and sold by the drug dealers. 4. D. oleolides, Schreb., is a small plant met with in the Western Himalaya from Garhwal to Afghanistan. It is best known by the following names - kūlīlā, kānlī, gandālīn (gandālīn), kaghūn, gech, pirkī buta, etc. The roots are boiled and given internally as a purgative; the bark and leaves are also said to be used medicinally; the berries are reputed to induce nausea, and according to Brandis, a spirit is distilled from them in the Sutlej valley. It is just possible, therefore, that this may be the Mezereum of Indian medical writers. It is commonly reported that camels will not eat it and indeed that it is poisonous to them.

5. Edgeworthia Gardneri, Meissn.; Fl. Br. Ind., v., 195 is a closely allied plant to the species of Daphne, and one which would seem to be an even more important
source of Nepal paper than D. cannabinum. It is a large elegant bush of the Central and Eastern Himalaya from Nepal to Bhutan, Manipur and Burmaindistinguish to China and Japan. It is known in India as the kaghuti, argili, etc., and might be called the true Nepal paper plant. The mitaumata of Japan, and, according to Hemsley (Journ. Linn. Soc., xxvi., iii., 401), is Edgeworthia chrysantha. It is regularly cultivated in that country for its paper bark.

NEPAL PAPER.—Quite recently Stein (Ancient Khotan, 1907, 426) has announced the discovery of an actual specimen of Daphne paper, the date of which has been determined as the middle of the 8th century. This was found in the ruins of Endero and was examined both microscopically and chemically by Prof. J. Wiesner. The material was found to be a well-macerated fibre of the Thymeleaceae, presumably Daphne. From the fact of no Daphne being known to occur in Eastern Turkestan, it has been inferred that the paper had been made in Tibet. [Cf. Wiesner, Denkchr. Akad. Wiss. Wien., Math.-Nat., xxxi., 17-8.] It is thus permissible to regard this as the oldest recorded sample of what is commonly spoken of as "Nepal Paper." But even during the beginning of the 19th century, Nepal did not produce enough Daphne paper to meet the demands of India. Buchanan-Hamilton (Acc. King. Nepal, 1819, 232-3) tells us that the local supply did not suffice and that Nepal had to import both the paper and the raw material from Tibet. Kirkpatrick (Acc. King. Nepal, 1811, 80) speaks of one of the two species seen by him as being the paper-plant of Tibet. It would thus be more correct were the paper in question called "Tibet Paper," and this change in name would be in direct accord with the discovery narrated by Stein. [See Paper and Paper Materials, p. 982.]

It is perhaps hardly necessary to repeat that there are two important plants from which the so-called Nepal paper is made:—(a) E. Gardneri and (b) D. cannabinum. Perhaps the earliest account by a botanist of this paper-material is that given by Wallich, who figures and describes three species and tells us that Edgeworthia was regularly cultivated in Nepal for its paper-yielding bark. In 1837 Lord Auckland, while Governor-General of India, called for further information, and various reports were in consequence prepared and submitted to the Government of India. Atkinson and other more recent writers repeat the statement that the Bhot country sends to this day large supplies into Nepal. Still, however, no material progress has been made, and Nepal paper is no nearer than it was a hundred years ago to becoming a commercial commodity. In fact it may be doubted whether any bark fibre is ever likely to be of value, unless for very exceptional purposes; it is too expensive as a modern paper-material. Nepal, Kumaon and Sikkim are the chief regions where India's supply of the so-called Daphne or Nepal paper is obtained. The reader should consult Bronsometia, p. 180, and Paper Materials, p. 566, for further particulars. [Cf. Wallich, As. Res., 1820, xiii., 383-90 and 3 pl.; Lace, Journ. Linn. Soc., 1891, xxviii., 312; Morris, Cantor Lect. in Journ. Soc. Arts, 1895, lixiii., 938; Dodge, Useful Fibre Plants of the World, 1897, 146; Kanjilal, For. Fl. U. Prov., 1901, 281; Wiesner, Die Rohst. des Pflanzenr., 1903, ii., 432; Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 121-2.]

Datisca Cannabinia, Linn. ; Fl. Br. Ind., ii., 656 ; Pharmacog. Ind., 1891, ii., 98 ; Bentham, Rev. Cenn Storici di Targioni-Tozzetti in Journ. Hortic. Soc., 1855, ix., 152 ; Datiscaee. The akalbir, akalbar, kalbar, bhang-jala, bajr, waftangel (waft-lanj), drinkhari, sida atsu, etc.

History.—The vernacular names given to the species of this genus can hardly be said to distinguish the various forms that exist. The Sanskrit names
Datura

POISONOUS PLANTS

Datura or dhatura and unnatta mean "insane," and hence might have been given to an introduced plant (on its properties being recognised); in fact might be upheld as not necessarily involving an ancient knowledge. The better known vernacular names are either derived from the above or have meanings in the languages to which they belong that denote the well-known properties of the drug. As met with in India the species of Datura have the appearance of introduced plants. They frequent waste lands near human dwellings or invade the borders of fields or cover abandoned cultivation. They do not exist as individual plants that take their own positions in a blended vegetation, but appear as invading cohorts and here and there become so abundant as to exterminate all other plants. No form of Datura exists, in fact, under such conditions as to justify the emphatic opinion that it is indigenous to India.

It is customary to read of "the white-flowered datura" and of "the purple-flowered kala-datura" as if these conditions implied specific distinctions. Not only so but many writers affirm that the purple-flowered form is a more deadly poison than the white, but that belief doubtless rests mainly on the theory of signatures. Any of the Indian forms may have white or purple flowers, may have single or double flowers, and may have thorny or smooth fruits. How far the chemical properties of these plants are affected by cultivation, by soil or by climate, it is at present impossible to discover. One thing, however, is certain, that the Daturas have been, and to some extent are still, cultivated plants, so that the differences recognised between the so-called wild plants of one region and of another may be due to their being more recent escapes from a special cultivation. Possibly all the Indian forms constitute but one or at most two species. D. Stramonium might be called the type of the temperate and alpine series and D. Fastuosa that of the tropical assemblage.

D. Metel, Linn.—This is found chiefly on the N.W. Himalaya and the mountains of the Deccan.

D. Stramonium, Linn.—Is met with on the temperate Himalaya from Baluchistan and Kashmir to Sikkim. The capsule is erect and deeply four-valved. This seems far more likely to be the white Datura.
of medical writers than var. alba above. It is described as the tattur of the Panjāb and the kachola of Afghanistan. Lawrence (Valley of Kashmir, 1896, 77) mentions that Kashmir exports the seeds largely to the Panjāb and that they fetch Rs. 5 a maund. The var. Tatula appears to be the plant of which the dried fruits (strung on thread) are sometimes imported into India from Persia. These imported fruits are sold under the name yharbūlī in Bombay and maratia mūghū in Madras. Poisoning from eating tatuleh is recorded in the Kew Bulletin (1889, 275–8; 1896, 233).

The medicinal uses of the species of Datura centre chiefly in their poisonous property and in the pernicious and criminal advantage often taken of these all too prevalent plants. Barry points out that the seeds of Datura may be mistaken for those of Cupsicum. Reduced to a powder they are criminally mixed with food and can often only be detected through the microscopic structure of the fragments of the seed-coat that may be discovered in the food or the contents of the stomach.

**Habitat.**—A native of Kashmir and the Western Himalaya at altitudes of from 5,000 to 9,000 feet. It is also commonly held to be a native of Europe (except the extreme north), of Abyssinia and North Africa, of Madeira and the Azores, and of North Asia eastwards to Siberia and Kamshatka. Throughout India it is cultivated by the Europeans, mostly from annually imported seed, and by the Natives from an acclimatised if not indigenous stock. In many parts of the country a greenish-white carrot is preferred as being very hardy and productive. This rises some two or three inches above the soil, is a coarse root which possesses little of the flavour of the European carrot, but is able to withstand the extreme heat of summer, and may be raised in some parts of the country throughout the year. It thus produces a return at seasons when other tubers or roots are scarce or not available. This is particularly the case in Bihar (Patna) and some parts of the United Provinces.

**History.**—Sir George Birdwood (Memo. Carrot for Famine Relief in N. Ind., 1896) gives a detailed and learned account of the history of this plant. This occupies many pages, and can hardly be abbreviated without greatly lessening its value. The carrot appears to have been regularly used in India from fairly ancient times. The Emperor Baber (Memoirs, 1519 (Leyden and Erskine, transl.), 1932, 347) narrates his having eaten a dish of fried carrots. In the Ains-i-Akbari (Blochmann, transl., 63–4, 67) mention is made of “wild carrots” (shaguq) and of cultivated carrots. Terry (Voy. E. Ind., 1655 (ed. 1777), 91–2) speaks of the good carrots of Surat, and Fryer (New Acc. E. Ind. and Pers., 1672–81, 119) makes special mention of those of the Deccan. While much reliance cannot be placed on names of plants as historic evidences, it is significant that throughout the languages of India, indeed from Central Asia to Cape Comorin, there should prevail in every language a name for the carrot (gāger, gājār, gāzara, gārjara, etc.) which seems to have come from a common source. To that name is frequently added a further word meaning “root” or “tuber.” Thus in Tamil it is the
THE CARROT

DAUCUS CAROTA
Carrot
gajjara-kellangu. The derivation of the Latin name carota and of the French carotte is probably direct from the Greek karoton. The Sanskrit garjara originated the Persian zardak and the Arabic jegar. In fact, the evidence of cultivation would lead to the inference that the carrot spread from Central Asia to Europe, and if so it might be possible to trace the European names from the Indian and the Persian. Indeed the carrot seems to have been grown and eaten in India while in Europe it was scarcely known as more than a wild plant. In Anglo-Saxon it was weal-mora, wall-mora, walec-mora, elap-wype, but it was confused with the parsnip till about the end of the 11th century. These names recall the German mohre, moraka, the Russian morkov, the Sanskrit mula, mulaka, and the Kashmiri mor-mujb, and they all denote "root."

Bengal.
Sowing Season.

Cultivation.—Bengal.—A writer in Indian Gardening (Oct. 27, 1898) says in his experience (in Chumparan) the seed should be sown broadcast early in November. Of the imported varieties the Large White Vosges and White Belgian succeeded best. The crop continued to yield till the end of May. Other writers in the Northern and Central portions of the province speak of sowings in August and the crop coming into season in January and February. Muckerji (Handbook Ind. Agri., 1901, 357) observes that the carrot has a special value as a nourishing famine food and fodder. The Red Mediterranean variety grown at the Cawnpor Experimental Farm seems to be the best. The Yellow Mediterranean is most highly spoken of as a cattle food. The yield of the White Mediterranean carrot is almost equal to or even higher than that of country carrots, but the roots are hard, coarse and insipid. When grown without manure the country carrot gives a much larger yield than any of the European varieties. The proper time for sowing carrot seed in the plains is from September 15 to October 15. It is best to sow in drills and ridge the drills after the plants have appeared, then thin out. The quantity of seed used is 8 to 12 oz. an acre. The yield comes to 200 to 500 maunds per acre, if loose soil near the village be chosen, deeply cultivated, well pulverised, weeded and irrigated. The seed had better be mixed with wood-ashes at the time of sowing, and unless the soil is quite moist, water should be poured in the drills immediately after sowing. [Cf. Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 166-7.]

U. Prov.

United Provinces.—Duthie and Fuller (Field and Gard. Crops, 1893, pt. iii., 9) say the area occupied by the carrot is not separately estimated in the agricultural returns, but the average under carrots, turnips and radishes for the three years ending 1889-90 amounted to 41,463 acres. The carrot is generally sown in September or October; the roots are ready for use after two months, and may last for three or four months. A loamy soil is preferable. Under favourable conditions an outturn of over 200 maunds is possible. At Cawnpor 60 maunds is said to be the average, but at Basti only 33 maunds. The bazar price in ordinary seasons is from 8 to 16 sees an anna.

Panjáb.

Panjáb.—Brief notices are made of carrot cultivation in the Panjáb. In Jhang it is said "the zamindar's food consists largely of carrots" (Replies Famine Comm., 228). In Sialkot (Gaz., 68) the carrot is spoken of as grown all over the district, and the superior European kinds are little known.

Bombay.

Two Crops.
Transplanted.

Bombay.—Of Gujarat it has been said that carrots of two kinds are cultivated—"the long-rooted" and the "blunt spindle form." They are grown at various times in different parts of the province, generally in garden beds from seeds sown broadcast, but are sometimes transplanted from nurseries during the rabi season. They take three months to mature,
CULTIVATION—TWO CROPS

DELPHINIUM

ZALIL

though by nipping off the heads growth may be prolonged. The young plants are also taken up when half grown and sent to market. The produce is from 5,000 to 10,000 lb. an acre. The carrot is also grown in Gujurat from August to May, and the crop gathered four months later. In Kach it is much raised as a field crop. In Poona and Khandesh the carrot is cultivated very largely on black soil, with the help of manure. Of Ahmednagar a curious process is reported of obtaining carrot seed: When the crop is ready the husbandman cuts off a thick slice from the crown end of the carrot. This he puts two fingers deep below the soil in any place where there is a liberal supply of water. After a few weeks the roots produce a vigorous flower stem, the seed of which is gathered four or five months after having been thus transplanted. There are accordingly two crops in the year—one, the root produced from the seed, the other the seed produced from the root (see *Raphanus sativus*, var. *candata*, p. 912). In the Deccan, according to Woodrow (*Gard. in Ind.*, 1889, 340), the carrot may be grown as a culinary vegetable where the rainfall is not over 25 inches annually, during the rainy season. Large sowings for fodder should be made in October and November, and if late rains are favourable good crops may be grown on a deep retentive soil without irrigation.

*Mysore* is stated to produce a very good quality of carrot, but in Madras and Burma the root seems to be raised only as a garden vegetable.

**Food and Fodder.**—The so-called root constitutes an important vegetable in the markets frequented by the European community. Although certain classes of Hindus in Bengal object to eat the carrot, on account of some fanciful resemblance to beef, still the Natives of India, as a whole, are year by year taking more kindly to it. At the same time it must be added that, though by the Muhammadans and certain Hindus the carrot has been cultivated for ages, it is only within recent years that it has become a recognised article of diet. By certain classes the young carrots are used only as pickles. By others “the root is first boiled in water, then squeezed out and cooked in *ghi*.” In Europe it has become a recognised article of cattle food. Carrot-tops afford a useful fodder, and the contention that the roots might be resorted to in times of famine is strengthened by the fact that the tops would be of value to the cattle. [Cf. *Agri. Ledg.*, 1898, No. 12.]

**Seed.**—The seed yields by distillation a medicinal oil. [Cf. *Taleef Shereef* (Playfair, transl.), 113.] In the Hemp Drugs Commission Report (iv., 415) mention is made of the seeds constituting one of the spices used in flavouring *bhang*. Lawrence (*Valley of Kashmir*, 67) says carrot seeds are employed to mix with caraway. The chemical constituents of the root are crystallisable and uncrystallisable sugar, a little starch, gluten, albumen, volatile oil, vegetable jelly, malic acid, salina matters, lignin and a peculiar crystallisable, ruby-red neutral principle, without odour or taste, called *carotin*. [Cf. Pharmacog. *Ind.*, ii., 136.]

**DELPHINIUM DENUDATUM, Wall.**; *Fl. Br. Ind.*, i., 25; *Ranunculaceae*. The *mirbisi* or *jadwar* of certain writers (names that more strictly speaking denote species of *Curcuma* or of *Aconitum*, which see); is also the *minila* of the North-West Himalaya. *D. saniculacefolium, Boiss.*, has been supposed by some, but incorrectly, to afford the *asbarg* dye and medicinal flowers.

*D. Zall*, *Aitch.* & *Hems.*, an abundant larkspur in Khorasan at altitude of 3,000 feet, where its spikes of golden flowers give a wondrous
The dried flowers and fragments of the flowering spikes constitute the asargs. It is the ghafiz, aspereag, gul jahil, zailil, zarir, tracyman, etc. Is imported by Trans-frontier traders, who bring it to Multan and other Panjab towns where it is employed along with akalber and alum to dye silk. Chem. Soc., 1898, No. 190; Imp. Inst. Tech. Repts., 1903, i., 214; ii., 221.]

**Indian Species and Varieties.—** The account given in the Dictionary of this very difficult and imperfectly known genus of edible plants was written in 1888. It was subsequently arranged by the Government of India that a concentrated effort should be made to secure fuller and more accurate information. Collections of live tubers, accordingly, began to arrive in 1894, and continued to be received during the subsequent years. It was agreed that the yams as received should be cultivated in the Royal Botanic Gardens, Calcutta. They are therefore being systematically studied. A preliminary and unofficial report has already appeared, written by Prain and Burkill, and descriptions of certain species have been given in the Journal of the Bengal Asiatic Society, but further material and more detailed information are deemed essential before the final report can be given to the public, and this seems likely to assume the form of a monograph of the Indian species of the genus. All that need be attempted here, therefore, is to abbreviate the Dictionary article, and to abstract and incorporate from Prain and Burkill’s preliminary report (and all other recent publications) such additional information as seems calculated to bring the present account abreast of existing knowledge.

Prain (Bengal Plants, i.e.) sketches very briefly the classification that seems likely to be followed in the future. The Bengal species are referred to two great groups according as the stems twine to the left or to the right of the observer. This brings the following together as those that twine to the left—D. damonon, pentaphylla, tomentosa, butifera, deltoidea, and inaculata; those that twine to the right, D. angulina, aculeata, nummularia, Hamiltoni and alata. Within these groups the species are assorted according to the characters of the leaves, inflorescence, capsules, seeds and aerial bulbs. It may be useful to set forth in alphabetical sequence of their names the economic information of the chief Indian species and varieties:

**D. aculeata, Linn.;** Prain, l.c. ii., 1067; D. globra, D.E.P.; D. Wallachii, Hook., f., Fl. Br. Ind., vi., 295. A plant cultivated in Bengal, Assam, the Deccan, South India and Burma; in the last province it is apparently also wild.

This is the commonest of all the Indian cultivated yams. It is a large climber with quadrangular winged stems which twine to the right. The capsule is broader than long and the seeds winged all round. Leaves rather sharply angled. Inflorescence only occasionally produced and often zig-zag in structure. Tubers very frequently large, sometimes four to eight feet in length and as thick as the thigh (Conserv. For. Repts. S. Circ. Mad., May 1889), at other times small and globular like an average-sized potato. One or two species of yam are frequently alluded to in Sanskrit literature, and this would appear to be perhaps the form most often mentioned. Roxburgh assigned four or five tubers to sepa-
rate specific positions, chiefly on account of their shape and colour. He, however,
admitted that he would be quite prepared to accept all these races (for they
appear to be little else than races) as belonging to the same species. These were
D. atropurpurea, globosa, purpurea and rubella (Roxb., Fl. Ind., iii.,
797-801). They are classified into tubers elongate, at times club-shaped, the
flesh being white throughout in alata proper, pink under the skin in rubella,
purple throughout in purpurea; tubers short, roundish, and flesh wholly
white in globosa; rosy purple under the skin in globula, and rosy purple in
atropurpurea. J. D. Hooker places these names as denoting "imperfections
known and undeterminable species." Prain and Burkill, however, after a careful
study of the live plants, have recorded Roxburgh's four forms above named
under D. alata, Linn. and have formed varietal positions for each (Note, i.e.
1903-4, No. 846). These are as follows:—
(a) Var. alata proper; D. Hamiltoni, Hook., f. (in part). The White Yam.
This is said to be a large climber, fairly abundantly cultivated in Bengal,
Assam, the United Provinces, the Central Provinces, the Deccan, South India,
Burma and Ceylon. It varies very greatly, however, in some of its areas.
(b) Var. globosa; D. globosa, Roxb., Duthie and Fuller, Field and Gard. Crops,
pt. iii., 11; D. globosa, D.E.P., iii., 131; the Common Yam. This is a
climber that is fairly extensivly cultivated, more especially in the Central
Provinces and Madras. It is the chupri-alu, fermo-nari.
(c) Var. rubella; a large climber, extensively grown, especially in Bengal,
the Central Provinces, Western India and the Deccan. It yields a long tuber,
red outside, known as the guraniya-alu.
(d) Var. purpurea; the Dark Purple Yam: the Malacca Yam, or lab-guraniya.
A large climber fairly extensively cultivated.
D. anguina, Roxb.; Fl. Br. Ind., vi., 293; Prain, Beng. Plants, ii., 1066. A
large climber met with occasionally in the forests and jungles of the lower hills
in Nepal to Bhutan, also Chota Nagpur and Assam. The tuber is only eaten
by the poor or in times of scarcity, and is called kuuk-alu.
D. bulbifera, Linn.; D. sativa, Benth.; D. pulchella and D. crispa, Roxb.;
Hermann, Parad. Bot., 1698, t. 217; D. sativa, Wild. Duthie and Fuller,
Field and Garden Crops, pt. iii., 11, t. lxxx.; D. sativa, Linn. Hooker (Trimen,
Fl. Ceyl., iii., 279) calls this "the wild uneatable state of the cultivated
plant." This fairly extensivly climber is common in the hedges and thickets of
India and Burma. It is a distinct species, the capsule being longer than broad,
and the seeds winged at the base only; the leaves are bright shining green and
the transverse nerves rest within channels. The tubers are round, not larger
than a man's fist. The stem, like that of D. alata, bears numerous little tubers
by which the plant may be propagated. The aerial tubers also afford characters
by which the varieties may be separately recognised. The underground tubers
of the wild plant are insipid and often hardly edible, unless repeatedly boiled
and washed in running water before boiling. Nevertheless, the wild forms
collectively constitute a fairly important article of food in times of scarcity and
famine. [Cf. Acosta, Tract. de las Drogas, 1578, 321.]
(a) Var. bulbifera proper.—The agricultural states of this variety are often
designated in India as D. sativa, and the recently introduced forms are spoken
of as the Otaheite Potato. The wild tubers are regularly eaten, though more
bitter than the cultivated. An interesting officil correspondence recently took
place regarding the successfull conveyance (by Capt. H. D. Larymore) of seed-
tubers of the so-called Otaheite Potato from the Andaman Islands to West Africa.
(b) Var. pulchella; D. pulchella, Roxb.; D. sativa, Linn.; Fl. Br. Ind., vi.,
293 (in part); D. bulbifera, D.E.P. A climber fairly generally met with in
cultivation. It is in India often known as the rāt-alu.
(c) Var. crispa; Roxb., Fl. Ind., iii., 802. A fairly prevalent climber in
India and Burma, known as zamin-kand.
D. deltoidea, Wall.; Prain and Burkill, Journ. As. Soc. Beng., 1904, lxiii.,
pt. ii., suppl., 1-2, 5-6. This is a common species in the N.W. Himalaya at
altitudes between 3,000 and 8,000 feet—flowering time in May. It is an ex-
tensive climber, often covering trees more or less. Stewart gives a long list of
vernacular names which in the Dictionary it was suggested belonged to all the
species met with in Upper India. Even to the present day a distribution of these
names has not been accomplished. The tubers are often very large, but
apparently not eaten. In Kulu they are called shingli, and used for washing
wool. Stewart says that in Khayhan they are called kris and used in

washing silk. Lawrence (Valley of Kashmir, 75, 78) calls them krite (or krits), and remarks that they are much used in washing wool and also in medicine. The same tubers, according to Atkinson, are in Kumaon known as gun. Some writers appear to regard them as poisonous.

D. daemona, Roxb.: Fl. Br. Ind., vi, 289; Rec. Bot. Surv. Ind., 1898, ii, 274; 1903, ii, 143, 189. A large climber of the tropical forests of India and Burma. Stems twining to the left, sometimes prickly; leaves digitately 3–5 nerved; capsule longer than broad and seeds winged at the base only. This wild yam is extensively used as a famine food, chiefly in Burma and the Central Provinces and Central India. It appears never to have been cultivated. Some writers, however, say the roots are highly poisonous and cause intoxication but are rendered edible by boiling and steeping in running water, this treatment being repeated two or three times. Gammie (L.c. 190) says that when tigers kill cattle, the villagers insert a quantity of the flour from the powdered roots of the vaiga kand into the body of the "kill." The poison permeates the flesh to such an extent that when the tiger returns and eats the carcass it becomes infatuated and mad, and the villagers then make short work of it. Ridley (Malay Pl. Names, in Journ. Roy. As. Soc. (Strait Branch), 1897, 90) speaks of the tubers being used in the manufacture of dart poison. (Yearbook of Pharmacy, 1898, 62–3).

D. fasciculata, Roxb.: Prain, Beng. Plants, 1903, ii, 1066. The kidney-shaped yam, Karen Potato. A small climber somewhat like D. alata but more graceful; of a vivid green colour, the stem twining to left and dotted over with small wart-like prickles. Leaves pubescent reniform or orbicular with sharp stipular thorns. Tubers fasciculata, numerous, usually white, but in Burma and the Malay Islands a form exists which has reddish-coloured tubers. This is obviously derived from the wild D. spinosa, which differs only in the fact that the upper rootlets are spinose. Much confusion seems to exist regarding the name pindalu. In some localities of South India it denotes the white round tubers of one or two races of D. alata. In other provinces it is restricted to the present plant. I found (during special investigations conducted in 1894) the latter usage throughout Berar, where the clustered yam is fairly plentiful and popular. It is ordinarily grown as a garden crop near the homestead, on stakes 8 feet high and 2 to 3 feet apart, around pan-leaf houses, or in fields, along with the brinjal. In some localities, as for example Nirmal and Bassoine in Bombay, it is cultivated as a pure field crop. Roxburgh tells us that in his day it was grown to a considerable extent in the vicinity of Calcutta not only for food but to make starch. Being, in some respects, more like a potato than a yam it is often called the potato of this and that place—e.g. "Karen Potato."

D. giabra, Roxb.: Fl. Br. Ind., vi, 294; Prain, Rec. Bot. Surv. Ind., 1905, iii, 288; D. nummularia, Lamk.: Beng. Plants, ii, 1067. So far as India is concerned, however, it would appear to be rarely if ever cultivated, though the tubers are regularly collected and eaten by the hill tribes, more especially in times of scarcity and famine. It occurs on the lower North-West Himalaya, in Nepal, Sikkim, the hills of Bengal to those of South India and Burma, distributed to the Malaya Peninsula and China. It is very often called ban (wild) alu or aru (yam), shora-alu. [Cf. Wood, Rec. Bot. Surv. Ind., ii, 143.]

D. belophylla, Vogt (sp.); D. sagittata, Royle; Prain, l.c. 1064. It seems probable that this should be retained as a distinct species. It is a large climber met with on the lower Himalaya and mountains of Bengal (Parimath). The tubers are edible but the plant is not recorded as met with under cultivation.

D. oppositifolia, Illn.; Roxb., Fl. Ind., iii, 804; Fl. Br. Ind., vi, 292. A large climber with terete unarmed branches and with the leaves almost opposite. It is a native of tropical India from the Deccan to Assam, Sylhet, Chattagong, Burma, Ceylon and China. It is wild in India but appears to be cultivated in the Malaya and Java. It is one of the most important wild tubers with the people of the Deccan and Central Bengal. The root and aerial tubers are eaten as well as the young flowering spikes.

D. pentaphylla, Illn.; D. triphylla, Roxb.; Fl. Br. Ind., vi, 289; Rec. Bot. Surv. Ind., ii, 143; iii, 288; Prain, Beng. Plants, ii, 1066; Nuren-Kelengu, Rheede. Hort. Mal., vii, tt. 34, 35. The Kawan or Fiji Yam. Met with throughout tropical India on the lower hills from Kumaon to Burma, Ceylon and Malacca. It is an
extensive climber, the stem prickly below and sometimes bulbiferous. It affords large edible tubers that are eaten practically all over India, especially with the Kathodias of the Konkan, the Svarahs of Ganjam and the Lepchas of Sikkim. The flowering stems and young leaves are also eaten, especially in times of scarcity. But it is said to afford both poisons and innocuous forms, the latter being made edible by repeated boiling and washing. It is apparently, however, never cultivated in India, except perhaps in Pondicherry. [Cf. Circ. Roy. Bot. Gard. Ceylon, 1905, iii., 16-7; Achart, Quinze cents, Pi. dans L’Ind., 1905, 206.]

**D. spinosa, Roxb.—** This plant has been confused with *D. fasciculata* and *D. acutenta, Linn.* It is, in fact, placed by Prain (l.c. 1066) as a variety of *D. fasciculata*. Its most generally accepted names are *madhavalu* in Sanskrit and *mahali* in Bengali, but these are also assigned to *D. acutenta, Linn.,* so that it seems probable the two plants are often confused by the people of India as also by most botanists. The tubers are largely eaten in the countries where procurable.

**CULTIVATION.**—Of the yams above briefly indicated three species are very generally grown in India as subsidiary foods. These are *D. alata, D. bulbifera* and *D. fasciculata*. Under each of these species, however, there are several varieties and even a large assortment of cultivated races, so that the yams are not only varied but abundant plants. It is, in fact, only within the very driest tracts (such as some portions of Rajputana, Sind, the Western Panjab and the Deccan) that yams are not to be found. Wild yams are also very prevalent and constitute an important article of food with the poor, more especially the inhabitants of uncultivated tracts, and in times of famine they often become of the greatest possible value. Lewin (Wild Races S.E. Ind., 1870, 27) says that in the hills of that country wild yams are so plentiful that no man, able to search for food, need starve. Speaking in general terms, a line drawn from Khatmandu and Lucknow to Ahmedabad would sever India into two portions—the Southern (more especially its south-eastern tracts) might be described as the yam-producing area of India, and the Northern (more especially its north-western tracts) the non-yam-producing division. Through Bengal and Assam the yam country extends to Burma, Siam, the Malaya (Peninsula and Archipelago) to China and Japan.

In the *Dictionary* a few passages from De Candolle were quoted and the contention advanced that the historic importance of the Indian cultivated yams had been depreciated owing to no work of sufficient merit having recorded their Sanskrit and vernacular names. “Roxburgh,” says De Candolle (l.c. 77), “enumerates several Dioscorea cultivated in India; but he found none of them wild, and neither he nor Piddington mentions Sanskrit names. This last point argues a recent cultivation or one of originally small extent, in India, arising either from indigenous species as yet undefined, or from foreign species cultivated elsewhere.” . . . “The absence of distinct names in each province also argues a recent cultivation.” A very extensive assortment of vernacular names for each species has been recorded, however, by Prain and Burkhill, and these amplify materially the names given in the *Dictionary*. They thus abundantly substantiate the opinion of India being one of the great centres of original production (if not the chief Asiatic centre) for yams. It seems likely that both the sweet-potato and the ordinary potato, being more tractable, have not only largely supplanted the yams but usurped their classic names and history.

Asa Gray (Scient. Papers, i, 322) says that Columbus when he discovered Cuba and St. Domingo found the Natives cultivating two kinds
of edible roots. "These were called in the language of the islanders of St. Domingo, Ages (Ajes) and Yuca." The last mentioned is Manihot and may be dismissed from further consideration, but the former (it is nearly certain) was a species of Dioscorea. This the Spaniards (being ignorant of the language of these islands) called name, niame, inha—corruptions, it is supposed, of an African name (with which they were already familiar) for a similar edible tuber. Clusius (Hist. Exot. Pl., 1605, 237–8, reprinting Garcia de Orta, 1563, Coll., xviii., 3) speaks of the African slaves of Portugal eating the tubers of a Colocasia which they called inha me. Hence that name had, at an early date, reached Europe and India. Some of the companions of Columbus had doubtless seen the inha me tubers of Africa, and were thus ready to assign that name to the West Indian tuber when their attention was drawn to it. To this circumstance is accordingly due the constant use (by 16th and 17th century writers) of inha me (or, as it ultimately became, thame and finally yam) as a generic denomination for any and every edible (starch-yielding) tuber.

There would seem little doubt that the Indian word ālu (in Sanskrit and Hindi and ala in Sinhalese) originally denoted a starch-yielding edible tuber, possibly in its earliest signification the edible species of Dioscorea, though in later usage it came to mean Amorphophallus and even Colocasia. A prefix was employed to denote the separate species. Hence we have in Sanskrit the dândalu (elongated ālu), madhvālu (sweet ālu), pindalu (round ālu) and raktdalu (red-ālu). In the Sanskritic vernaculars we have similarly chũpīrālu, gurimā-ālu, kanta-ālu, khām-ālu, māu-ālu, pindalu, ratālu, and sasnidalu. But in the aboriginal languages there is a vast assortment of names not only perfectly distinct from each other and in no way traceable to the Sanskrit, but which have either a direct specific or in some cases even a generic signification:—ato sang, Bengo-nari, bir sang, gun, genasu, kalangu, kullu, kniss, kris, myauk, piska, taguna and tar (or tarar). Most of these names (many others might be given) denote knowledge prior to the Aryan conquests of India and thus leave no room for doubt that the cultivation of yams is quite as ancient (if not more so) in India as in any other country. Indeed from the fact that names are given in the West Indies and other tropical countries, traceable to the Sanskrit, or to some Indian vernacular, there would seem no doubt that some of the best-known cultivated forms in other regions were derived originally from India. And what is more curious, not a few of these are being brought back to India to-day as special West Indian plants, oblivious of the fact that, just as with the improved rice brought from Carolina and the superior wool-sheep from Australia, they had been procured in the first instance from India.

Propagation.—The yam may be propagated either by means of aerial tubers or small underground tubers or portions of large tubers. If the former be employed, the first year's crop is poor but the second excellent. It is preferable to use sets of the underground tuber weighing about half a pound. The best soil is a deep friable sandy loam. Stiff heavy soils are unsuited, as the tubers cannot expand properly and good drainage is essential. The selected land should be dug to a considerable depth and fairly well manured. It is then lined, 3 to 4 feet apart, and the seed tubers set on the ridges at distances of 18 inches. Some cultivators prefer to start the seed tubers in a nursery and to transplant to their permanent position when a foot or so in height.
AREA AND YIELD

Alongside is secured a stake (usually a bamboo) perhaps 8 to 15 feet in height above ground, and it is customary to bind these together at the top in clusters of four. It is also not uncommon to grow special trees on which the climbing stems of the yams may be trained. When this is the case pits are dug alongside of the trees and filled with new soil and manure and the sets deposited within these. Occasionally (as, for example, in Bihar) the plants are allowed to trail on the ground, but the yield is believed to be then smaller. In the West Indies, however, the crop is often treated in this way, and apparently with satisfactory results. It is also affirmed that in China the trailing stems are pegged or layered into the ground, and thus caused to root, the result being that tubers are formed at the new points of growth. With certain species, having a rhizome-like underground stem and one or two large tubers, the lower edible portion is cut off and the upper rhizome planted for next year's growth. This, however, is rather the careful system pursued with wild yams than a regular method of agricultural propagation. Planting is done in April and the crop comes into season about December. This is the usual practice, but a wide range of seasons exists in direct adaptation to local conditions and the species of plant grown. Thus in Arcot it is said the yam is cultivated in January and harvested in August and September. In the Konkan yams are sometimes grown alone and the crop comes into season about October. In Upper India, according to Duthie and Fuller, the tubers of D. bulbifera are planted in May and June and dug up every three years. Of D. alata, var. globosa, these authors say it is planted in June and the crop gathered the following February.

Yield.—The yield depends largely on the plant grown, the nature of climate and soil, the degree of cultivation, and the proportion of the produce treated as edible. The yield has been variously put at from 3 to 10 tons an acre, or approximately the same as the yield of potatoes. But yams are in India most frequently a supplementary crop to ginger, turmeric, brinjal, sweet-potato or maize. Yams are moreover more nutritious than ordinary potatoes, so that the combined produce may be accepted, from the standpoint of food supply, as highly satisfactory.

Chemistry.—Bhaduri (Rept. Labor. Ind. Mus. (Indust. Sec.), 1902-3, 25) says the acidity of yams is due to the presence of needle-shaped crystals of calcium oxalate, and the poisonous property to the presence of the alkaloidal principle Dioscoreine first isolated by Boorsma of Java. Hooper (i.e., 1903-4, 32) gives the results obtained during the examination of some forty kinds of these tubers. The poison was found most abundant in D. daemona, but was often present in D. bulbifera and D. pentaphylla. "The average amount of moisture in fresh tubers was 80 per cent., and the average percentage composition of the dried tubers was: fat 1·02, albuminoids 10·87, carbohydrates 77·01, fibre 5·16, ash 5·94, and nitrogen 1·73. The starch of the yams was examined microscopically and certain species were found to have characteristically shaped granules, which distinguished them from other species."

**THE EBONY TREE**

**Diospyros, Linn.**—Fl. Br. Ind., iii., 553–72; Gamble, Man. Ind. Timbs., 453–63; Cooke, Fl. Pres. Bomb., i., 98–107; Prain, Beng. Plants, i., 651–4; Brandis, Ind. Trees, 428–36; Ebeneceae. A fairly important genus which embraces about 59 species of Indian forest trees. They occur chiefly in South India, Ceylon, Burma and Eastern Bengal. Only four extend to Northern India, while the genus may be said to be not represented in the Eastern Himalaya. All the species yield useful timbers, of which the best are the various forms of Ebony (D. Ebenum and D. melanoxylon), known in the vernaculars of India as ebans or tendu. The most important are:—

**D. Ebenum, Koenig.**—Roxb., Fl. Ind., ii., 529; Trimen, Fl. Ceyl., iii., 94. The Ebony, ebans, abnás, tendu, khenda, temrá, tai, acha, nulláti, shengúran, kaka-tátí, tukí, kare, bale, mushtímbí, karunkátí, mallaí, kathíva, etc., etc. A large tree not very common in India, where it is found in the Deccan and Kārnátak, chiefly in dry evergreen forests in the Ceded Districts. In Ceylon, however, it is one of the chief woods, very common in the dry regions of the Northern Provinces. (Cf. Herbert Wright, The Genus Diospyros in Ceylon, its Morphology, Anatomy and Taxonomy, 1904.)

This species is perhaps the best ebony-yielding tree and the only one which gives a black heart-wood without streaks or markings. Gamble says 74 lb. is the average weight per cubic foot for the heart-wood. In Europe it is extensively used for ornamental turnery, cabinet-work, piano keys, rulers, etc., and in China for chopsticks, pipes, carved stands and vases. Ebony does not appear to be exported from India to any material extent, but in Ceylon the average sales for 1892–1902 were 300 tons yearly. The average price Gamble gives at 185 Rs. per ton. The Indian Forester (1905, xxxi., 37, app.) gives £6 to £10 per ton as the price of East Indian Ebony.

**D. Embryoepis, Pers.; Roxb., Fl. Ind., ii., 533; Rec. Bot. Surv. Ind., ii., 30, 115, 240, etc.; iii., 233; Talbot, List Trees, etc., 211; Trimen, i.c. 93.**

The gá, makur-kendi, káí, timbóri, tumbika, paní-chika, karunkátí, kawí-kattári, kollet-upra, tumil, tindukí, nitá-tumma, kusharta, hiíge, banthó, varánchik, etc., etc. A dense evergreen tree found throughout the greater part of India in shady wet places and near streams. It is frequently cultivated both for ornament and for its large red, velvety fruits.

Many writers speak in general terms of a gum obtained from this plant, but do so in such a manner as to suggest a confusion between a true gum and an extract prepared from the fruit, the pulp of which is used in book-binding, and in place of tar for paying the seams of boats. According to some writers the pulp is used direct; others say an extract or decoction is prepared. Buchanan-Hamilton (Stat. Acc. Dénaj., 1833, 152) thus describes the process pursued in Bengal:—"It (the fruit) is beaten in a large mortar and the juice expressed. This is boiled, mixed with powdered charcoal and applied once a year to the outside of the planks." Duncan (Monog. Dyes and Dyeing in Assam, 1896) observes that the half-ripe fruits are pounded in a mortar and then kept six or seven days in water until they have decomposed. A gummy solution results, which is poured off and the sediment thrown away. The brownish liquid thus obtained is used in dyeing and tanning. It is made into a good black by being combined with myrobalans (Terminalia Chebula) and proto-sulphate of iron (hira-kash). The infusion is largely employed for tanning fishing nets and lines, and it makes them more durable.

**D. Kaki, Linn.**—A small tree met with in the Khasia hills and perhaps also in Upper Burma. It is cultivated here and there over the moister tracts of India as a fruit tree, but is only suited to very large gardens. It is the CHINESE DATE PLUM or Persimmon, and in Burma appears to be known as tay, teh. The fruit ripens during August and is about the size of a large apple with twin almond-like stones. The rind is of a rich, ruddy colour. It has a rather disagreeable odour, and in flavour is suggestive of an overripe apple. A fine preserve is said to be made from it by the Chinoso. (Cf. Roxb., Fl. Ind., ii., 528; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 221–2.)

**D. Kurzii, Hiern.**—One of the most important trees of the Andamans, termed in English Marblewood; in Burmese tekañah, thikya, and in the Andamans pecha-da. Gamble remarks that this wood would be of great value in the

DIPTEROCARPUS, Guertn., f.; Fl. Br. Ind., i., 295-9; Gamble, Man. Ind. Timbs., 1901, 70-3; Prain, Beng. Plants, i., 251-3; Brandis, Ind. Trees, 65-6; DIPTEROCARPUS. A genus of lofty trees, which embraces some 50 species, natives of tropical East Asia. Of these 17 occur in the Indian area and some 8 or 9 in India proper. On purely economic grounds I propose to treat as species plants that may be only doubtfully distinct botanically, but in doing so I am practically following the lead given by Prain. The various forms are chiefly noted for their oleo-resins and timbers. The unimportant species are:

D. alatus, Roxb., Fl. Ind., ii., 614. A very large tree, native of the tropical forests of Burma, where it is known as white kanyin or kanyinbyan. It gives a large quantity of a rather thin wood-oil. Gamble remarks that this is probably considerably mixed with that of eng. [Cf. Roxb., Trans. Soc. Arts, 1806, xxiii., 413.]

D. costatus, Guertn., f.; D. alatus, Fl. Br. Ind., i., 298. This, like D. toxis, is called letia-garjan in Tippera.

D. Griffinii, Miq.—A tall tree of the Mergui and South Andaman Islands. This broad-leaved tree affords one of the qualities of Andaman gorgan-oil. Gamble remarks that these are probably considerably mixed with those of eng.

D. indicus, Benth.; Brandis, Journ. Linn. Soc., xxxi., 26; D. turbinatus, Fl. Br. Ind., i., 295 (in part); Talbot, List Trees, etc., 1902, 33; Cooke, Fl. Pres. Bomb., 1901, i., 84. The guga, challane, ennei, kalpoyin, varangu, etc., a lofty tree of the overgrown forests of the Konkan, Kanara, Malabar and Travancore. The wood-oil trees of Western and Southern India.

The Conservator of Forests, Coorg, gives an account of the wood-oil prepared in that portion of the west coast of Southern India. He says—"We have two oil trees in the Western Ghat Forests of Coorg. Both, I believe, are species of DIPTEROCARPUS, but have not been able to get the flowers to identify them. The oil is contained in the pores of the wood, and is collected by cutting a hole into the centre of the tree. One species yields a yellow oil and the other a dark red.
The former is sold in the bazaars mixed with dammar (the produce of *Vateria indica*) as varnish at 5 annas a bottle. The latter also makes a fair varnish. It has a strong copaiba-like smell and would probably be useful in medicine.'

One at least of these oils must be regarded as afforded by the present species, whether it be accepted as distinct from *D. turbinatus* or only a variety of it.

D. Lewis, *Ham. Mem. Warn. Soc.*, 1832, vi, 298–9; *D. turbinatus*, Roxb., *Fl. Ind.*, ii, 612 (in part); *Fl. Br. Ind.*, i, 295 (in part). Prain speaks of this as a tall tree met with in Tippera, where it is known as *telia-garjan*. He remarks that as so accurate an observer as Buchanan-Hamilton separated his *levis* from *turbinatus*, on account of their different economic properties, it seems better to leave the two trees as distinct species. In a letter to Roxburgh dated Oct. 16, 1798, Buchanan-Hamilton speaks of four species of "gurgeon" found by him in Chittagong, which doubtless included the present species.

D. obtusifolius, Teysm.—A large deciduous tree of the eng forests of Prone and Martaban. It is the *kanyingok*, *inbo*, *in-kohe*.

D. pilosus, Roxb., *Fl. Ind.*, i, 615. A tall evergreen tree of Assam, Chittagong and Burma. It is best known as the *hollong*. Brandis observes that it yields a semi-fluid resin, and it is described by Hooper as white (*Rept. Labor. Ind. Mus.* (Indust. Sec.), 1904–5, 24). Gamble speaks of the wood as good but not suited for tea-boxes. Peal refers to it as employed for canoes. This is possibly the tree mentioned by Robinson (*Desc. Acc. Assam*, 1841, 62).

D. tuberculatus, Roxb., *Fl. Ind.*, ii, 614. The Eng Tree, *eng*, *in*, *sooala*. A large deciduous, gregarious tree forming the "in (eng) forests" of Burma, Chittagong and Siam. It is said to be very characteristic of laterite soils and to take the place of the *sal* in Northern and Central India.

Oleo-resin.—It was for some time thought that the *eng* tree did not give a wood-oil, but Mr. J. W. Oliver explained that it yielded a thick oil or rather oleo-resin. The reader will find Mr. Oliver's most interesting report in the *Dictionary* (iii, 160–1). The method of extraction is very similar to that for *garjan*-oil, explained below. The congealed resin which remains behind, after the removal of the oil, is scraped off and used for torches which are made of rotten wood, mixed with the resin and rolled up in the leaves of the *sathvea*, a species of screw-pine. In some localities, however, the rotten wood is soaked in the oil itself and wrapped up in the leaves of a palm-*salu* (*Licuala peltata*). Nisbet (*Burma Under Brit. Rule and Before*, 1901, 365) says that "twenty years ago the chief luminant used after dark through the rural tracts, except those of the dry zone within easy reach of the central petroleum fields, was a small torch about a foot and a half long made of chips of dead wood and the resinous oil of the kanyin or wood-oil tree *D. turbinatus* rolled in palm leaves. . . ." "These kanyinsi torches were sold in bundles in every bazaar. While burning they emitted incessant smoke and a strong oily smell, pungent and differing vastly from the European idea of fragrance. At one time the manufacture of these torches formed an industry wherever the wood-oil trees abounded; but now, in consequence of improved communications and of large imports of kerosene at low rates, torch-making is only betaken to in jungle tracts in order to eke out the means of livelihood during bad years, when the shadow of misfortune darkens the threshold."

The oil is used for waterproofing bamboo baskets, etc. With regard to the wood, Gamble (*I.c.* 72) says, "The Eng is probably the best of the woods given by the species of *Dipterocarpus*, and it is in considerable demand and use for building and boats." In point of weight it would seem to average 54 lb. (*Cf.* Brandis, *Ind. For.*, 1875, i, 365; *Semler, Trop. Agrik.*, 1900, ii, 536–7.) Hooper (*Agri. Ledg.*, 1902, No. 1, 15) mentions a tannin extract obtained from the bark of this tree.
GARJAN OIL

**DIPTEROCARPUS TURBINATUS Garjan**

_D. turbinatus_, Gaer., f.; Buch.-Ham., Mem. Wern. Soc., 1832, vi., 300; Roxb., Fl. Ind., ii., 612 (in part); Ribbertrop, Forestry in Br. Ind., 1900, 10. Kanyin Oil Tree, garjan, dulia garjan, kanyoung, kanyin, kanyin-ni, kanyin kohe, etc. An evergreen tree of Eastern Bengal, Chittagong, Burma, and (according to Gamble) of the Andaman Islands. Distributed to Singapore.

One of the loftiest of Indian trees, being sometimes 250 feet in height. Hooker (Himal. Journ., ii., 348) in his account of Chittagong says: "This is the most superb tree we met with in the Indian forests: we saw several species, but this is the only common one here; it is conspicuous for its gigantic size, and for the straightness and graceful form of its tall unbranched pale grey trunk and small symmetrical crown: many individuals were upwards of 200 feet high and 15 in girth." In recent official correspondence mention has been made of a broad and narrow-leaved _garjan_ oil plant. The latter has been determined to be a special variety of _D. turbinatus_, for which the name _andamanicus_ has been suggested, and the former is _D. Griffiihi_ (see above).

**OLEO-RESIN.**—With regard to the various species of _Dipterocarpus_ that yield wood-oil (_garjan_), the following information was obtained some few years ago from the Government of Burma: "Kanyin oil is the produce of _D. levis_ (kanyin-in = red kanyin) and of _D. alatus_ (kanyin-byn = white kanyin), which are common in evergreen forests, and probably of other species of similar habitat." It seems likely, however, that the source of the superior quality of oil has changed within recent years owing to the comparative extermination of the plant most noted in former times. It is also highly probable that the plant valued at the present day may be a species but indifferently known to botanists. Every here and there, more than one grade of oil is described by popular writers, whereas in most cases only one species of wood-oil tree is recognised. It is on that account that I have retained for the present the names used in the Dictionary, namely, _D. levis_, _D. tuberculatus_ and _D. turbinatus_.

_Garjan Oil_ is in Burma generally collected in the dry weather only—(November to May). In the Andaman Islands it does not flow before January 15, and is finished by April 25. The oil is obtained by cutting two or three deep pyramidal hollows (the apex pointing towards the interior) near the foot of the tree, and by applying fire to the upper cut surfaces. The fluid then collects at the bottom of the hollow, which is emptied every three or four days. Fire is applied after the oil is removed, and the upper surfaces of the hollow are chipped three or four times during the season. In Tharawaddy district, where trees are not very plentiful, it is considered that twenty are about as many as one man can attend to. The yield of twenty trees would be 100 _viss_ for the season, worth Rs. 25. In Prome district the oil may be said to come into the market in the form of torches similar to those already discussed under _D. tuberculatus_. In the Forest Administration Reports of the Andaman Islands (1897-8, 7; 1899-1900, 4, 5; 1901-2, 13; 1903-4, 7) particulars are given of the methods pursued in collecting the oil. In the Chittagong district it is prohibited to tap the trees owing to the large number already killed. This prohibition it is understood does not extend to the hill tracts. A recent official communication, for example, states...
DIPTEROCARPUS TURBINATUS

Kanyin

that the extraction of the oil is not pursued there because it is not re-
numerative enough.

THE GARJAN OIL PLANT

very little is known for certain of the industrial uses of the oil, still
less of the resinous concretion as distinct from the liquid oil. The
former is fairly extensively employed by the Burmese for torches, and
the oil is largely used in preserving bamboo wickerwork and in paying
the seams of boats. As a varnish it is believed to protect woodwork from
the ravages of insects. In Europe it has been in fact made into a varnish,
and is reported to be a useful ingredient in lithographic ink. It was in
the Dictionary pointed out that an important way of utilising the article
might be found in taking advantage of Mr. Laidlay's discovery that it
acts as a solvent to caoutchouc. Sir W. O'Shaughnessy remarked
fifty years ago that it would likely be found a perfect substitute for the
expensive balm of copaiba. In the Journal Chemical Society (1902,
xxi., 1404) it is affirmed that "Chinese wood oil" is not suitable to replace
linseed oil in the preparation of varnishes. It cannot be heated above
160° C. Capital (April 1904) gives useful particulars regarding Chinese
wood-oil—a substance which cannot possibly be mistaken for garjan
(see p. 46).

Chemistry.—In the Dictionary will be found an abstract of the results obtained
by the distinguished authors in the Pharmacographia. More recently Hooper
has published his examination of the samples procured by the Reporter on
Economic Products, from which the following passage may be furnished:—
"Eighteen samples of garjan balsam from Bombay, Madras, Tippera, Chittagong,
Assam and Burma had been submitted to analysis. The specific gravity ranged
from 0:957 to 0:999, the percentage of volatile oil from 36-9 to 71-1, and
the acid number from 3:12 in a Chittagong sample to 21:9 in one from Rangoon.
These oils, procured from D. turbinatus, D. toxis, etc., were very irregular
in composition and physical contents, and would lead one to believe that
adulteration is practised in certain quarters. The balsam secreted by D.
tuberculatus and known in the trade as 'Jusi' is more uniform in composi-
tion. It has a thick honey-like consistence with a high sp. gr. and acid
value, but a low proportion of volatile oil. Samples of the oleo-resin of
D. Griffithi and D. turbinatus, var. andamanicus, collected from botanically
authentic sources from the Andamans, were of exceptionally good quality. The
chemical analysis of a series of balsams of this character enables one to
recognise their peculiar reactions, so that it is easy to detect substitutions and
adulterations. During the course of the inquiry a sample of oleo-resin from South
India, although labelled Dipteroncitus, was found to be the product of
the 'gen nemaram' (Harthwickia pinnata). . . To thoroughly understand the
differences of composition of gums, resins, and oleo-resins, samples should be
collected from the trees and the conditions of age, climate, soil, etc., studied on
the spot." [Of. Wieiner, Die Rohat. des Pflanzenr., 1900, i., 236-7; Tschirch
700-1; Pharm. Journ., 1905, lxiv., 722; Tschirch, Die Harze und die Harzebe-
hilter, 1906, i., 489-512; Hooper, Rept. Labor. Ind. Mus. (Indust. Sec.), 1906-7,
8; Pharm. Journ., 1907, lxviii., 4.]

Medicine.—This substance is not very largely used in Indian medicine, and
does not appear to have been known to the early authors. It is apparently
alluded to in the Makhzan, but it is not mentioned by Dutt in his Materia Medica
of the Hindus. The most recent opinions on the subject only need be here
quoted. Dr. Dougall and subsequently Mooden Sheriff (Mat. Med. Med.,
1891, 49-50) drew attention to the properties of the oil. The latter says,
"The best medical properties of this oil are its usefulness in gonorrhea and
gleet, and in all forms of psoriasis, including lepra vulgaris." Again: "With
regard to its usefulness in psoriasis and lepra vulgaris, I am not aware of any
other local stimulant which is more efficacious in those diseases than this drug.
But in the Pharmacographia Indica (i., 192) mention is made of the investigations
conducted by the Government of India, and it is then added that "as far as
we have heard the new treatment has not been a success." [Of. Dymock, Mat.
TRADE IN GARJAN OIL

Med. W. Ind., 1883, 88–9; Waring, Bas. Med. Ind., 1897, 70–2; Ponder and Hooper, Mat. Med. Ind., 1901, 32.

Gamble (l.c. 71) remarks that the Wood of the garjan tree is used in house-building and for dug-out canoes, as also for packing-cases, but that it is soon destroyed by white ants. Its large size, however, makes it valuable for temporary purposes; logs 40 to 60 feet in length are sometimes procurable. With regard to weight he tells us that the specimens he had examined averaged 50 lb. per cubic foot. [Cf. For. Admin. Rept. Burma, 1899–1900, 18; Working Plans Rept. Pyinmana, 1904, 16–7.]

Trade.—Milburn (Or. Comm., 1813, ii., 315) mentions wood-oil, and explains the uses it is put to. Royle, writing in 1840 (Prod. Res. Ind., 77), speaks of wood-oil, but says it has never become an article of commerce. Flückiger and Hanbury (Pharmacog.) state that the world’s supply is obtained from “Singapore, Moulmein, Akyab, and the Malay Peninsula and that it is a common article of trade in Siam.” Dymock (l.c. 91) remarks—“Garjan Balsam is not an article of commerce in Bombay; small quantities may be sometimes obtained in the Native drug shops. The Government supplies have been obtained from the Andaman Islands.” Moodoon Sheriff (l.c. 49) writes that in Madras wood-oil is common in large bazars; he describes several forms and gives their prices. A firm of Calcutta merchants, in a letter dated October 25, 1900, undertook to supply garjan oil in 40-gallon casks at Rs. 47 per cwt. delivered in Calcutta. An official correspondence in 1901 resulted in the discovery that some objection existed in the minds of European merchants in Rangoon to engage in the traffic in kanyin (garjan) oil. One firm reported that the quality of the oil varies very much, and the price accordingly. The quotation given by them at that time was Rs. 60 per 100 viss—equal to about Rs. 20 or £1 6s. 8d. per cwt., but this does not include casks or drums. The Conservator of Forests in a communication of the same date was of opinion that if an assured demand arose, there would be little difficulty in procuring local persons willing to supply the oil in Pyinmana Division, the Ruby Mines Division and Tenasserim Circle. It will thus be seen that very little of a satisfactory nature can be furnished regarding the Indian supply of this article. There are four chief centres of production—Burma, Andaman Islands, West and South India and Chittagong. The last mentioned, though formerly perhaps the most important, is the least valuable at the present day, and therefore it may be said that the supply, such as it is, comes almost exclusively from Burma and the Andaman Islands and is exported from the port town of Rangoon chiefly. The returns in one province appear as lb., in another as viss, in a third as gallons, so that a combined statement is impossible. Moreover, in official statistics it is sometimes grouped with “resin,” at others with minor forest produce. One point only seems indicated, namely that with the growth of the Chinese wood-oil (Aleurites fordii, p. 46) a decline in both the supply and demand of garjan has taken place.

DOLICHOS, Linn.; Leguminose. A genus of twining herbs of which there are 20 species, six natives of India and two of economic value:

Horse-gram.
DOLICHOS
BIIFLORUS
Kulthi

i., 382. Horse-gram, kulthi, kurthi-kalai or kurthi or kuriti, kalath, khulti,
kolatha, kulat, gahat, horec, barat, rolong, qadli, botang, wulavalli, ulava,
hurali, hula, hule, papadi, mithera, simbi, bei māh, khārek, pē-ngapi, etc.;
guār, sometimes given to this plant, more correctly denotes *Cytomopsis
gsoraloides*.

Varieties and Races.—According to Baker (*Fl. Br. Ind., Lc.*) there are two
forms of this plant, *D. uniformis*, a sub-erect annual, and *D. biflorus*, a more
or less twining plant. The habitats of these forms are not separately recorded.
He apparently treats of both when he says it occurs on the "Himalayas to
Ceylon, and Burma, ascending to 3,000 feet in Sikkim, sometimes cultivated.
Distributed everywhere in the tropics of the Old World." The writer, however,
is of opinion that a mistake may have been made in linking the Himalayan
with the plains plant. Roxburgh refers to two forms, one with grey, the
other with black seeds, both of which he implies are cultivated in Bengal and
Madras. The grey-seeded plant, *D. biflorus*, is erect, has twining branches,
as is about 2 to 3 feet high. Roxburgh then adds—"I have never found
it but in a cultivated state." As already observed, there would appear to
be room for doubt as to whether the grey and the black-seeded forms of
Roxburgh are the two forms of modern writers, or whether both of Roxburgh's
plants constitute but cultivated races of one of these forms. In popular works
on economic products the horse-gram of Madras is viewed as *D. uniformis*, and
under either of these names (*D. uniformis* or *D. biflorus*) a pulse is described
as grown in almost every district of India, but chiefly in Madras and Bombay.
It is a little difficult to believe that the plant of the tropical plains is the same
as that of the temperate Himalaya, but of course this is by no means impossible.
Duthie, however, says that as grown on the Himalaya it is more robust, the
pods larger and broader, and the seeds grey. Mollison (*Handbook Ind. Agri.*,
1901, iii, 82-4) speaks of two varieties: one, grown sparingly in the Ahmed-
nagar and Kaira districts, has creamy white seeds; the other, commonly
cultivated, has grey variegated seeds. But that this cultivated pulse should
be regarded as a native of India is abundantly confirmed by the existence of
a Sanskrit name—*kulaitha*—from which no doubt many of the above vernaculars
(kulthi, etc) have been derived.

**CULTIVATION.**—Of the plains it may be said that this pulse is grown
either as a green manure or as a cattle food and fodder. Mr. Robertson
(*Saidapet Farm Repts.*) deals with the advantages of using it as a green
manure. Since then, however, the subject of the influence of leguminous
crops on the soil has undergone a complete revolution. Their chief value,
it is now believed, lies in their power to fix the nitrogen in the soil through
the agency of the organisms contained in their root warts. Few Indian
crops are perhaps more valuable in this respect than the horse-gram,
especially when grown as a fodder plant, or still more so as a green manure.
The advantages of growing the crop as a source of fodder are extolled
by various writers. Robertson, for example, says that it produces
from 2,000 to 4,000 pounds of fodder in two months, at a cost of about
Rs. 3 per ton, and thrives with a minimum rainfall in very hot weather.
The ease with which it may be cultivated recommends it most highly as a
catch crop for forage purposes, either to be grazed on the land or fed in
the stalls. The plant may be made to grow at almost any season of the
year. It requires but one shower of rain to start its growth, but even if this
be not obtained, the seeds have the power of remaining alive for months
in the soil and of germinating when rain does fall. After the removal of
the rabi crop it is contended that a highly advantageous course is to
rapidly dress the soil, sow horse-gram, and in a month's time commence
to use the stems and leaves as fodder. By this means the soil is saved
from becoming baked with the advancing heat of summer, and the roots
left in the soil greatly improve it, even should the cultivator be unable

504
to devote the entire crop as a green manure. The following brief account, province by province, may be found instructive:

**Bengal and Assam.**—Horse-grain is very little cultivated in the Lower Provinces. It is said to be grown to a limited extent in Shahabad, and fairly abundantly in Chota Nagpur, both as a grain and a fodder crop, but not in Lower Bengal. Mukerji (Handbook Ind. Agri., 1901, 263) observes that the time for sowing *kulthi* for grain is October or November, and for fodder June, August and November, three times on the same field. It may be reaped during several months, according to the purpose for which required, but the general harvest is December-January. The quantity harvested per acre Mukerji gives as 300 lb. of grain, or 5 tons of green fodder per crop. Banerjei (Agri. Cuttack, 1893, 80-1) discusses its merits as a *rabi*, while Basu (Agri. Lohardaga, 1890, 34) calls it a *kharif* crop. Speaking of Assam in a subsequent report (Agri. Ledq., 1903, No. 5, 135), he says that *kulthi-māh* is grown to a small extent in Kamrup and Darrang. In the Tezpur Sub-division it is cultivated by Nepalese and coolie settlers, and in Upper Assam and Nowgong is unknown. Only one variety is grown. The method of cultivation and time of sowing and reaping are very much as with *māti-māh*. About 5 seers of seed are sown per acre; thin seeding is desirable, the object being to allow the plants to creep and spread over the ground. A good crop may yield up to 6 maunds of pulse per acre.

**Upper India.**—Duthie and Fuller (Field and Garden Crops, pt. iii., 2, t. lxxxi.) say that in the United Provinces *D. biflorus* is grown mostly as a rainy-season hill crop, ascending the hills to 7,000 feet. Atkinson (Himāl. Dist., 343, 460, 696) and Stewart (Pb. Plants, 1869, 68) make very similar statements. According to Sir J. B. Fuller, *Dolichos biflorus* is grown in the southern districts of the Central Provinces as a cold-weather crop, but is of importance only in the Chanda, Bhandara and Balaghat districts.

**Bombay.**—Mollison (Textbook Ind. Agri., 1901, iii., 83) observes that *kulthi* takes the third place among the pulses of the Presidency, and according to statistical returns occupies over 500,000 acres annually. The Agricultural Statistics give an average for the five years of over 2,700,000 acres under "other food grains including pulses." Briefly stated, it may be observed that Gujarat and the Konkan are unimportant sources of supply, but that the Deccan and the Karnātak are fairly important (especially the districts of Ahmednagar, Satara, Poona, Dharwar, Belgaum and Bijapur). The principal cultivation is in the *kharif* season as a row or mixed crop, subordinate to bājri, hemp (*ambadi*) and niger seed; only rarely is it a pure crop. Occasionally, however, it is grown in the *rabi* season as a second crop in rice fields. It is very sparingly cultivated in Bombay as a green manure. Of the Deccan, Mollison says *kulthi* participates in the general cultivation given for bājri (*Pennisetum typhoidenum*). The fields in which it is grown are rarely manured oftener than once in three years. The land is usually prepared by working a heavy-bladed harrow (*rakhar*) two or three times in the hot weather, and again two or three times after rain in June. As a mixed crop it is sown in July, and may occupy every fourth row. The crop is generally bullock-hoed twice a year. If sown in July, the crop will be ripe at the end of October or early in November.

**Madras.**—The crop is very important in this Presidency. Nicholson
THE HORSE-GRAM PLANT

(Man. Coimbatore) tells us that it grows on the poorest soils, and with the minimum of rainfall. Horse-gram land is seldom manured, otherwise than by casual droppings of cattle: it is usually ploughed, sown, and the seed covered by a second ploughing; or the seed is simply scattered broadcast over the natural surface and then ploughed in. As it requires only one good rain after appearing above ground, it frequently gives a fair crop when nothing else can live. When the south-west monsoon rains are too late for kāmbu (būjra) it is frequently sown as a substitute in September, but it is also sown largely in November after the first burst of the north-east monsoons. It is pulled up by the roots, thrown into heaps, and then trodden out by cattle. The yield is up to 1,200 lb. Nicholson (l.c., 1898, ii., 176) gives 194,777 acres as the average under *D. biflorus* for the years 1888–93. Mr. H. Goodrich, Collector of Bellary, says a mixed soil is best suited for the crop. The fields should be ploughed and harrowed once or twice, but not irrigated nor (generally) manured. Several other Madras writers, however, give very different accounts of the requirements of this plant, so that the practice seems to vary considerably within the Presidency. In the *Survey Settlement Report of South Arcot*, for example, it is said: "The land is ploughed four or five different times after the month of May, and the gram sown between the latter part of August and the end of September. It is gathered in the middle of March." So again, Moore (*Man. Trichinopoly, 72*) speaks of it as a precarious crop. In the North Arcot District, Cox (*Man. North Arcot, 1894, ii., 184*) gives 48,897 acres as the average under *D. biflorus* for the years 1887–93. Unfortunately, while several writers mention figures of area for the districts with which they are familiar, no definite statement of the Presidency as a whole can be furnished, for the reason that horse-gram does not appear to be separately returned. The official figures under "gram" for Madras come to an average (for the five years 1900–5) of almost 150,000 acres. But under "other food grains including pulses" 7,092,389 acres are shown as the area in 1902–3, though it has since contracted to 5,753,913 in 1904–5. It is thus fairly certain that "horse-gram" must be included under the latter, and that the former denotes Bengal gram (the true gram) grown in the Madras Presidency. As indicative of the possible regions of greatest cultivation of this pulse, it may be here added that Bellary had in 1902–3 (when the largest area for the period 1900–5 was returned), 822,685; Anantapur, 771,267; Karnul, 708,877; Kistna, 554,757; and Salem, 590,619 acres devoted to the combined food crops mentioned above.

**Mysore.**—Rice (*Mysore Gaz., 1897, i., 119–20*) says the horse-gram is of two kinds, black and white, sown intermixed. In the east the worst qualities of soil are generally used, and on the same fields sāme (*Panicum crus-galli, var. frumentaceum*), hāraka (*Cecropia longa*), and huchchellu (*Guizotia abyssinica*) are cultivated, without one crop injuring the other, or a rotation being even considered beneficial. For horse-gram plough twice, in the course of a few days, any time in October–November. Then, after a shower, sow broadcast; or, if rain does not fall, steep the seed for three hours in water and plough into the soil. It requires no manure, and in three months is ripe for harvest.

**FOOD AND FODDER.**—The interest in this pulse is mainly as an article of cattle food, the green stems and leaves being a valued fodder,
when grown for that purpose. Although not deemed a superior pulse it is largely used by the poorer classes, being perhaps the cheapest of pulses. The pea is generally soaked for twelve hours, then husked, thus reducing it to the form of dál or split-peas. The husk obtained is regarded as a valuable cattle food. The split peas may be reduced to meal, or boiled, or fried and eaten with rice or other articles of diet. The flour is fairly extensively employed in the preparation of sweetmeats. In some parts of the country the grain is dry roasted (parched), then sold to the consumers, who boil it in the preparation of dál.

The pea is boiled entire and given when cold as an article of cattle food. It is one of the chief pulses so used in Madras and Bombay. Some years ago Robertson performed a series of experiments to test the merits of boiled as compared with steeped horse-gram both on draught cattle and horses. The verdict was in favour of the steeped grain. [Cf. Rept. Agri. Dept. and Exp. Farms Mad., 1871, 4-7.] It is most important that in any attempts that may be made to extend this use to other parts of the world, the distinction should be clearly observed between the horse-gram of Madras (the article here dealt with) and the far superior pea known as Bengal gram (Cicer arrietinum, pp. 295-302)—the true gram of India. It is also extremely important that both these and all the other peas and beans of India should be recognised as distinct from the khesári (Lathyrus sativus, p. 703)—a pulse with an evil reputation that has on more than one occasion injured the prospects of a foreign demand for Indian pulses.

The fodder is either a by-product of the cultivation of the pea (bhusa) or it is a special crop grown and reaped at successive intervals, the plants not being allowed to form fruit. For fodder purposes it may even be sown on the same land two or three times within one year, and the soil is thereby improved rather than injured, as the pulse both cleans it of weeds and adds largely to its nitrogenous property.

Chemistry.—With regard to the chemistry of horse-gram, Church (Food-Grains of Ind., 162) gives the following analysis. In 100 parts, unhusked:—water 11.0; albuminoids, 22.5; starch, 56.0; oil, 1.9; fibre, 5.4; ash, 3.2. The nutrient ratio is 1:2.7, and the nutrient coefficient 83. [Cf. Leather, Agri. Ledg., 1901, No. 10, 360.] The seeds are used medicinally in the Panjáb. Arjun (Bomb. Drugs, 40) says a decoction of D. unijtorus is employed by the Natives in certain diseases of women. [Cf. Kanny Lall Dey, Indig. Drugs, 1896, 118.] The seeds are moreover reputed to yield an oil.

Area.—As already explained, the official statistics under which this pulse should be recorded are referred to two sections:—“Gram” and “Other food-grains including pulses.” It seems likely that the former denotes Cicer arrietinum and that the latter includes the horse-gram. In 1905-6 the total area in British India under gram came to 11,024,170 acres, and the others to 28,022,722 acres. The available information regarding the production of gram will be found under Cicer. It need only be added that of the area devoted to the “others,” a fair proportion, especially in Madras and Bombay, would be the present pulse. The following may be given as an analysis, province by province, of the areas under “others”:—6,284,192 acres were in Madras; 4,451,000 in Bengal; 4,248,816 in Agra; 2,417,785 in Oudh; 4,743,321 in the Central Provinces; and 2,575,116 in Bombay. These returns give, therefore, the only possible
relative indication as to the production of horse-gram, but in Bombay the actual area was 545,738 acres.

Cultivated Forms.—Wild and cultivated throughout India; it ascends the Himalaya to 6,000 or 7,000 feet in altitude. De Candolle (Orig. Cult. Plants, 346) says its culture dates perhaps from three thousand years, but that he can find no trace of its being early diffused in China, Western Asia or Egypt. Hosie (Rept. Prov. Sou'ch'uan, China, 1904, 11) says it is called suu chi tou (four-seasons bean) because it is cultivated throughout the year. Henry (Econ. Bot. China, 12) remarks that its Chinese name is pien-tou, and that there are two varieties, one with purple, the other with white flowers. So also in India there are two cultivated varieties, though these have not been distinguished in the Flora British India. Prain defines them as follows:

Var. Lablab proper; pods longer, more tapering at point, seeds with long axis parallel to the sutures. This is D. Lablab, Linn., Sp. Fl., 1019; D. lignosus, Roxb., Fl. Ind., iii., 305 (non Linn.).

Var. lignosus (Linn. sp., non Roxb.); pods shorter, more abruptly truncated at end, seeds with long axis at right angles to the sutures. Roxburgh, it will thus be observed, reversed the incidence of the Linnaean names.

Prain (Journ. As. Soc., t. 430) remarks that the epithet "lignosus" is much more appropriate when applied to "Lablab" than when given to the plant to which Linnaeus assigned it. "Roxburgh identifies his 'Lablab' the plant figured by Rumphius (Herb. Amb., v., t. 136), in an identification that is obviously just; Linnaeus gives this very figure as one of the types of his D. lignosus."

History.—Adams (Comment. in Paulius Egoineus, 1847, iii., 470) observes that Serapion, on the authority of Aben Mesual, describes the properties of a climbing plant which he calls lebleb. Adams accordingly adds that there is every reason to suppose the lebleb of Serapion and Avicenna was Dolichos. De Candolle (Lc. 347) gives, on the other hand, an account of the origin of the word lubia. He remarks that it possibly comes from the Greek lobos, which means any projection, like the lobe of the ear, a fruit of the nature of a pod, etc. Asa Gray (Scient. Papers, i., 353), reviewing De Candolle, comments that "the name (lubia) seems to be clearly referable to the Greek. It has not been traced earlier than to Jahia Ebn Serapion, an Arabian physician of the 9th or 10th centuries. Whatever 'De Simplicibus,' compiled chiefly from Dioscorides and Galen, was translated into Latin in the 15th century." The word "lobiya (king of beans)" occurs among the list of autumn (kharif) crops known to Akbar, and lexicographers would seem to regard the word lubia as of Persian origin. At the present day, in Upper India, it would appear to be applied to two plants, Vigna and Dolichos. Considering the time these plants come into season, it seems probable that the lobiya of the Ain-i-Akbari (Blochmann, transl., 63) was Vigna Catjang (p. 1107). I accordingly restrict the word lobiya to that plant; and, if this be correct, it is probable that none of the species of Dolichos, were known to the Persian writers of classic times. Moreover, no species of Dolichos would seem to have the properties attributed to the lebleb of the Arab writers. This reasoning would accordingly assign to the species of Dolichos an Indian origin, an opinion confirmed by the fact that both D. bipolaris and D. Lablab are met with as wild species, the cultivated races of which bear many purely indigenous names. In the Taleef Shereef (Lc. 147) "Lobia" is mentioned as a common culinary grain.

CULTIVATION.—Bengal and Assam.—Lablab is not a regular agricultural crop in any part of India. It is more correctly speaking a garden plant, and is trained to form arbours over the doorways of village huts. For example, the Director of Land Records and Agriculture says that different varieties are cultivated all over Bengal as garden vegetables. The Rev. Dr. A. Campbell tells us of Chota Nagpur that it is largely cultivated
PROVINCIAL PRODUCTION

but that he never found it wild. Basu (Agri. Lohardaga, 79) remarks that it is sown in July to August. It is allowed to climb on trees or hedges, and the green pods are procurable in January to March. Mukerji (Handbook Ind. Agri., 1901, 263) writes that the time for sowing is July (the quantity of seed per acre being 5 to 8 lb.) and that the time of harvesting is January and February, the yield being 250 to 400 lb. per acre. Banerjee (Agri. Cuttack, 1893, 118–9) observes that it is planted in specially prepared holes or pits about the middle of June. The plants flower in November–December and the crop is obtained in February–March. Speaking of Assam, it is met with not only in the valley proper but also in the Naga, Garo, Khasia hills and Manipur—each locality having distinctive indigenous names for it. About 45 seers of pods are obtained from each plant in the year, and the average price is six pice a seer.

United Provinces.—Duthie and Fuller (Field and Garden Crops, pt. ii., 29) observe that in these provinces this pulse is commonly grown along the borders of tall crops and allowed to twine itself on the plants standing on the margin. Castor-oil is a favourite support. It is never grown as a field crop by itself, as it requires artificial support. Duthie (Fl. Upper Gan. Plain, 229) remarks that it is extensively cultivated for its pods, which are harvested in the cold season.

Central Provinces and Berar.—It is often met with as a field crop in these provinces. Two forms are seen, one with white, the other with dark purple flowers. They are usually grown in lines through the fields, special supports being furnished, or they are left to crawl and to take such support as they can from the stubble of the associated crop.
